PREFACE TO THE THIRTEENTH EDITION

This book has been compiled with three general classes of readers in mind, i.e., the **student,** the **repairman,** and the **car owner.**

Uppermost in the mind of the author has been the needs of the **student**—the man who is seeking to master the many mechanical and scientific principles involved in the completed automobile. The plan of the book is to present this information in the form of Instructions, in place of the conventional chapters. If the student will proceed systematically through the book, digesting each Instruction before passing to the next, and if, in addition, he can have a car available for practical demonstration and experiment, he should emerge at the end with a mind stored with all the necessary facts and principles to make of him a fully equipped car mechanic.

The one great aim of the author has been to make the book **practical.** Fundamental principles are necessarily discussed in every case, but always in the light of their practical relation to the subject involved. Mere technical discussions are entirely avoided.

To make the book as practical as possible, the **underlying principles** involved in each subject are first discussed. The truck and the tractor are each related to the automobile, and hence they are given full space in the general scheme of the book. The scientific principles embodied in the highly developed cars of today underlay the earlier designs, now discarded. Hence many of the old designs are illustrated and discussed, in order that the developed designs of the modern type may be thoroughly understood.

When once the student has mastered the **fundamental principles,** he will understand the various developments now on the market, no matter how diversified they are. And, by way of additional assistance, the book undertakes to point out the differences in method employed by the different makes of cars now in use.

The **Index** is so complete as to enable the reader to put his finger on any subject, even though it is discussed on several different pages or is illustrated at different points. Familiarity with the Index is urged as a means of greatly increasing the usefulness of the book. The Table of Contents and the Index, used intelligently, will quickly lead the reader to any subject on which information is sought. It may be well, however, to add that the book embodies thirteen principal sections:

I. ASSEMBLY OF THE AUTOMOBILE
II. THE AUTOMOBILE ELECTRIC SYSTEMS
III. THE STORAGE BATTERY
IV. WIRING DIAGRAMS
V. IGNITION AND CARBURETION
VI. TIRES
VII. GARAGE AND SHOP EQUIPMENT
VIII. REPAIRING AND OVERHAULING ENGINE AND CAR
IX. OXY-ACETYLENE WELDING
X. COMMERCIAL CARS
XI. TRACTORS
XII. FORD CAR, TRACTOR, ETC.
XIII. DATA; SPECIFICATIONS; HORSEPOWER; USEFUL INFORMATION

These are supplemented by special instructions and illustrations on the Ford car and the Ford wiring circuits; the Aeroplane and the Liberty engine; the Continental engine; the Dixie magnetos; Engine Construction.

In short, the student will find the entire field so comprehensively covered that, no matter what may be his need for information, it can be found.

And, since every student is a potential **repairman,** it has been the serious endeavor of the author to make the book a complete book of instruction embodying all the accumulated knowledge of car builders, engineers, and master mechanics engaged in the automotive industry.

If the book is used by the **repairman** as it should be used, he will have it always available for immediate **reference,** at the bench as well as at home. If he will use the book intelligently, in the light of what has been said, he will find practical suggestion and advice covering every question that he will encounter in the shop, in the garage, or on the road. The book will save him from errors of judgment and from overlooking the real cause of trouble in a car; and it will serve to teach him things that he does not know, or methods that are time-saving and economical.

The average **car owner** is in much the same situation as the student, in his need of the necessary knowledge to enable him to meet emergencies with intelligence, and to maintain his car without relying on advice from others.

Every driver of a car should realize that in an emergency his trouble may be any one of a possible thousand or more. How is he to detect the nature of his trouble, or to tell what must be done? This book enables him, without loss of time and without annoying experiment, to put his finger on the specific defect, and tells him what to do as permanent repairs or as a temporary remedy. A free use of the book makes him "master of his fate."

Extremely few car owners attempt even the simple repairs needed on their cars. They lack the information necessary to decide what is wrong and how it should be remedied. To this class the advantage of this book lies in telling them what work ought to be done on the car, and, if done by a repairman, whether it has been done right. A study of the book at spare intervals will give the car owner information by which to diagnose his own car troubles, and to determine the extent of the repairs needed. The advantage to the man who knows these things is incalculable.

This, the 13th edition, has been completely re-written. Moreover, the thousands of illustrations have been assembled with a view to showing graphically every point discussed. Many of these are not drawn to scale; the exaggerations that they show are intentional, in order to bring out clearly the point discussed and the principle involved.

The author has drawn freely on the accumulated knowledge of that highly intelligent body of men who together represent the many branches of the automotive industry. He is glad to take the opportunity afforded here of expressing his profound gratitude for the generosity and co-operation with which each one of them has placed his own special knowledge at the author's disposal.

The author is equally under heavy obligations to the several trade journals of the automotive industry. His warm personal relations with the various editorial staffs and the free drafts that he has made on their pages are appreciatively and gratefully recognized. The present is an opportunity that is gladly availed of to enable him to express his sense of gratitude and friendship covering personal relations of many years' standing. Specifically, the author is indebted to *The Automobile* (New York), *Motor Age* (Chicago), *Motor World* (New York), and *Automobile Dealer and Repairer* (New York). While credit is given in the following pages wherever it is due, it is a pleasure to the author to express his obligations in a comprehensive manner.

TABLE OF CONTENTS

The Index to this book can readily be found by turning to the colored insert in the back of the book.

Instructions How to Find Subjects, as well as other pointers, are given on page **1153** of the Index. We advise that the reader turn first to this page and read it carefully, and follow the instructions given.

GENERAL ASSEMBLY

INSTRUCTION NO. PAGE
1. **Assembly of the Automobile** 1
2. **Drive Methods:** Drive Gear Reduction . 6
3. **Steering; Springs; Brakes** 10
4. **Axles; Differentials; Bearings** 15
5. **Clutches:** Principle and Construction . . 20
6. **Transmission:** Principle and Construction 25

THE GASOLINE ENGINE

7. **The Gasoline Engine:** Principle and Construction 30
8. **Engine Parts:** Assembly; Types . . . 36
9. **Valve Timing:** Valve-Stem Clearance; Valve Lift; Timing the Valves; Meaning of Degrees 58
10. **Firing Orders:** One, Two, Three, and Four Cylinder Engines 76
11. **Six, Eight, and Twelve-Cylinder Engines:** Firing Order; Rotary-Valve and Rotary-Cylinder Engines; Sleeve Valve Engine; Overhead Cam-Shaft Engine 80
12. **Continental Engines** 93

CARBURETION

13. **Carburetion:** Early Carburetion Principle; Parts; Carburetor Principles; Gasoline; Priming Methods; Heating Methods; Vaporizing Gasoline; Size of Carburetor to Use; Gasoline Troubles; Gasoline Tank and Gauge; Fuel-Feed Methods; Vacuum Gasoline Fuel-Feed System . . 95
14. **Carburetor Adjustments:** Mixture; Troubles and Remedies; Float Adjustments; Tools for Repairing Carburetor; Examples of Principle and Adjustments of Leading Carburetors 117

COOLING AND LUBRICATION

15. **Cooling the Gasoline Engine:** Cooling Methods; Water Circulating Pumps; Fans; Radiators; Water Thermostats; Water Temperature; Water Cooling Troubles; Overheating of Engine; Non-Freezing Solutions; Air-Cooling Methods; Heating a Car 145
16. **Lubrication:** Engine Lubrication Methods; Purpose of Lubrication; Oil Gauges; Kind of Engine Oil to Use; Engine Lubrication Troubles; Relation of Carbon to Lubricating Oil; Pointers on General Lubrication of a Car 157

ELECTRICITY; IGNITION

17. **Elementary Principles of Electricity and Magnetism:** Purpose of Ignition; Ignition Methods; Low-Tension Coil Ignition; Principle of a Low-Tension Coil . . . 175
18. **High-Tension Coil Ignition:** Vibrator-Type Coil; Condenser Principle; Master Vibrator Coil; Distributor Principle . . 188
19. **Modern Battery and Coil-Ignition Systems:** High-Tension Coil (Non-Vibrator Type); Open and Closed-Circuit Ignition System; Distributor; Resistance Unit; Safety Gap 196
20. **Delco Ignition:** Coils; Distributors; Interrupters 213
21. **Tests and Adjustments of the Vibrator Type of High-Tension Coil:** Ford Ignition 222
22. **Testing Ignition Coils of Non-Vibrator Type:** Condenser & Resistance-Unit Tests 226
23. **Spark Plugs:** The Missing Spark; Spark Intensifier 233
24. **Wire for Ignition Systems** 240
25. **Low-Tension Magneto,** Principle of . . 242
26. **High-Tension Magneto:** Principle; Types 256
27. **Magneto Installation:** Driving the Magneto; Magneto Speeds 287
28. **Ignition Timing:** Timing the Magneto; Timing Miscellaneous Ignition Systems . 291
29. **Care and Repair of the Magneto** . . . 308

ENGINE STARTERS

30. **Engine Starters:** Ignition; Priming; Compressed-Air; Gasoline and Air; Electric . 317
31. **The Electric Starting Motor:** Principle of an Electric Motor; Windings 319

ELECTRIC GENERATOR

32. **The Electric Generator:** Construction and Principle; Armature Windings 331
33. **Generator Field-Windings and Regulation Methods** 345
34. **Motor-Generators:** North-East (with Ignition System); Simms-Huff; U.S.L. . 367

ELECTRICAL SYSTEMS

35. **Delco Electric Systems** 383
36. **A Study of Leading Electrical Starting and Generating Systems:** Pointers for Studying Electric Systems; Wiring Diagrams . 411
37. **Wiring of a Car:** Starting, Generating, and Lighting 425
38. **Lighting a Car** 431
39. **Signal Alarms; Speedometers** 443

TROUBLES, TESTING, ADJUSTING

40. **Electric Parts of a Car:** Preliminary Instructions for Locating Troubles of the Electric System 448
41. **Digest of Troubles:** Electrical Troubles; Engine Troubles; Miscellaneous Troubles 454
42. **Testing Devices for Electrical Tests:** Ammeter, Voltmeter Construction; Tests 463
43. **Tools and Equipment for the Automotive Electrical Repair Shop:** When to Test on the Car and on the Bench 473
44. **Different Methods for Testing the Electrical Parts of a Car:** Lighting Tests; Armature Tests; Field Tests; Generator, Starting Motor, and Cut-Out Tests . . 482

TABLE OF CONTENTS

INSTRUCTION NO. PAGE

45. **Example of a Modern Method of Making Electrical Tests:** (Ford Generator, Motor, and Cut-Out as an Example) 507

STORAGE BATTERY

46. **The Storage Battery:** General Description; Connections; Care 521
47. **The Storage Battery:** Internal Construction; Principle of Action; Electrolyte; Hydrometer Tests 529
48. **Testing Storage Batteries:** Voltmeter Tests; Cadmium Tests; High-Amperage Discharge Tests 545
49. **A Digest of Storage-Battery Troubles:** External and Internal; Pointers . . . 556
50. **Storage-Battery Charging Equipment** . . 564
51. **Charging Batteries:** Putting in Storage . 572
52. **Equipment for Storage-Battery Work:** Layout of a Shop for Storage-Battery and Electrical Work; Tools and Supplies; Charging Equipment 580
53. **Repairing Storage Batteries** 586

TIRES

54. **Tires:** General Description 591
55. **Tire Construction; Care and Repair of Tires:** Vulcanizers; Tools 608

OPERATING AND CARE OF A CAR

56. **Operating a Car:** Gear Shifts; Control Levers and Pedals of Some of the Leading Cars; Pointers on Selecting a New Car; Judging and Testing a Second-Hand Car . 629
57. **Care of Car:** Pointers on Driving; Washing, Polishing, and Cleaning Car; Home-Made and Other Polishes; Painting a Car at Home; Pointers on Shipping a Car . . 643
58. **Traffic Regulations:** Rules of the Road; Pointers on Driving 651
59. **Touring:** Touring Equipment and Pointers 656

AUTOMOBILE REPAIRING AND ADJUSTING

60. **The Automobile Repairman:** Pointers for the Beginner; Starting in the Repair Business; Light Tool Equipment for the Auto Mechanician 661
61. **The Garage:** Building and Equipping . 665
62. **The Repair Shop or Service Station and Its Equipment** 691
63. **Small Tools for the Shop:** Wrenches, Flat and Socket Type; S.A.E. Cap Screw and Bolt Sizes; U.S. Standard Bolt Sizes; Tap and Die Sets; Portable Electric Drills; Electric Bench Grinder. . . . 695
64. **Precision Tools for the Automobile Mechanic; How to Use Them:** How to Read Micrometer Calipers; How to "Mike" up Cylinders, Pistons, etc 701
65. **Miscellaneous Repairing:** How to Solder; How to Braze; How to Case-Harden and Temper Steel, etc.; How to Straighten Metal Parts; Repairing Radiators; Adjusting Silent Chains; Gaskets 719
66. **Oxy-Acetylene Welding and Cutting** . . 741
67. **Top Repairing** 753
68. **Repairing and Adjusting a Car:** Overhauling a Car; Cleaning and Lubricating; Removing Carbon; Causes of Loss of Power; Compression Tests; Grinding Valves; Testing for Engine Knocks; Refacing and Reseating Valves. . . . 757
69. **Engine Bearings:** Main Bearing Adjustments; Fitting Bearings; Scraping, Burning-In, Boring, Reaming, Lapping, etc.; Crankshaft Alignment; Cam Shaft Adjustments; Connecting Rod and Piston Pin Bearings and Alignment; Relation of Vibration to Balance 781
70. **Pistons:** Types, Construction and Fitting; Piston Clearance; Standard and Oversize Pistons; Piston Repairing; Lapping Piston and Rings in Cylinders; **Enlarging Cylinders:** Different Methods of Finishing Bores of Cylinders 807
71. **Piston Rings:** Types, Construction, and Fitting; Piston-Ring Gap Clearance; Piston-Ring Groove Clearance; Measurements of Piston Rings; Standard and Oversize Piston Rings; Testing and Fitting Piston Rings. 825
72. **Adjusting and Repairing Clutches, Transmissions, and Universal Joints**. . . . 838
73. **Rear Wheels, Differential, and Rear Axles for Passenger Cars:** Types; Adjustments and Repairs 863
74. **Brakes:** Types; Care and Adjustments . 884
75. **Steering Gears; Front Axle; Front Wheels:** Types; Care of; Adjusting; Lubricating and Overhauling; Alignment; Adjusting Front-Wheel Bearings . . . 898

COMMERCIAL CARS. TRACTORS

76. **Commercial Cars:** Trucks; Types and Construction; Axles; Worm-Gear Ratio; Repairing; Adjusting; Taxicabs . . . 911
77. **Tractors:** Types; Engines; Kerosene as a Fuel; Fordson Tractor; Repairing . . 981

MISCELLANEOUS SUBJECTS

78. **Miscellaneous Engines:** Farm-Lighting Plants; Two-Cycle Engines; Diesel Engines; Gas Producers; Stationary Engines 1002
79. **Motorcycles:** Engines; Transmissions; etc. 1007
80. **Miscellaneous Cars:** Woods Dual Power Car; Magnetic Gear Shift; Steam Car; Owen Magnetic Car (Electric Transmission); Principle of the Airplane. . . 1015
81. **Remodeling Old Cars:** Speeding Up Old Cars; Speeding Up a Ford 1023
82. **Useful Repair Hints and Suggestions** . . 1035
83. **General Data:** Horsepower; Specifications; Tables; Miscellaneous Data 1042
84. **Dictionary:** Meaning of Motor Terms. . 1074
86. **The Liberty Engine** 1142

FORD AUTOMOBILE

85. **Model "T" Ford:** Principle; Construction; Carburetion; Electric System; Repairing 1080

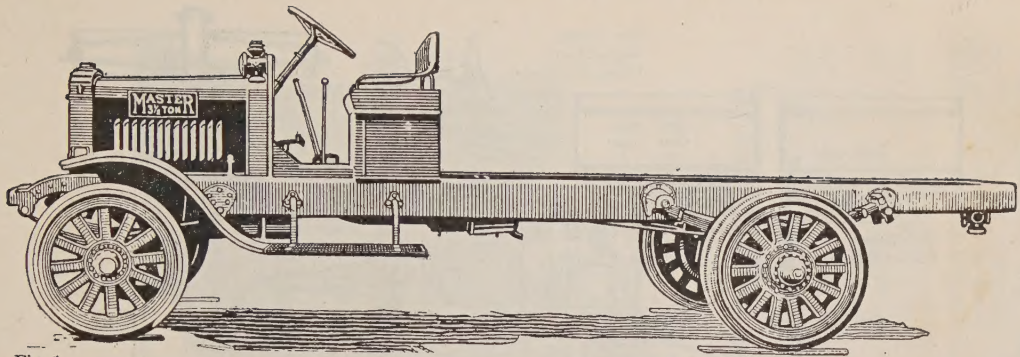

Fig. 1

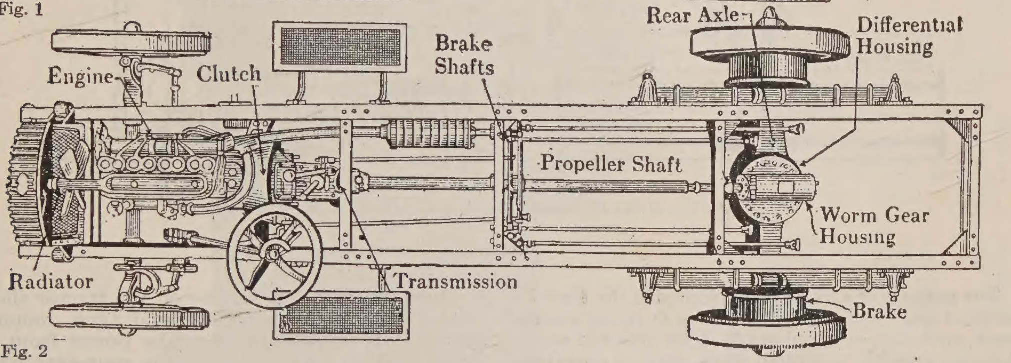

Fig. 2

A Truck

The principle of the truck is similar to the principle of a passenger car type of automobile.

The engine is usually a four-cylinder type of engine, for reasons explained under the Truck Instruction. (See Index.) The truck engine is a slower-speed engine than the automobile engine. The average maximum speed of a truck engine is 900 to 1,000 r.p.m. The engine speed is controlled by a hand throttle and foot accelerator, as in the case of the automobile engine, but **a governor is employed,** for reasons stated under the Truck Instruction, which is to prevent undue "racing" of the engine when changing gears or releasing the clutch.

By governing the engine speed, the car speed is also limited. For instance, the governor can be set to govern the engine speed at 950 r.p.m., which gives a maximum car speed of 14 m.p.h., which is the average speed of a heavy-duty truck.

The speed of a passenger type of automobile varies from 1½ m.p.h. to 50 or 60 m.p.h., and a governor is not employed. The engine speed of a passenger type of automobile varies from 150 r.p.m. to as high as 2,500 to 3,000 r.p.m. The truck, however, being designed for commercial use, must necessarily be more efficient; hence the employment of a governor.

All complicated devices are eliminated on a truck, for the sake of efficiency. For instance, the electric starting motor is seldom used. Instead, the engine is cranked by hand in connection with an "impulse starter" (see Index). Instead of a coil, battery, generator, cut-out, timer, and distributor being used for **ignition,** a high-tension magneto is usually employed. The gravity fuel-feed system is used instead of a vacuum or pressure feed. The tubular type of radiator for **cooling** is used instead of the cellular type. The cellular type, as generally used on automobiles, is more artistic in appearance, but the tubular type has larger openings, is less liable to clog, and is easier to repair.

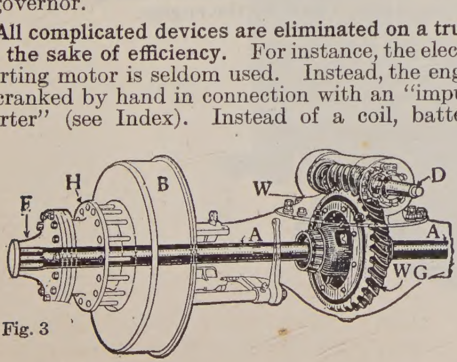

Fig. 3

The drive method usually depends on a propeller shaft connected with (**D**) to a worm gear (**W**) to a worm-driven gear (**WG**) on the differential. The worm gear gives a greater reduction and is silent and possesses enormous strength.

The rear axle is usually a full-floating "live" axle. Axle shafts (**A**) are split and the inner ends are connected to differential gears and the outer ends to the hub flange (**F**).

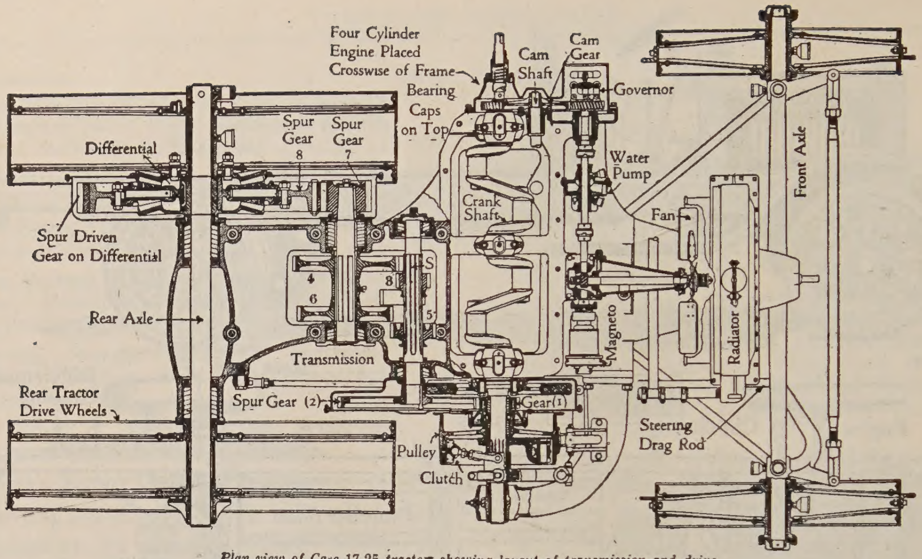
The transmission is usually a three-speed forward and reverse, and is similar to an automobile transmission, but of heavier construction. **Gear ratios:** On the truck shown above: **on first speed,** rear wheels make 1 revolution to every 24 of the crank shaft of the engine; **on second speed, 1 to 13.6; on high speed, 1 to 8.**

The clutch used on the truck shown above is a dry-plate multiple-disk type. The disk type of clutch is extensively used, as is also the cone type of clutch.

The tires on the truck illustrated are solid 34″ x 4″ single, in front; 36″ x 7″ in rear. The "dual" solid tire, also the "pneumatic cord" truck tire is also extensively used.

The steering gear used on the truck shown above is the Ross; see Index under "Steering devices."

From the foregoing specifications of a truck and after a study of this book, it will be noted that a truck differs only in a few details from the principle of the passenger-car type of automobile.



Plan view of Case 17-25 tractor, showing layout of transmission and drive

A Tractor

The purpose of a tractor is explained in the Tractor Instruction. Note that in addition to doing **tractor work,** such as pulling plows or other drawbar work, it is also possible to do **belt work,** such as operating threshing machines, etc.

The illustration above is that of a four-cylinder engine tractor. Most all tractor engines are four-cylinder, for reasons explained under the Tractor Instruction.

The construction of a tractor differs considerably from that of an automobile or truck, but the same underlying principles of the engine and drive system are employed.

The engine used on a tractor is a slow-speed engine, and has usually a long stroke. This particular tractor engine has a bore of 4½ in. and a 6 in. stroke. **A governor** is employed for the purpose explained under the subject of "Governors." The speed of the engine is governed to 900 r.p.m.

The ignition is usually a high-tension magneto, with an "impulse starter" (see Index for explanation of an impulse starter). Most tractor engines use magneto ignition for reasons stated in the Tractor Instruction.

The tractor engine operates for long periods of time at full power. Therefore it must be built heavier and more substantial than the automobile engine, as, for instance, in the bearings, etc.

The fuel is usually gasoline to start with and kerosene to run on after the engine is started and thoroughly heated. **The heating** of a tractor engine, in order to use kerosene or low-grade fuels, is a very important factor.

Drive system: The engine on the tractor shown above is a four-cylinder, vertical type, mounted transversely on the frame. The power from the crank shaft is transmitted to the **spur-gear transmission** by means of a clutch. From the transmission, power is transmitted to the rear axle by means of a spur-gear drive. The differential is employed as shown in the illustration. Power is transmitted to both rear wheels, which are 52 in. in diameter and have a 12-in. face.

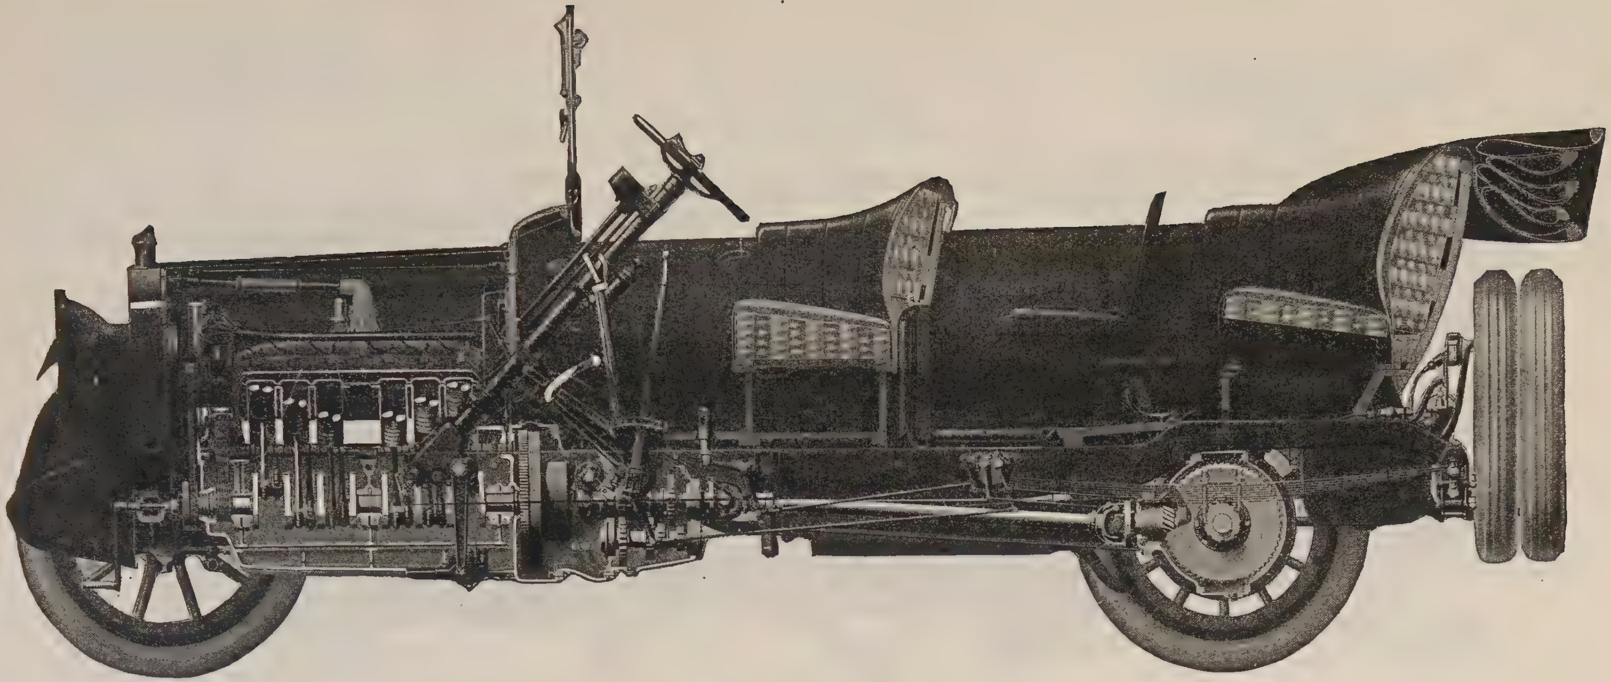
The speed of the average tractor is 2 m.p.h. on slowest speed, and 2¾ m.p.h. on high speed (see also Index under "Tractors").

The belt power is obtained from a 16-in. pulley mounted on an extension of the engine shaft, and runs therefore at engine speed—900 r.p.m.

The tractor illustrated (the Case 15–27 h.p. tractor) has a wheel base of 76½ in., and its overall dimensions are: length, 126 in.; width, 72 in.; height (without exhaust pipe), 68 in. The shipping weight is 5,500 lbs.

The tractor pulls three 14-in. plows in tough sod, or four plows under usual conditions. It is also adapted for other drawbar work, requiring a similar amount of power, and it will operate either a 20 x 36-in. or a 26 x 46-in. thresher (belt work).

It will be observed that the tractor, while it differs widely in construction, from that of the truck or passenger car automobile, is, in many respects, similar in principle, the main difference being in the drive system and fuel used by the engine.



A Twelve-Cylinder Automobile

The modern automobile employs either a four, six, eight or twelve-cylinder engine. The illustration above shows a twelve-cylinder car.

The engine, clutch, and transmission are housed in one unit, called a "unit-power-plant."

The drive on the car shown above is a propeller shaft with a spiral or helical drive pinion which meshes with a spiral-driven ring gear on the differential of the rear axle. Straight-tooth bevel gears are also used on many makes of cars.

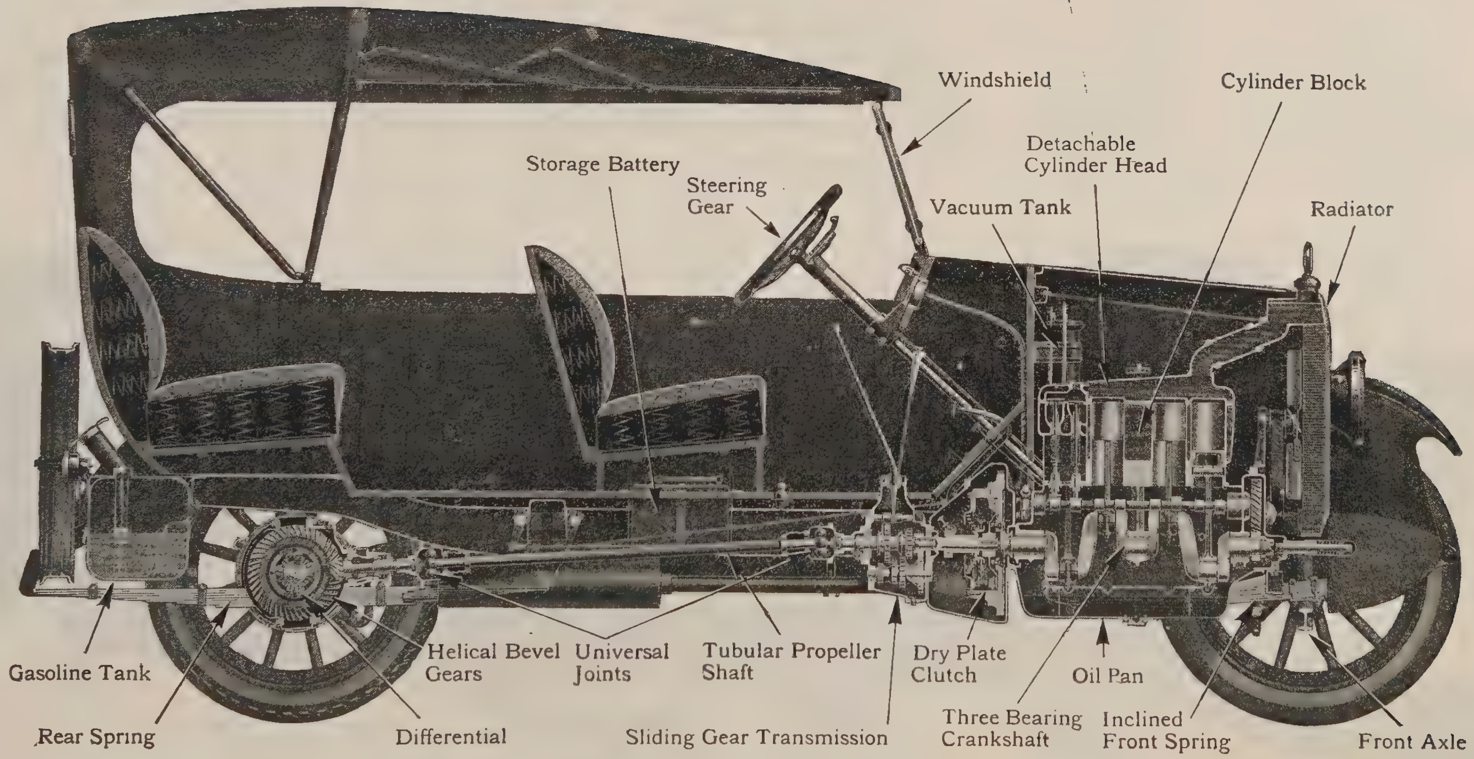
The engine is started by an electric motor, which derives its electric current supply from a storage battery. The storage battery is kept charged by a dynamo or generator, driven from the engine.

The gasoline feed is from the gasoline tank in the rear of the car. In this instance, the gasoline is fed to the carburetor by air pressure. On many other modern cars the vacuum principle is extensively used.

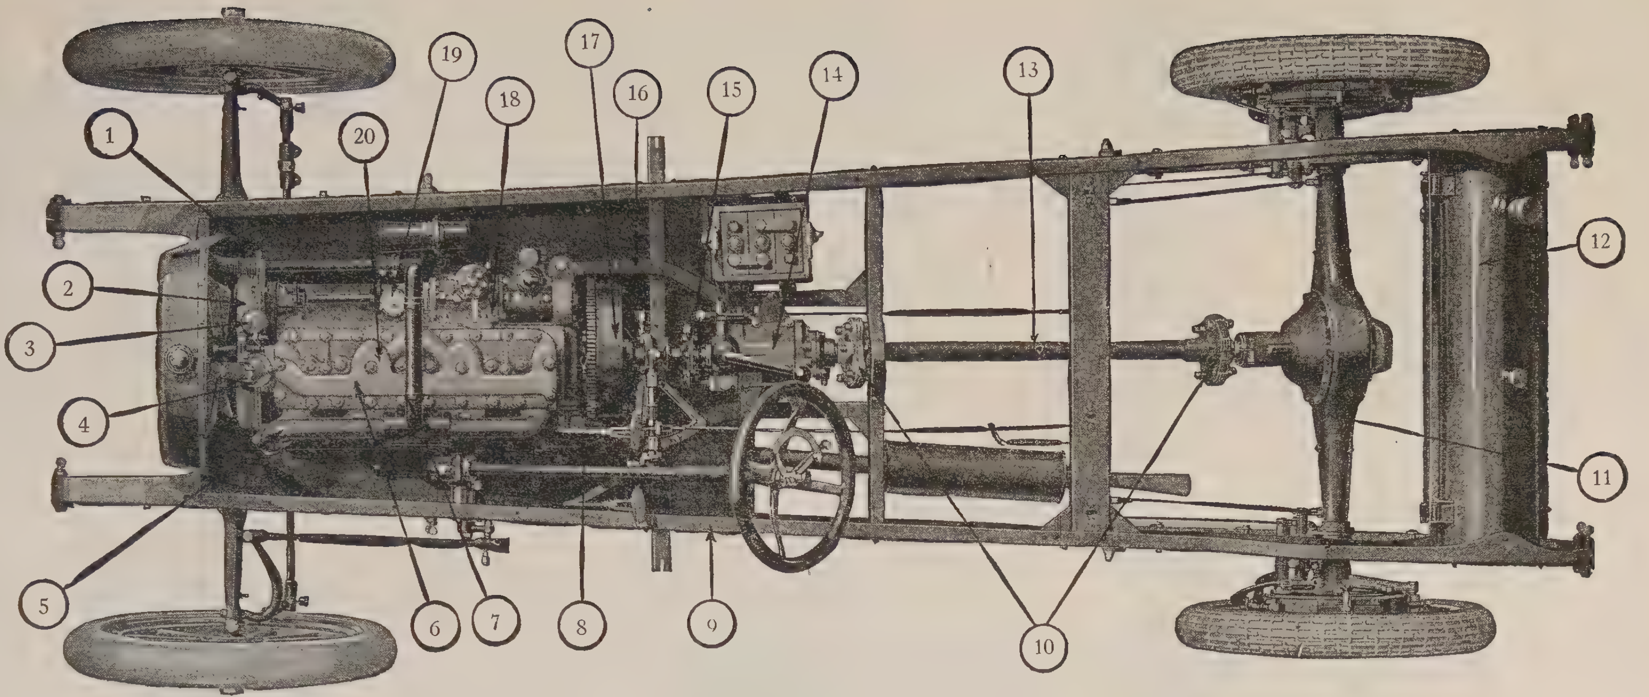
The speed of the engine is controlled by a foot accelerator and hand throttle. Owing to the great variations of speed, the governor is not employed on passenger-car automobiles. The speed of automobile engines varies from 150 to 2,500 r.p.m., and is sometimes as high as 3,000 r.p.m.

The ignition, in most instances, and in the car shown, is of the coil, battery, timer, and distributor type, but many use the high-tension magneto.

Cooling is a forced circulation, by means of a water pump. A sylphon or water thermostat is used for reasons stated in the discussion on the subject of "Cooling." The cellular type of radiator is used.



A Four-Cylinder Automobile (Allen)



A Six Cylinder Automobile (Studebaker Light-Six)

1. Silent chain adjusting nut.
2. Aluminum timing-gear case.
3. Oil-filler pipe.
4. Thermostatic water regulator.
5. Exhaust manifold.
6. Aluminum detachable head.
7. Warm-air stove and pipe leading to carburetor.
8. Starter motor and Bendix drive.
9. Deep-channel section straight-side frame.
10. Flexible-disk universal joints, requiring no lubrication.
11. Pressed-steel rear-axle housing.
12. 15-gallon gasoline tank with protecting shield.
13. Tubular propeller shaft.
14. Transmission suspended at three points on subframe.
15. Flexible-disk coupling between clutch and transmission.
16. Sub-frame carrying engine, clutch, and transmission.
17. Flywheel containing single-plate dry-disk clutch.
18. Accessory unit containing generator, water pump, oil pump, distributor, coil, and relay.
19. Horizontal carburetor.
20. Horizontal intake manifold, water manifold, and detachable head.

Specifications: five passenger; 112-inch wheel base; 40 h.p. 6-cylinder engine; 3⅛ in. bore x 4½ in. stroke; weight of car complete, 2,500 lbs.; 32 x 4 in. tires. **See** Index for other parts of this car.

ASSEMBLY OF THE AUTOMOBILE

The automobile is made up of four component units: the running gear, the power plant, the drive system, and the control members.

These parts are subdivided into other units, and each of these will be treated separately farther on. Although the construction of the different makes of cars may vary, the principle or purpose of the parts remains the same.

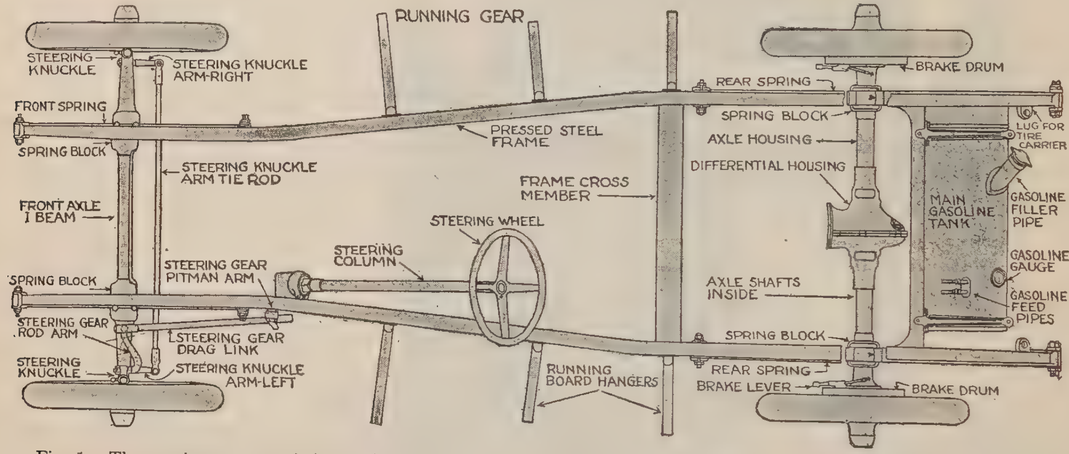


Fig. 1. The running gear, consisting of the front and rear axles, springs, pressed steel frame, and steering device. The main gasoline tank is shown attached.

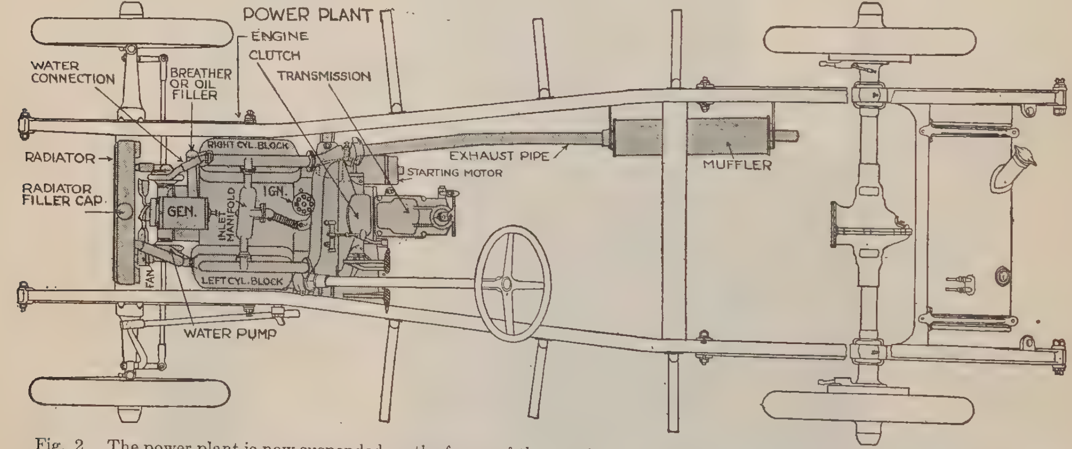

Fig. 2. The power plant is now suspended on the frame of the running gear. The power plant in this example consists of an eight-cylinder V-type engine with the clutch, clutch housing, and transmission all mounted as one unit. It is, for this reason termed a "unit power plant."

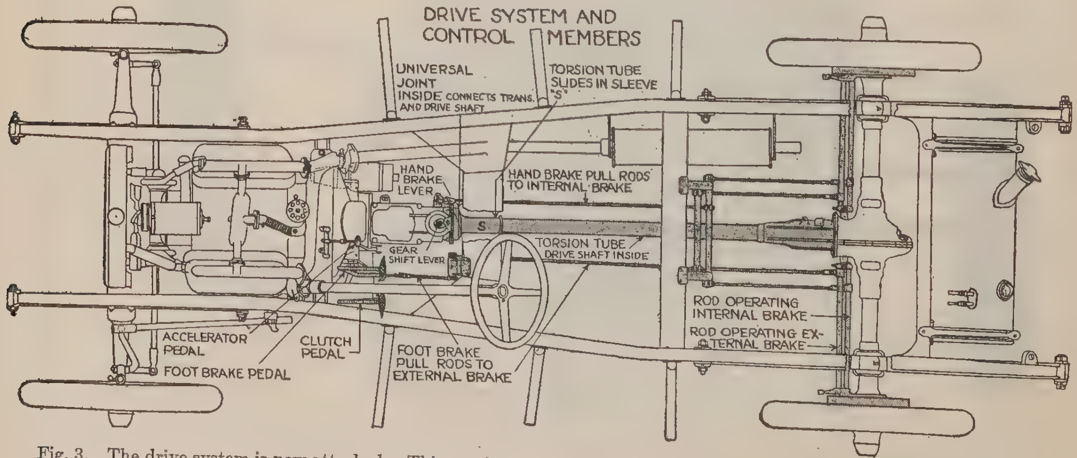

DRIVE SYSTEM AND CONTROL MEMBERS
UNIVERSAL JOINT INSIDE CONNECTS TRANS. AND DRIVE SHAFT
TORSION TUBE SLIDES IN SLEEVE "S"
HAND BRAKE LEVER
HAND BRAKE PULL RODS TO INTERNAL BRAKE
S
GEAR SHIFT LEVER
TORSION TUBE DRIVE SHAFT INSIDE
ACCELERATOR PEDAL
FOOT BRAKE PEDAL
CLUTCH PEDAL
FOOT BRAKE PULL RODS TO EXTERNAL BRAKE
ROD OPERATING INTERNAL BRAKE
ROD OPERATING EXTERNAL BRAKE

Fig. 3. The drive system is now attached. This consists of a propeller or drive shaft encased with a universal joint inside of the torsion tube. On many cars the drive or propeller shaft is not encased. The above is termed the *chassis.*

INSTRUCTION No. 1

ASSEMBLY OF THE AUTOMOBILE

GENERAL EXPLANATION

The Kinds of Motor Cars

There are three different kinds of motor cars: first, the gasoline motor car; secondly, the steam car; thirdly, the electric car.

The gasoline motor car is by far the most popular and it is with this that we are mainly going to deal.

The steam car, silent, smooth, and easy on tires is comparatively seldom seen.

The electric car, almost invariably in the form of a brougham or coupé, is heavily handicapped by being unable to run for more than a few hours without a fresh charge of electricity from its headquarters, and is in less general use. Our attention will be devoted to the car with the gasoline engine for the motive power.

The Component Parts of a Motor Car

A car may be made up as a whole of two distinct parts, the body and the chassis.

The body, which is the work of the body builder and which has been brought by him to a wonderful pitch of perfection, hardly concerns us, so we will unscrew the half-dozen or so bolts that secure it to the frame of the chassis and stand it to one side —for the present, at least—so that we can examine the chassis underneath.

The chassis is the entire car (Fig. 3, opposite), with the exception of the body. The chassis, for our purpose, must also be divided into its main parts as follows: the running gear, the power plant, the transmission system, the control system, the equipment and accessories.

The running gear consists of parts as follows: front and rear axles, wheels, springs, frame.

The power plant (Fig. 2, opposite), consists of parts as follows: the motor with its fuel system, the carburetion system, the ignition system, the cooling system, and the lubrication system.

The drive system consists of parts as follows: the clutch, the change-speed gears, the drive shaft with its universal joints, and the differential.

The control system consists of parts as follows: the steering device, the throttle and spark control, the hand levers, the foot pedals, and the brake system.

The construction of the parts of a motor car may vary, but their purpose is the same. While it is true there are hundreds of different firms making automobiles, they all employ in the construction of their cars the parts enumerated under the various headings. For instance, one manufacturer may suspend the power plant on the main frame, others use a sub-frame; some use a clutch of the cone type, others use a clutch of the multiple disk type—but they all use frames and they all use clutches. Farther on we shall explain the different constructions involved in these parts; but bear in mind that the fundamental principle or purpose of each part does not change.

As we progress, the reader will gain an idea of the different constructions of the component parts now in general use. For instance, there are two kinds of front axles in general use: the tubular type and the solid type. There are two types of construction of rear axles in general use: the live axle which revolves and is driven by a bevel gear and pinion, and the dead axle which does not revolve, but on which the wheels are driven by chain and sprocket; and so on, throughout the whole construction of a car.

It is now clear that if the reader masters the principle and purpose of these parts, it will be no difficult matter to understand the variations in construction, and when he has completed the study of the various constructions he will have gained sufficient knowledge to enable him to understand the construction of all cars.

Purpose of the Parts of the Running Gear

The **front wheels** run free on the axle, and guide the car. They are called the guiding wheels and are moved from side to side by means of a steering device, and the direction of the car is controlled in this manner. The rear wheels are revolved by the engine and drive the car.

The **front axle** is fitted with **steering knuckles** on which the guiding wheels run. These steering knuckles are moved by means of a rod which connects to the steering device. The front axle is fitted with **spring blocks** and spring clips which hold the springs in place.

The **rear axle** revolves. The housing over the axle is fitted with spring blocks and clips similar to the front axle, that is, if it is a "live" axle.

The **springs** act as a cushion and protect the machinery and the occupants of the car from undue vibration and shock. They also hold the frame.

The **frame** of an automobile is made of pressed steel and is the foundation which supports the power plant, change gears, levers, steering device, fuel tank, body, etc. Each part is bolted to the frame and is kept in proper relation to each of the other parts. The frame is usually hung, with the springs resting on the axles, as shown in Fig. 1, and is called the "overslung" method of frame suspension. Sometimes the springs are fastened below the axles, called the "underslung" method.

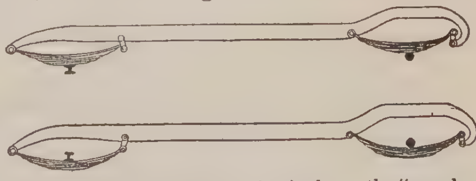

Fig. 1. In the upper illustration is shown the "overslung" spring suspension which is used on the majority of the cars today. Note that here both front and rear springs and also the frame are above the axles. In the lower illustration is shown the "underslung," a form of spring suspension in which the frame is above the axles, but with the springs below, a method seldom used. A popular spring system is the cantilever.

A sub-frame is sometimes placed inside of the main frame to support the power and drive plant.

The **steering device** is usually attached to the frame. By turning the steering wheel, the car is guided through the control of the direction of the front wheels.

Brakes are fitted to automobiles for stopping or slowing down, and are usually fitted to a drum on the hubs of the rear wheels.

Purpose of the Parts of the Power Plant

The **engine** furnishes the power that drives the car. It is usually located in the front part of the frame, if it is a multiple-cylinder type of engine.

Suspension. Multiple cylinder engines usually have four, six, eight, or twelve cylinders. If of the double-cylinder opposed type, it is usually placed across the frame. If a multiple cylinder, "single-unit power plant," it is usually suspended at three or four points. This is called "three-point" or "four-point" suspension.

The **carburetor** mixes air with gasoline, and is connected direct to the intake pipe on the engine. The carburetor is connected to the feed pipe from the gravity tank.

The **gasoline tank** is usually placed under the seat or at the rear of the car, and gasoline is fed to the carburetor through a small pipe or by the vacuum system (as explained under Carburetion).

The **exhaust pipe** connects to the exhaust manifold and runs to the muffler, which is usually placed at the rear of the car. The exhaust pipe permits the burned gases to escape. The muffler, placed at the extreme end of the exhaust pipe, silences or muffles the noises from the explosions in the engine cylinders.

The **ignition system** is a part of the electric plant. It consists either of a storage battery and coil, dry cells and coil, a generator, or a magneto. The coil and battery electric system was formerly placed on the dash, while the magneto or generator is placed on the engine and is run by the cam shaft or crank shaft, through the medium of silent chains. The modern coil and battery system with a timer and distributor is now placed on the engine.

The **cooling system** consists of the radiator, water pipes, circulating pump and fan. The object of the cooling system is to keep the engine from getting too hot when the explosions take place inside of the cylinders.

The **lubrication system** of the engine is for the purpose of keeping the bearings and rings and other moving parts from wearing. This subject as well as the others mentioned will be treated separately, farther on.

Purpose of the Transmission and How the Rear Axle Shafts Are Revolved

The **transmission,** or the speed-change gears, is that part which transmits the power from the engine to the driving wheels through a system of speed-change gears.

A **clutch** is placed between the engine and the transmission; this permits the engine to run free, or, when "thrown in," connects the engine to the change-speed gears and drives the car. The clutch is operated by a foot pedal and is thrown "in" or "out" by the driver.

In a locomotive, the piston rods are connected direct with the wheels, through the medium of the cross-head, and connecting rod, so that when steam is applied the locomotive moves. **In an automobile,** the engine may be disconnected from the transmission by means of the clutch, so that the motion of the transmission or of the entire car may be stopped without stopping the engine.

Change-gear principle: When a bicyclist wants to race on a level track he gears his wheel up high, so that one revolution of the crank takes him the greatest possible distance. Yet if he takes this wheel on the road and encounters a hill, he must get off and walk or exert an extra lot of power—he needs a wheel geared lower.

In the same way, when an engine is required to do more than ordinary work, as climbing a hill, the transmission or change-speed gear contains from two to four changes of gears and helps out the engine by changing to the gear ratio requiring less motive power. It allows the car to move at various speeds while the speed of the engine is unchanged.

When in low gear, the engine makes quite a number of revolutions (10 or 15), while the wheels revolve once, which makes the car move forward slowly, but with considerable force, so that it can go up a steep hill or through sand or mud.

When in second or intermediate gear, the engine makes from 7 to 12 revolutions to one revolution of the wheels, which moves the car faster than the low or first change of gears, but with less force.

When in third or high gear, the engine makes from 3 to 5 revolutions to one revolution of the wheels, which gives the car high speed over good roads.

If the car should be going up a steep grade while on high gear, the work would be more than the engine could do, and it would stop unless one of the lower speeds were shifted in. There would then be considerably more pull on the wheels.

The operation of the change of gears is effected by means of a side or center lever. Change of gears can be made instantly. The transmission also contains a set of reverse gears, which, when thrown in, will reverse the motion of the car without reversing the motion of the engine.

The **transmission** may be connected so that it drives the wheels by the following methods: First, by a **driving shaft** (Fig. 2) connected to the rear axle, which it revolves by means of bevel gears, the wheels and axle turning together. This axle revolves and is called a "live" axle. Second, by a **single chain** (Fig. 3) connected to a "live" rear axle, the wheels and axle turning together (now obsolete).

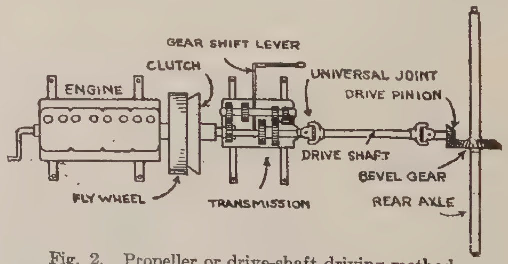

Fig. 2. Propeller or drive-shaft driving method.

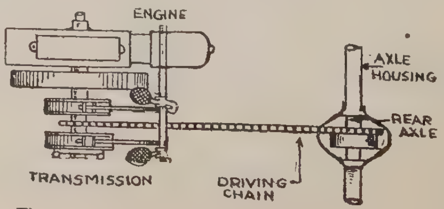

Fig. 3. Single-chain driving method (obsolete).

Third, by **two chains** (Fig. 4), one connected to each rear wheel, which run free on the axle, like a buggy. This is called a "dead" axle because it does not revolve.

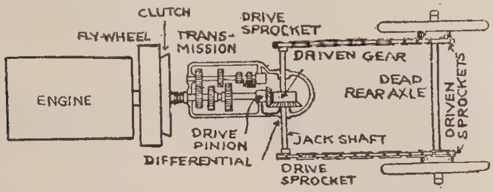

Fig. 4. Double-chain drive method. Seldom used on passenger-car automobiles, but used on trucks to a limited extent.

Drive System

The connection between the engine and the wheels is called the "drive system."

The **drive shaft** connects with the end of the transmission shaft by means of a universal joint. A universal joint is usually at the rear end connecting with the differential drive pinion shaft.

The **universal joints** permit the parts mounted on the rear axle to move up and down, thus preventing the movement of the axle from interfering with the drive of the car.

The **torque rod** is usually placed between the housing on the rear axle and the transmission case. The object of the torque rod (or torque arm, as it is now called) is to prevent the axle housing from twisting when the power or brakes are applied.

The **drive pinion** connects to the rear end of the drive shaft and drives the large bevel gear, which is connected to the differential.

The **front wheels** on an automobile run free on the axle. For this reason the outside wheel is able to revolve faster than the inside wheel when the car is turning a corner.

When a vehicle turns a corner, the outside wheels revolve faster than the inside wheels, because they travel a longer distance.

The **wheels in the rear** must do the same thing; if they were forced to revolve at the same speed, one would slide because it could not keep pace with the other.

When they run free on the axle, they would take care of this themselves, but as both are driven by the engine, the transmission or rear axle is fitted with a **differential,** at times erroneously called a **compensating gear.** This device is automatic, and permits the wheels to revolve at variable speeds, although both are driven by the engine.

Wheels

Tires made of rubber are fitted to the wheels to take up the vibrations that are too sudden for the springs to absorb.

The wheels of an automobile are smaller in diameter than horse-drawn vehicles, due principally to the fact that at the high speed the automobile travels, the wheels would have to be built entirely too heavy to sustain the strain. Automobile wheels must be very strong, because of the weight that they must support, and the strain that they are under. They are made of wood or wire (see illustrations, Figs. 5, 6, and 7).

Wheels are divided into three classes (Figs. 5, 6 and 7): wood, wire, and disk wheels, the latter type being made of wood or metal.

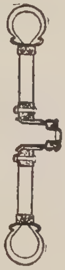

Fig. 5

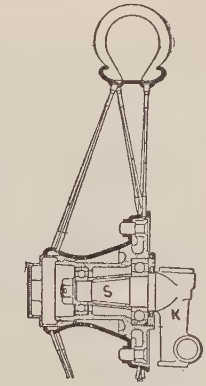

Fig. 6

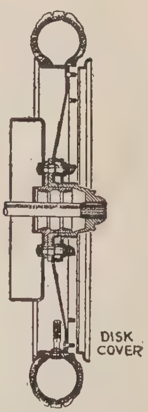

Fig. 7

Fig. 5. Sectional view of a "wood artillery" type of wheel.
Fig. 6. Sectional view of a wire wheel.
Fig. 7. Sectional view of a disk wheel.

Wood Wheels

The wood wheel predominates, but does not possess the lasting qualities of metal, and costs less. It is usually termed the "artillery type" (see Fig. 5). A steel rim is fitted over a wood felloe which holds the tire.

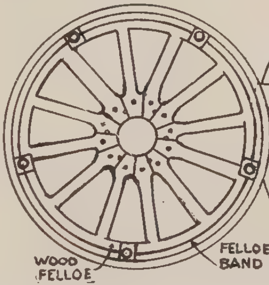

Fig. 8

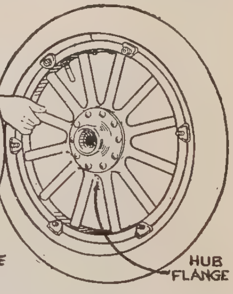

Fig. 9

Fig. 8. Wood wheel without hub flanges, but with rim mounted.

Fig. 9. Wood wheel with hub complete, rim and tire mounted.

The artillery type of wood wheel is shown in Figs. 8 and 9. Note that the spokes meet at the center and are bolted between the metal hub flanges. Wood felloes are shrunk on to the wooden spokes to carry a steel felloe band, and on the steel felloe band, a steel rim is fitted to take the tire.

Easy riding qualities always have been claimed for the wire wheel, and this is largely due to the fact that the weight is centered in the hub and that the car weight is suspended from the top spokes, whereas in the wood wheel the weight is taken on the spokes at the bottom. Road shocks, therefore, are more readily transmitted through the wood spokes to the hub of the wheel than in a wire wheel. With a wire wheel, it is claimed, acceleration is much improved because the wheel is set in motion more easily by virtue of the lighter rim. In other words, the hub of a wire wheel, wherein is centered the weight of the wheel, literally wraps the spokes about it, and the spokes in turn pull the light rim after them.

If wood spokes become loose and squeak the cause is usually due to dryness, from lack of washing. To remedy, swell the spokes by soaking well with water. When wood spokes break, new ones can be fitted.

Wire Wheels

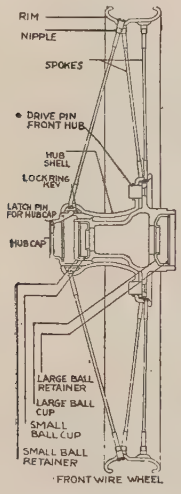
Wire wheels are lighter and are generally of the demountable type, that is, the wheels are demountable, but not the rim. The triple-spoke construction is the favored type.

When wire wheel spokes break or become loose, new ones can be inserted or loose ones tightened, similar to the treatment given to bicycle spokes. Hub caps on wire wheels must be tight, otherwise there will be an intermittent clicking noise.

The parts of a wire wheel are shown in Figs. 10 and 11. The rim on this wheel is of the clincher type. It could be, and usually is a straight-side type of rim. The "Ford," "Overland Four," and "Maxwell 25" use 30 x 3½ clincher rims, but most all other cars use straight-side rims.

Rims are not demountable on wire wheels (see Index under "Wire wheel rims").

Wire wheels usually come in sets; five detachable and interchangeable wheels and five hubs make a set—four on the car and one spare, all detachable at the hub. All are usually interchangeable, front or rear, right or left. Unscrewing and replacing the hub cap is all that is necessary in changing the wheels. The spare wheel may be carried with the tire inflated ready for immediate attaching to any of the hub mountings. Wheels of this type are usually equipped with a built-in locking device, which adds safety without interference to the quick-change feature. See also Index under "Wire wheels."



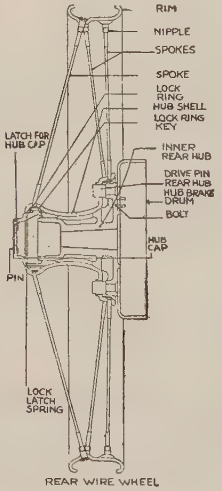


Fig. 10. Rear wire wheel with 30 x 3½ clincher rim for a Ford. Note the brake drum attached to the hub flange.

Fig. 11. Front wire wheel with 30 x 3½ clincher rim for a Ford. The parts are shown in the illustration.

Disk Wheels

Disk wheels are now popular and add considerably to the appearance of a car. The steel disk is usually dished and welded or bolted to the felloe, or the wheel is made in one piece with demountable rims. The hub is usually bolted to the disk. Disk wheels are also made of wood.

Easier riding qualities, rapidity of wheel change, and the ability to keep them clean are some of the major things claimed for the disk wheel.

The wood disk wheel is made from the same grade of wood as used for airplane propellers and is laminated in such a way that the grain in each lamination runs in a different direction. These wheels are claimed to be of about the same weight as spoked wheels, but to have four times the lateral strength.

With many of the disk wheels it is not necessary to carry a spare, only a rim being necessary. On others the entire wheel is changed. See Index under "Disk-wheel rims."

Mud guards or fenders are always fitted over the wheels, to protect the car and occupants from the mud thrown by the wheels.

Meaning of Wheel Base and Tread or Track

The wheel base of an automobile is the distance (in inches) between the rear axles and the front axles. The long wheel base rides easier than a short wheel base. The frame must be sufficiently stiff, however, to prevent sagging from the weight resting on it. The wheel bases vary from 80 inches on runabouts to 144 inches on larger cars.

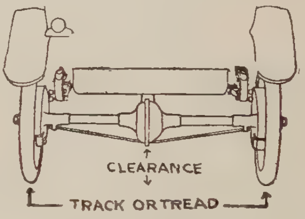

Fig. 12

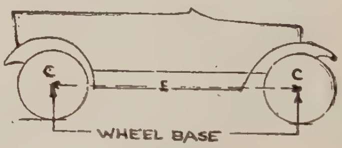

Fig. 13

The tread (also called track) is the distance the two wheels are apart measured parallel with the axle. The standard tread is 56 inches, measured from center to center.

The treads of wagons and carriages vary in different parts of the country. In the Southern states it is 60 inches; in the West 48, and in most of the other parts of the country 56 inches. Small, light cars are sometimes made with a smaller tread than 56 inches, but this is exceptional.

The road clearance is the distance from the lowest point of the car to the road. For rough roads, a greater clearance is required than for smooth roads, as a high place in the road would strike parts of the machinery that hung too low. The front axle, which is solid and heavy, is usually curved down in the center, so that it will be the first part of the car to strike a high place, thereby protecting the delicate parts behind it.

The Body

The automobile frame, with all parts of the running gear, the transmission, engine, and other parts of the mechanism, when it is without the body, is called the **chassis**. Different types of bodies may be attached to a chassis, and are generally fastened down with bolts.

Although there are many special makes of bodies which are given special names, the illustrations that follow will give the reader the names of the standard type of bodies.

Body Nomenclature

The following descriptions of the various types of bodies, illustrations of which are shown below, are those proposed and recommended by the Passenger-Car Body Division as the standard recognized by the S. A. E. (Society of Automotive Engineers).

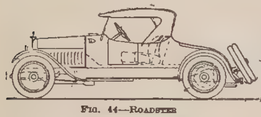

Fig. 44—Roadster

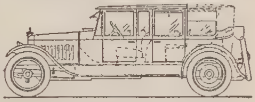

Fig. 55—Berline-Landaulet

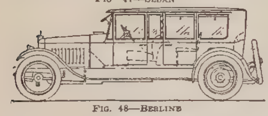

Fig. 48—Berline

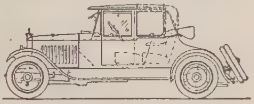

Fig. 56—Coupe Landaulet

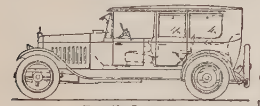

Fig. 49—Limousine

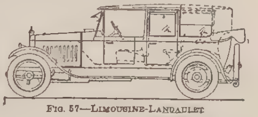

Fig. 57—Limousine-Landaulet

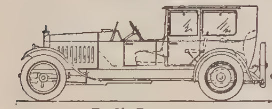

Fig. 50—Brougham

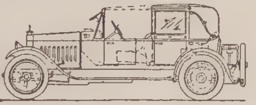

Fig. 58—Cabriolet

Roadster (Fig. 44): A small open-type body, having one fixed cross-seat for two passengers and a space or compartment at the rear for carrying luggage. Folding seats fitting into the luggage compartment are sometimes used. The conventional type has two doors and a folding roadster top with emergency side-curtains that are removable.

Coupe (Fig. 45): An enclosed single-compartment body, with one fixed cross-seat. This seat may be straight and accommodate two persons, or be staggered and accommodate three persons. With the latter arrangement, a folding seat may be placed beside the driver's seat, thus making it a four-passenger body. The conventional body has two doors and two movable glass windows on each side; the roof is permanent; and there is a luggage compartment at the rear.

Phaeton[1] (Fig. 46): An open-type body, with two fixed cross-seats for four or five passengers. Folding seats in the tonneau for two additional passengers are sometimes used. The conventional body has four doors and a folding phaeton-top with emergency side-curtains that are removable.

Sedan (Fig. 47): An enclosed single-compartment body, with two fixed cross-seats for four or five passengers. Sometimes the front seat is divided by an aisle. Folding seats in the tonneau for two additional passengers are sometimes used. The conventional body has four doors, but some models have only two. There are three movable glass windows on each side and the roof is non-collapsible.

Berline (Fig. 48): A body of the same general description as the sedan, except that there is a partition at the rear of the driver's seat that makes it an enclosed two-compartment body. Generally one glass window in the partition is made so that it can be moved horizontally or vertically.

Limousine (Fig. 49): A partially enclosed body, with a non-collapsible roof that extends the full length of the body and is attached at the front to the windshield standards. Only the rear portion of the body up to the partition at the rear of the driving seat is fully enclosed. Forward of this partition, the sides are enclosed only from approximately the belt downward. There are two low doors and one fixed cross-seat for two in the forward section. In the rear section there is one fixed cross-seat for two or three. Folding seats for two additional passengers are sometimes used. There are two doors in this section, and two movable glass windows on each side.

Brougham (Fig. 50): A body of the same general description as the limousine, except that the non-collapsible roof extends only over that portion of the body that is entirely enclosed.

Landaulet (Fig. 52): A body similar in appearance to the brougham, except that the enclosed section is shorter from back to front, and the roof is fully collapsible up to the partition at the back of the driver's seat. The body has one fixed cross-seat in the rear section for two or three passengers, two doors made with either flappers or hinged upper parts, and glass windows in the doors only. The rear quarters, back and top, are covered with leather or fabric. There are outside joints to support the top.

Sedan-Landaulet (Fig. 53): A body of the same general description as the sedan, except that the top back of the rear doors is collapsible. Forward of this point the roof is non-collapsible, and the windows are the same in number as in the sedan. The rear quarters, the back above the belt, and the roof are covered with leather or fabric.

Brougham-Landaulet (Fig. 54): A body that bears the same relation to the brougham as the sedan bears to the sedan-landaulet.

Berline-Landaulet (Fig. 55): A body that bears the same relation to the berline as the sedan-landaulet bears to the sedan.

Coupe-Landaulet (Fig. 56): A body that bears the same relation to the coupe as the sedan-landaulet bears to the sedan.

Limousine-Landaulet (Fig. 57): A body that bears the same relation to the limousine as the sedan landaulet bears to the sedan.

Cabriolet (Fig. 58): A body similar in appearance to the brougham and having the general characteristics of the landaulet, except that the falling pillar-hinge is set back from the pillar-line and shows the curved parting line through the leather. The rear section is therefore longer than that of the landaulet. The body has one fixed cross-seat for two or three, and folding seats on the partition for two additional passengers.

The distinction between the **Delivery Wagon** and **Truck** is in size and weight. The delivery wagon is usually a shaft-driven solid, or pneumatic-tired car, whereas the truck is a double-chain or shaft-driven solid or pneumatic-tired, heavier machine.

---

[1] The principal reason for recommending the use of the term "phaeton" instead of the term "touring" is that the latter has lost its significance as applying to any particular type of body, as all types are used for touring. The term "phaeton" is used extensively in Europe, and to a considerable extent in America, in connection with passenger-cars; it is the name of a horse-drawn prototype; it is inelegant and in a technical sense is not distinctive of any particular type of motor vehicle body.

INSTRUCTION No. 2

DRIVE METHODS: Drive-Gear Reduction

VARIOUS DRIVE METHODS

The power from the engine is transmitted through the transmission; and is applied to the propelling of the car by those parts called the drive.

There are three methods of transmitting power to rear-axle shafts: **the double-chain drive,** requiring a "dead" rear axle; **the single-chain drive** (seldom used); and **the shaft or propeller-shaft drive,** which requires a "live" rear axle.

There are seven drive methods: single chain (obsolete); **double chain; internal gear** (page 929); **double reduction** (page 925); **double reduction internal** (page 933); **worm** (pages 17, 914, 920, 954, 956); **bevel gear** (Fig. 3 below). The last mentioned is the type generally used on passenger cars.

Double-Chain Drive

The double-chain drive is seldom used on pleasure cars, but is used quite extensively on trucks. Trucks use chains, because trucks carry heavy loads and often have solid "dead" axles.

When, as is usual in cars of this type of drive, the engine is in front, the crank shaft is parallel to the sides of the car, and therefore at right angles to the rear axle. The power developed at the crank shaft must therefore be turned at right angles in order to apply it to the wheels (see Fig. 1). This is done by means of bevel gears, which are in the transmission case.

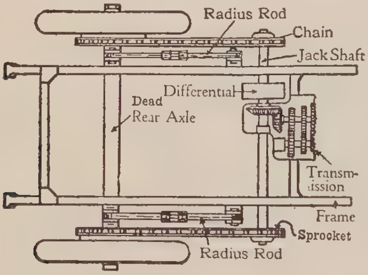

Fig. 1.

The power is transmitted from the crank shaft of the engine to the square shaft of the change-speed gear by gears, as explained farther on. The square shaft carries a bevel gear that meshes with another bevel gear carried on the jack shaft (Fig. 1).

The jack shaft passes across the car, running in bearings in the gear case and on the frame. It is held so rigidly that while it is free to revolve, its bevel gear is always in correct relation to the bevel gear on the square shaft of the transmission.

The jack shaft is in two sections, between the inner ends of which the differential is placed, the differential, of course, being beside the bevel gear that drives the jack shaft.

At each end of the jack shaft, outside of the frame, is a sprocket which is in line with a corresponding sprocket on the rear wheel of that side (Fig. 2). Over each pair of sprockets passes a chain that transmits the revolutions of the jack shaft to the wheels which run loose on the ends of the dead axle.

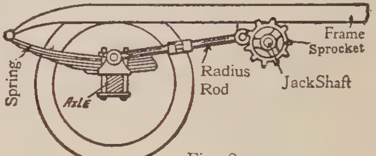

Fig. 2.

The chain most commonly used for automobiles is called a "roller chain." It consists of side pieces in pairs, each pair being secured to the adjoining pairs by rivets passing from side to side. On these rivets are steel rollers which revolve as they touch the sprockets. These rollers fit the space between the teeth of the sprockets, and as the chain bends around the sprockets the rollers are stationary, while the rivets turn inside of them.

To give the best service, the chain must run true; that is, the sprockets over which they run must be in line, the links of the chain must fit the teeth, and the sprockets must be exactly circular. If the sprockets are out of line, the chain will be forced to bend sideways. If the links do not fit the teeth, there will be a grinding that will cause rapid wear, and there will be danger of the chain jumping off. If the sprockets are not exactly circular, during one part of the revolution the chain will be slack, and during the other part will be drawn tight, stretching it.

The double-chain drive has advantages on heavy cars. By its use the weight of the car is carried by a "solid" or "dead" axle, which is lighter than a divided "live" axle of the same strength can be. If a solid axle is bent, it can be straightened easily, while it requires an expert mechanic to straighten a bent live axle.

The disadvantages of double-chain drive are the difficulty of properly lubricating the chains, their rapid wear in consequence, and the liability of chains to stretch and jump off the sprockets.

The worm-gear drive for trucks, with substantial axles of the "live" type, are now considered superior to the double-chain drive.

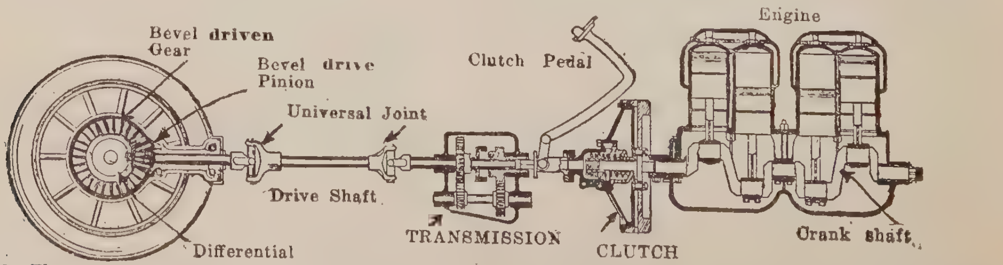

Fig. 3. The modern method for driving the rear axle is by means of a propeller type of drive shaft with a bevel drive pinion and bevel-driven gear on the differential on the rear axle. Commercial cars with shaft drive instead of double-chain drive often use the worm drive.

Propeller or Shaft Drive

In this type, a shaft connects with the square main shaft of the transmission and is extended to the rear axle, where it ends with a small bevel gear called the **drive or driving pinion.** See Figs. 3, 4, p. 28.

This driving pinion meshes with a bevel gear on the differential housing that is mounted between the inner ends of the two parts of the live rear axle, called the **axle-driven gear,** or differential "ring gear," or "master gear," "crown wheel," etc.

The propeller or driving shaft always has one, and sometimes two, universal joints in between the gear box and drive pinion on rear end, so that the moving of the rear end, as the axle receives the jolts of a rough road, does not affect its driving.

The drive and driven gears are contained within a casing or housing that supports the bearings for the parts of the axle and also the end of the driving shaft, so that the bevels are held in the same relation to each other, regardless of the moving of the axle.

The advantages of this type of drive are that all of the moving parts are enclosed and protected from dust, and run in grease or oil, which means perfect lubrication.

Radius Rods

Radius rods, also called "distance rods" and "strut rods," are mostly used on commercial cars using a double-chain drive. They extend from a point alongside of the frame in line with the jack shaft, thence to the rear axle. Thus they keep the chain at the proper tension and the distance from sprocket to sprocket the same, no matter how rough the road. A **turn buckle** is provided to insure adjustment. Radius rods are not used on propeller-shaft-driven cars in the manner described above, but on two or three propeller-shaft-driven cars they are used as shown in Fig. 7. Many worm-drive trucks are equipped with radius rods.

The Torque Member

Torque means turning movement, or twist. The **torque arm, torque tube, radius rod,** or the **rear springs** represent four different methods of preventing torque reaction. The torque arm, or radius rods extend from the cross-member near the transmission to the housing on the rear axle (construction varies).

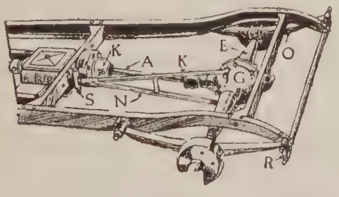

Fig. 4. One type of construction of a torque arm is shown in the illustration. Note the arm (**N**), extending from the rear axle housing to a spring arrangement or torque pillar attached to a cross member, in line with the drive shaft. See illustration (**S**) (**N**).

The tendency for the driving pinion to climb the ring gear when starting or driving a car causes the rear axle housing to twist in the opposite direction to the road wheels. So it is **torque reaction** which the torque member prevents.

What is known as the **"Hotchkiss drive method"** is where the torque and the drive are taken through the semi-elliptic rear springs. The main leaf of each of these is made strong enough for this added duty, and the construction does away with torsion tube, torque arm, and radius rods.

A torque tube is often used instead of a separate torque arm. The propeller or drive shaft revolves inside of the tube (see Fig. 6).

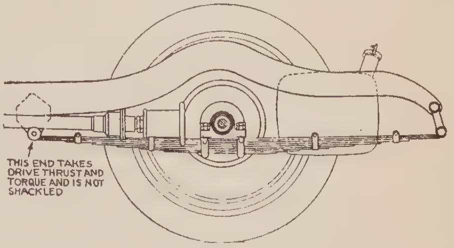

Fig. 5.

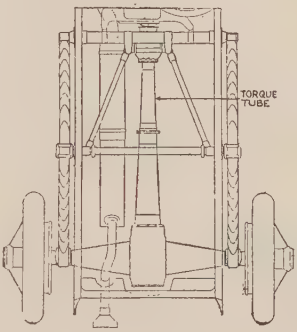

Fig. 6.

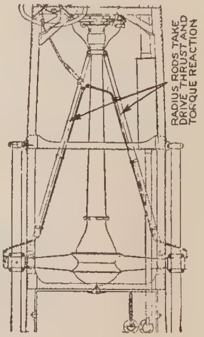

Fig. 7.

Fig. 5. "The Hotchkiss drive." A semi-elliptic spring is used to take the thrust. The forward end of the spring is not shackled, but oscillates on a pin, and this takes the thrust and torque. The rear end is shackled and is free to move under stress.

Fig. 6. A torque tube, which takes both the drive and torque; Rolls-Royce rear axle. See also **Fig. 7, page 16.**

Fig. 7. Radius rods on the Dusenberg, which take both the drive and torque (illustrations from *Motor World*).

Gears and Chains

Spur gears are noisy and are not used very much except for the transmission. They were formerly used for driving the cam shaft. The **helical,** or spiral tooth gear or silent chain, is now used to a great extent for driving the cam shaft.

The worm and worm gear are used extensively as a final drive on the rear axle of trucks.

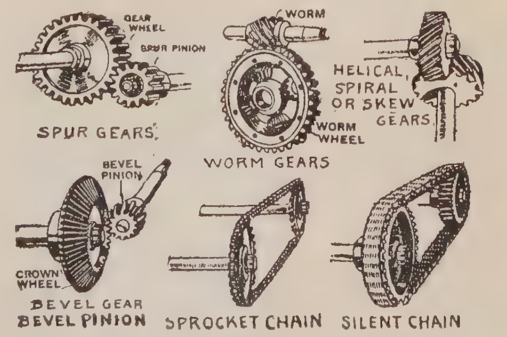

Fig. 8

The helical or spiral gear with straight face can be placed as shown in the illustration above, and may thus be used to drive pumps and distributors. **The bevel helical tooth gear** is used extensively for the final drive on rear axles of automobiles, and is termed a bevel gear with a helical or spiral tooth.

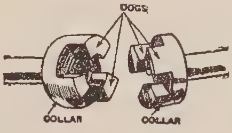
The bevel gear with straight teeth, as shown, is used for final drives, but the helical tooth bevel gear, being more quiet, has taken its place to a large extent.

The worm and worm gear make a wiping contact and the helical, more of a rolling contact. When accurately made, worm gears run with great smoothness and silence. The worm may engage either from above or below the gear wheel. The angle of the worm and gear may be as much as 45 degrees. The worm is made of hard steel and the worm gear of bronze. See Index under "Adjusting of the worm gear on a truck rear axle."

The sprocket chain is used on double-chain-driven trucks. See Index under "Chains for trucks," showing the roller-type sprocket chain.

The silent chain, with special sprockets to take the chain, is used extensively for driving the cam shaft, generator, etc., especially on "V"-type engines. See Index under "Silent chains."

The setting of bevel gears so that they will mesh properly without noise requires careful adjustment, as there must be as little play as possible without having the teeth bind. See Index under "Adjusting drive pinion."



DOG CLUTCH
Fig. 9.

The dog clutch is used in the transmission and can be used for couplings for various driving purposes, as for instance, with the magneto, etc.

When the "dog clutch" is used in the transmission, one dog is placed on the clutch shaft and the other on the square main transmission shaft. On modern transmissions, gears with internal teeth are used instead of the "dog clutch."

Drive Pinion and Driven Ring Gear

The drive pinion (R3) is shown in the illustration below (Fig. 10). This pinion is attached to the end of the drive shaft.

The differential ring gear (N3) is also shown in Fig. 10. This gear is attached to the differential housing, and is driven by gear (R3). Thus the drive is transmitted to the rear-axle shafts through the differential.

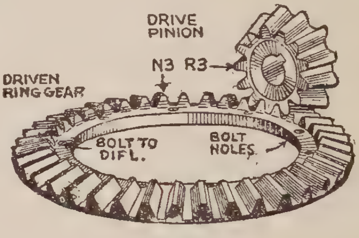


Fig. 10.

Note that both gears (R3) and (N3) have beveled teeth which are straight. The type of gears in general use have beveled teeth which are not straight but helical or spiral shaped.

DRIVE-GEAR REDUCTION

The speed of the crank shaft is reduced so that the road wheels turn once while the crank shaft revolves from three to five times with the high-speed gear engaged.

On cars with single-chain drive (now obsolete) this is done by having the transmission sprocket smaller than the axle sprocket. If the reduction is to be three to one, that is, if the crank shaft revolves three times to one revolution of the axle, the axle sprocket will have three times the number of teeth that the transmission sprocket has.

The reduction on side-chain-driven cars is sometimes made at the bevel driving the jack shaft, but usually at the sprockets.

On shaft-driven cars, the reduction is made at the rear axle-drive gears. The driven gear (N3) (Fig. 12) on the rear axle is given as many more teeth than the drive pinion (R3) on the driving shaft as is necessary for the reduction that is required.

In the worm drive, the reduction is governed as explained under "Worm-gear ratio"; see Index. In other words, the size of the worm could be changed without its changing the speed. (The angularity of course would have to be the same in both cases.)

To make the point clear as to just how the speed reduction is brought about in the worm drive, imagine the screw thread on a vise shaft which draws the jaws together. If that thread is coarse, with only a few to the inch, the jaws would move toward each other rapidly and of course it would take some power to move it; if, on the other hand, there were quite a number of threads to the inch, the jaws would move more slowly but it would take less power to exert the same pressure.

When the "gear ratio" of a car is spoken of, it is often referred to as the reduction between the engine crank shaft and rear axle. Thus, for instance, a "gear ratio of 4 to 1" is where the drive shaft makes four revolutions to one revolution of the road wheels on the high gear.

This term, "gear ratio," should be termed "total gear reduction," as the term "gear ratio" could be applied to the transmission, or to the rear axle. Thus a distinction is made as is explained below.

Difference Between "Rear-Axle Gear Ratio," "Transmission-Gear Ratio" and "Total-Gear Reduction"

Rear-Axle Gear Ratio

"Rear-axle gear ratio" refers to the number of times the rear axle turns over to one revolution of the propeller shaft (P), Figs. 11, 12.

To find the rear-axle gear ratio on any car, divide the number of teeth in the driven gear (N3) on the differential, which in this instance has 71 teeth, by the number of teeth on the drive gear, which in this instance has 16; thus $71 \div 16 = 4.437$, revolutions of the propeller shaft (P), to one of the axle shafts or wheels.

Transmission Gear Ratio

"Transmission-gear ratio" refers to the ratio between the engine crank shaft and the propeller shaft **P**.

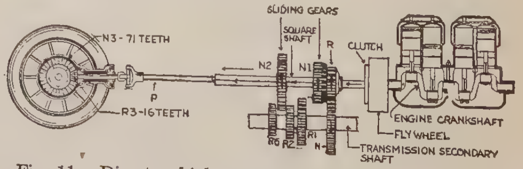

Fig. 11. Direct or high gear. Note that the drive is direct from the engine crank shaft to the drive pinion (R3), to the driven ring gear (N3). Gears (R) and (N) are meshed at all times.

On direct or high gear (Fig. 11), the ratio is 1 to 1, meaning that the engine crank shaft turns over one revolution to one of the propeller shaft (P), because the engine crank shaft is connected direct through the transmission to the propeller shaft **P**. Thus it is termed "direct drive."

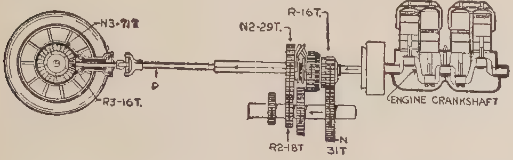

Fig. 12. Low or first gear. Note that the drive is from the crank shaft to the drive gear (R), to the driven gear (N), to the drive gear (R2), to the driven gear (N2), to the drive gear (R3), to the driven gear (N3).

On first or low speed (Fig. 12), the ratio is 3.121 to 1, meaning that the engine crank shaft turns over 3.121 times to 1 of the propeller shaft (P).

To find the transmission-gear ratio, multiply all of the driven gears together and all the drive gears together and divide the product of the driven gears by the product of the drive gears as follows:[1]

N,31teeth×**N2**,29t÷**R**,16t×**R2**,18t=3.121 obtained thus: 31×29=899, the product of the **driven** gears and 16×18=288, product of the **drive** gears, therefore, 899÷288=3.121.

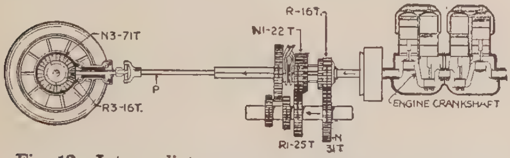

Fig. 13. Intermediate or second gear. Note that the drive is from the engine crank shaft, to the drive gear (R), to the driven gear (N), to the drive gear (R1), to the driven gear (N1), to the drive gear (R3), to the driven gear (N3).

On second speed (Fig. 13), the transmission ratio in this example is 1.705, meaning that the engine crank shaft makes 1.705 revolutions to 1 of the propeller shaft **P**. This transmission ratio is found by following the same rule:

N,31t×**N1**,22t÷**R**,16t×**R1**,25t=1.705.[1]

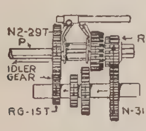

Fig. 14

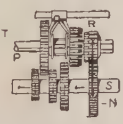

Fig. 15

Fig. 14. Reverse gear. Note that the drive is from the drive gear (**R**) to the driven gear (**N**), to the drive gear (**RG**), to the idler gear, to the driven gear (**N2**), to the drive shaft (**P**), to the rear axle. The idler gear gives a reverse motion to shaft (**P**).

Fig. 15. Neutral gears. Note that the drive is from the drive gear (**R**) to the driven gear (**N**). Gears (**R**) (**N**) and shaft (**S**) revolve independently of shaft (**P**). Thus the rear axle is not connected with the crank shaft of the engine.

On reverse speed (Fig. 14) the transmission ratio in this example is 3.74 to 1, meaning that the engine crank shaft turns over 3.74 times to 1 revolution of the propeller shaft (**P**). This transmission ratio is found by following the same rule.

N,31t×**N2**,29t=899÷**R**,16t×**RG**,15t=240,

thus:

899÷240=3,74.

Note: Sliding gear (N2) is pushed over to the extreme left and meshes with an "idler gear" behind gear (RG). The idler gear then meshes with (N2) and reverse gear (RG). This gives a reverse motion to propeller shaft (P). The teeth on the "idler gear" are not considered, as it is both a driven and a drive gear.

Total Gear Reduction

"Total gear reduction" refers to the number of times the engine crank shaft turns over to one revolution of the axle shafts or rear wheels. This is governed by the diameter of any gear transmitting power to the rear-axle shaft.

To find the total gear reduction, multiply the "transmission-gear ratio" by the "rear-axle ratio."

To find the total gear reduction when in first or low speed, multiply 3.121, the transmission ratio, by 4.437, the rear-axle ratio, and we have 13.847. Thus the engine crank shaft turns over 13.847 times to 1 of the rear-axle shafts or rear wheels.

To find the total gear reduction when in second speed: 1.705×4.437=7.565 revolutions of the engine crank shaft to 1 of the rear wheels.

To find the total gear reduction of third or high speed: 1×4.437=4.437 revolutions of the engine crank shaft to 1 of the rear wheels.

To find the total gear reduction of reverse: 3.74×4.437=16.594 revolutions of the engine crank shaft to 1 of rear wheels.

The foregoing examples of ratios are those used on the Cadillac Type 59 car. The Cadillac sometimes gives a 14-tooth drive pinion (R3) on the heavy closed cars and for touring cars used in hilly countries. The rear-axle ratio would then be: 71÷14=5.071 rev. of propeller shaft **P**, to 1 of the rear wheels.

Miscellaneous Ratios

Ford: Rear axle ratio N3, 40 teeth÷R3, 11 teeth=3.636. Transmission ratio, 1st speed 2.75; 2nd speed 1; reverse 4.

Overland 4: Rear axle ratio, N3, 45 teeth÷R3, 10 teeth=4.5, transmission ratio, 1st speed, 3.62 to 1; 2nd, 2.03 to 1; high, 1 to 1; reverse, 4.83 to 1.

Dodge: the rear-axle ratio is 4.17 to 1.

On some cars, for instance the Locomobile model 48, Mercer Series 5, and Pierce-Arrow Models 31 and 51, there are 4 speeds and on 4th the transmission ratio is 1 to 1. On Locomobile 48 and Pierce-Arrow 51, first speed transmission ratio is 4 to 1. On the Mercer, 3.75 to 1.

On some cars with four speeds, the 4th speed is higher than 1 to 1; for instance the Wasp with 4 cylinders 4¾×5½, the 4th speed transmission ratio is .73 to 1. The rear-axle ratio is 3.7, therefore the total gear reduction would be .73×3.7=2.701 revolutions of engine to 1 of rear wheels. On 3rd speed the Wasp transmission ratio is 1 to 1; on 1st or low, 2.69 to 1. The total gear reduction on 1st speed is 2.69×3.7=9.953 revolutions of the engine crank shaft to 1 of the rear wheels.

Truck-Gear Ratios[1]

Federal 2-ton truck: Rear-axle ratio, 9.25, transmission ratio, 1st speed, 4.40; 2nd, 3.08; 3rd, 1.76; 4th, 1; reverse, 5.28.

Federal 5-ton truck: Rear-axle ratio, 13.66, transmission ratio, 1st speed, 4.99; 2nd, 3.16; 3rd, 1.79; 4th, 1; reverse, 5.78.

Replacing a Drive Pinion

When replacing a drive pinion (R3) with one of a different diameter, it is always necessary also to replace the driven ring gear (N3), because the teeth will mesh too tight at either the big end of the tooth or the little end of the tooth, due to the fact that the teeth are cut at a different angle. See Index: "Differential gear, how to replace."

Relation of Engine Crank Shaft to Periphery of Road Wheels

If the rear axle ratio on a certain car is **4.437 to 1**, and say for instance, high gear is being used, then the rear wheels, no matter how large or how small the wheels or tires may be, will revolve 1 revolution to 4.437 revolutions of engine crank shaft.

It is then clear that the larger the rear wheels or tires, the harder will be the pull on the engine, and that the smaller the rear wheels or tires, the easier will be the pull by the engine.

---

[1] Driven gears are designated in the illustrations as (N), (N1), (N2), etc. Drive gears are designated as (R), (R1), (R2), etc.

INSTRUCTION No. 3

STEERING; SPRINGS; BRAKES

STEERING PRINCIPLE

Principle of Steering

The steering device is placed on the left-hand side of the car. On early model cars it was placed on the right-hand side.

The principle: In steering a wagon, pulling on one of the reins swings the horse to that side. The shaft or pole is attached to the axle, and the axle is pivoted to the king pin, and all swing with the horse.

If you go straight ahead, the front and rear wheels of any vehicle move in straight lines. To make a turn to one side or the other, the front wheels are swung so that they are at an angle with the rear wheels.

Whenever the front wheels stand at an angle with the rear wheels, the vehicle will turn, and it will continue ~~to~~ turn until the front wheels are swung back to a straight line again.

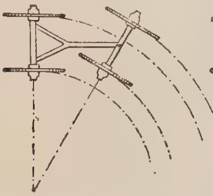

Fig. 1

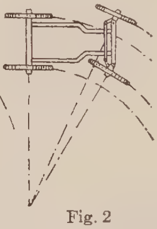

Fig. 2

Fig. 1. Showing how a front axle of a horse-drawn vehicle gives the direction in which a horse-drawn vehicle runs.

Fig. 2 Showing how the front wheels of an automobile give the direction in which the car runs. See next column, giving the meaning of **"turning radius."**

In a horse-drawn vehicle, the front wheels are square with the axle, for wheels and axle swing together. (See Fig. 1.)

In an automobile, the front axle does not swing, but each wheel swings on a pivot at the end of the axle, known as the **Ackerman principle.** (See Fig. 2.) See also page 910.

It would not be practical to steer an automobile as a horse-drawn vehicle is steered, for the axle would have to be very heavy to support the weight, and besides, it would be so hard to swing it that steering would be difficult. Another reason is that the body would have to be raised up high, so that the wheels could go under it in making a short turn.

A fixed front axle is always used on automobiles. The pivots on which the front wheels swing must be as close to the hubs of the wheels as possible, for the closer they are, the less leverage there will be to overcome, and the easier it will be to steer, with less liability to break.

When a wagon or automobile turns a corner, it moves in the arc of a circle.

In a horse-drawn vehicle, the front axle, because it swings on the king pin, always points to the center of the circle (Fig. 1). Notice that both wheels are perpendicular to the same radius of the circle and to the axle in Fig. 1.

The front axle of an automobile is fixed and cannot turn, and therefore only its pivoted ends point to the center of the circle (Fig. 2). Notice in Fig. 2, that the axle does not move, but that each wheel moves.

When running straight ahead, the front wheels of an automobile are square with the axle. When turning, the front wheels are not square with the axle, but at an angle with it.

Because each wheel is square with its axle end, and both axle ends point to the center of the circle, each wheel is square, or perpendicular to, a radius of the circle. If both were perpendicular to the same radius, which they are not, the wheels would be parallel with each other.

Thus, while the front wheels of a horse-drawn vehicle are always parallel to each other, the front wheels of an automobile turning a corner are not parallel to each other on the same radius.

The steering mechanism must be so arranged that the front wheels are parallel when the car is running straight ahead, but stand at an angle with each other when turning a corner.

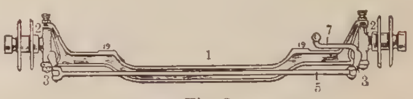

Fig. 3

Each of the pivoted axle ends (2, Fig. 3), which are called "steering knuckles," has a steering arm (3), projecting from it.

The ends of these two arms are connected by a rod called a "drag link, or tie rod" (5). When the drag link is moved endways, both wheels move with it.

The two steering arms are not parallel, but incline a little toward each other. If they were parallel, the two wheels would be parallel, no matter how the drag link was moved. As they are not parallel, moving the drag link moves one of the wheels through a greater angle than the other, depending on the direction in which the drag link is moved.

Turning radius: The radius in which a car can turn. For example, a turning radius of 15′ would mean that the car could be turned in a circle measuring 15′ from its center or 30′, or can be turned in a street 30′ wide if on one side of the street. If the steering device is on the left, a car can usually be turned in less space by turning to the right and vice versa.

Factors determining the turning radius are: (1) wheel base; (2) maximum angle at which the front wheel can be turned from the front. The average turning radius is 12½′ to 15′, or a circle of 25′ to 30′ dia. See Fig. 2, page 10, which will no doubt make the explanation clearer.

Steering Methods

There are two methods in general use: (1) the "fore and aft" method; (2) the "cross method."

The "fore and aft" method is shown in Fig. 4. With this method the reduction gearing is usually in the bottom of the steering device and the connecting rod (B) is usually behind the front axle.

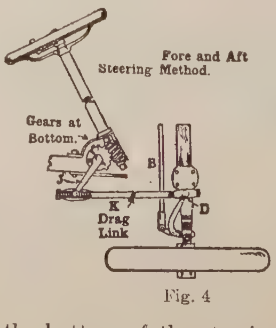

Fig. 4

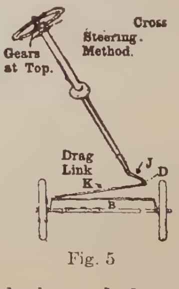

Fig. 5

The "cross steering" method is shown in Fig. 5. With this method the reduction gearing can be either at the top or bottom, and the connecting rod (B) can be either in front or behind the front axle.

The Ford and model "Four" Overland and Chevrolet "Four Ninety" employ planetary gears for reduction. The Ford gears are at the top of the steering column (Fig. 9), and on the Overland model "Four" and Chevrolet, the planetary gears are at the bottom.

Types of Steering Gears

There are a number of methods for reducing the ratio of movement of the steering column shaft to that of the arm (J).

(1) **Pinion and sector type** (see Fig. 6).

(2) **Worm and sector type** (Fig. 7). Note that the teeth are only on a section of the sector.

(3) **Worm and worm-wheel type** (Fig. 8).

(4) **Planetary type.** Note that the gears are at the top of the device on the Ford (Fig. 9), and at the bottom on the Overland model "Four," and Chevrolet.

(5) **Screw and nut type** (Fig. 10). Movement of this nut is up and down which moves the arm (J).

(6) **Screw and half-nut type** (Fig. 11). This is the Lavine steering gear. Adjustment is at the bottom of this device.

The breaking of any part of the steering connections is more likely to cause a wreck than the breaking of any other part of the car, and must be watched carefully. The parts must be kept tight enough to prevent play, but must not be so tight as to make steering hard. All parts must be kept well lubricated.

(See Index for "Steering gears, adjusting.")

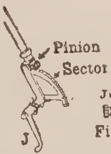

Fig. 6

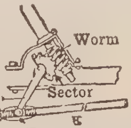

Fig. 7

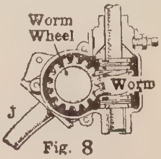

Fig. 8

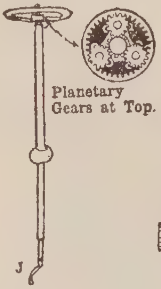

Fig. 9

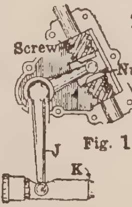

Fig. 10

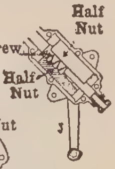

Fig. 11

SPRINGS

All vehicles intended to move at more than a very slow speed must be provided with springs. Springs not only protect the occupants from the vibrations of a rough road, but also keep the machinery from being shaken to pieces.

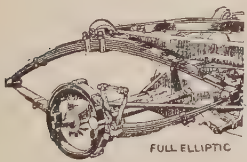

Fig. 12

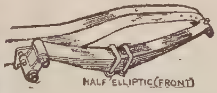

Fig. 13

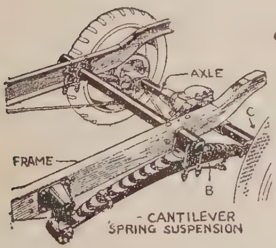

Fig. 14

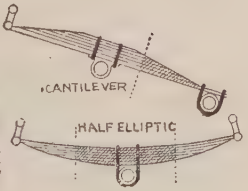

Fig. 15 (upper)
Fig. 16 (lower)

The size and strength of the springs depend on the weight of the vehicle. Springs that are too weak will not give sufficient protection, and if they are too strong they will not have enough resiliency.

Types of springs in general use are: Full elliptic, half or semi-elliptic, quarter-elliptic, three-quarter elliptic, and cantilever.

The full-elliptic was formerly used on a great many cars for the rear, as in Fig. 12. In some instances it was used in front.

The cantilever spring system (Figs. 14 and 15) is probably the most popular present-day practice. The illustration shows how it compares with the ordinary half-elliptic principle shown in Fig. 16.

In the cantilever spring the forward end is shackled and the axle is attached to the rear end. The center of the spring is attached to a trunion or bearing on the frame. Thus the spring has a certain amount of movement about its center. One good feature of this form of spring is that it reduces the unsprung weight of the axle. The shaded parts of the respective springs show the comparative amount of the unsprung weight. In the cantilever form of spring the heaviest part of it is supported by the frame. See also Fig. 5, page 7 (Hotchkiss drive).

The half-elliptic spring (Fig. 16) is used for the rear and, to a great extent, for the front, as in Fig. 13.

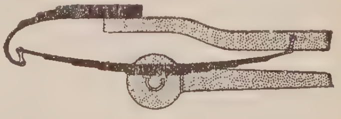

Fig. 17. Three quarter elliptic.

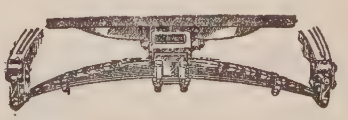

Fig. 18. Half elliptic-end supsension.

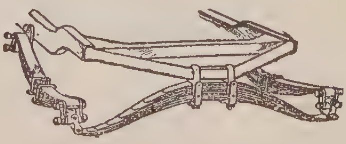

Fig. 19. Three half elliptic spring-coach style of suspension.

Other arrangements of half-elliptic springs for the rear are shown in Figs. 17, 18, and 19.

Breakage of a spring means breakage of one or more of the leaves. Breakage almost always occurs in the expansion that follows a heavy compression, and not during the compression. In other words, it is the **rebound** that breaks the spring.

Because the leaves slide on each other, they will wear and squeak if not properly lubricated.

To lubricate between the leaves it is necessary to relieve them of the weight they carry. This may be done by jacking up the body, or taking the springs apart, and spreading heavy grease or graphite on the leaves. This is quite a job and is seldom done.

SHOCK ABSORBERS

Breakage of springs usually occurs during a rebound. Devices called shock absorbers are attached to the springs to check their up movement. There are two types of shock absorbers in general use: the friction type, and the air or plunger type.

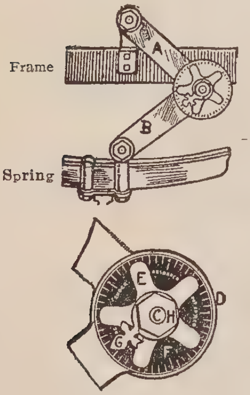

Fig. 20.

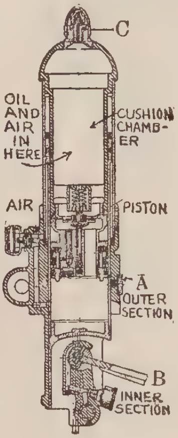

Fig. 21.

The friction type is shown in Fig. 20. All these movable frictional parts offer a constant resistance to the vibration of the spring both ways. It is easy to see that when the wheel strikes an obstruction, the arms come together, but instead of flying back, as does the free spring, it is retarded by the friction and moves gradually to its normal position, since the friction is always the same, while the tension of the spring diminishes as it approaches its normal position.

An adjustment dial (F) and indicator (G) provide means of securing the correct tension for the car. A spider compensating spring (E) takes up any little wear automatically, keeping the friction uniform after the adjustment has been made.

The arms (A) and (B) are joined to the frame and axle by two frictional joints, which also can be regulated.

The air or plunger type is shown in Fig. 21. It consists of an air chamber made up of two sections, one of which telescopes into the other. The outer section is attached to a bracket on the frame of the car, (**A**). The inner section is attached to one end of one of the springs, (**B**).

The chamber is partly filled with oil, through the filling-plug hole under the cap (C). The filling plug is fitted with an ordinary Schrader-tire type of air valve through which the chamber may be charged with air at any desired pressure, by means of an ordinary tire pump.

BRAKE CONTROL AND CONNECTIONS

Automobiles are fitted with two sets of brakes, called the "running service" or "foot brake," and the "emergency" or "hand brake," the terms "foot brake" and "hand brake" being the correct terms.

The foot brake is applied by pressing on a foot pedal, and is the one most in use because of its convenience, and is used most when running. Because it is used most, it requires more attention.

The usual method of connecting the foot brake is by a contracting band on the outside of the brake drum on the rear wheel hubs, called the "external contracting band brake."

The hand brake is usually applied by a lever at the side (or center) of the driver's seat, so placed that he may apply his whole force to it. This brake is seldom used while running. It is usually applied when the car is left standing, in order to keep the car from rolling down an incline. The hand-brake connects in almost every instance with the internal expanding brake inside of the brake drum on the rear wheel hubs, but occasionally will be found connected by a contracting band over a drum mounted on the main transmission shaft.

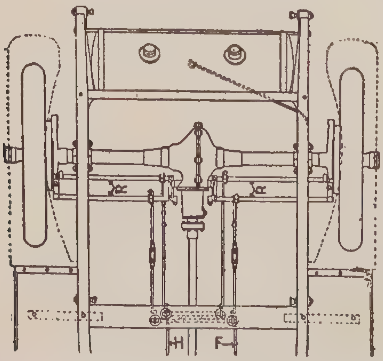

Fig. 22. Method of connecting the two brakes in rear. The adjustment for equalizing the pull on each rod, can be made at the turn buckles.

The foot-brake pedal is the right pedal and the left pedal is the **clutch pedal,** on almost all cars.

Brake Equalizers

When the foot-brake pedal or hand-brake lever is applied, the pull should be the same on each brake on each wheel. If one brake rod is longer than the other the brake effect is not equal on both wheels, and this has a tendency to make the car skid.

To overcome this, a brake equalizer is used, the principle of which is shown in Fig. 22. The rods (R) are placed in bearings; the rod (F), connects with the foot brake, and rod (H) with the hand brake.

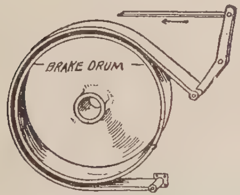
If a brake squeaks, it is an indication that it is dirty and needs cleaning. The dirt clogs the pores in the surface of the lining and glazes it over. Gasoline or, better, kerosene, will remove the dirt. The wheel should be removed and the linings cleaned with a stiff brush, such as a tooth or nail brush.

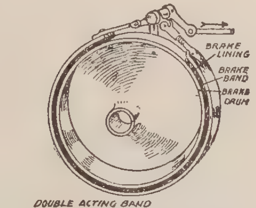
Types of Brakes

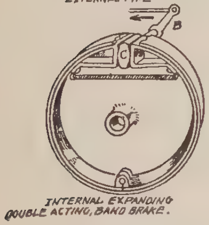
There are two distinct types of brakes in general use: the **external contracting** and the **internal expanding** type.

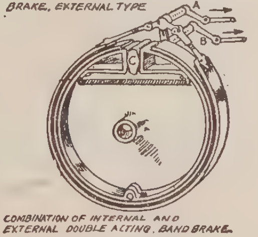
The **external band brake** is a flexible steel band faced with an asbestos or fabric composition, called "Raybestos" or "Multibestos," etc. Setting the brake causes friction between the brake drum and the linings, hence the use of asbestos composition.

Band brakes are of two kinds: **Single acting** and **double acting**, the latter being an improvement over the former.









A
B
C
COMBINATION OF INTERNAL AND EXTERNAL DOUBLE ACTING. BAND BRAKE.

Fig. 23 (upper)
Fig. 25 (lower)

Fig. 24 (upper)
Fig. 26 (lower)

The single-acting band brake (Fig. 23) binds only when the drum is revolving in one direction, having very little grip when the drum is revolving in the same direction in which the band is being pulled. This form is going out of use for automobiles, for it cannot be depended on to hold the car from running down hill backward.

The double-acting band brake (Fig. 24) is more practical, for it holds with the drum revolving in either direction. In this form, both ends of the brake are attached to the lever or pedal, and are so arranged that while one end is being pulled in one direction, the other end is being pulled in the opposite direction. This binds on the drum so tightly that it may be depended on to hold the car in any position.

The brake band may either be drawn around the outside of the drum, called the "external brake band," or expanded within it so that it bears against the inside wall of the drum, called the "internal expanding brake." Sometimes the internal brake is made of metal.

The external type of brake is usually of the double-acting contracting type, and is always placed on the outside of the brake drum attached to the hub of the rear wheels as at **OB** (Fig. 27).

A combination of internal expanding and external contracting brakes are shown in Fig. 26. Lever **(A)** operates the external brake and lever **(B)** the internal brake. See also Fig. 27, below.

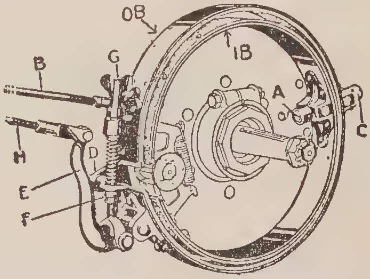


Fig. 27. A combination of an internal expanding and external contracting brake on brake drum of rear-wheel hub. **OB** is the outer or external and **1B** is the inner or internal. **B** is the hand-brake rod operating the internal brake. **H** is the foot-brake rod operating the external brake.

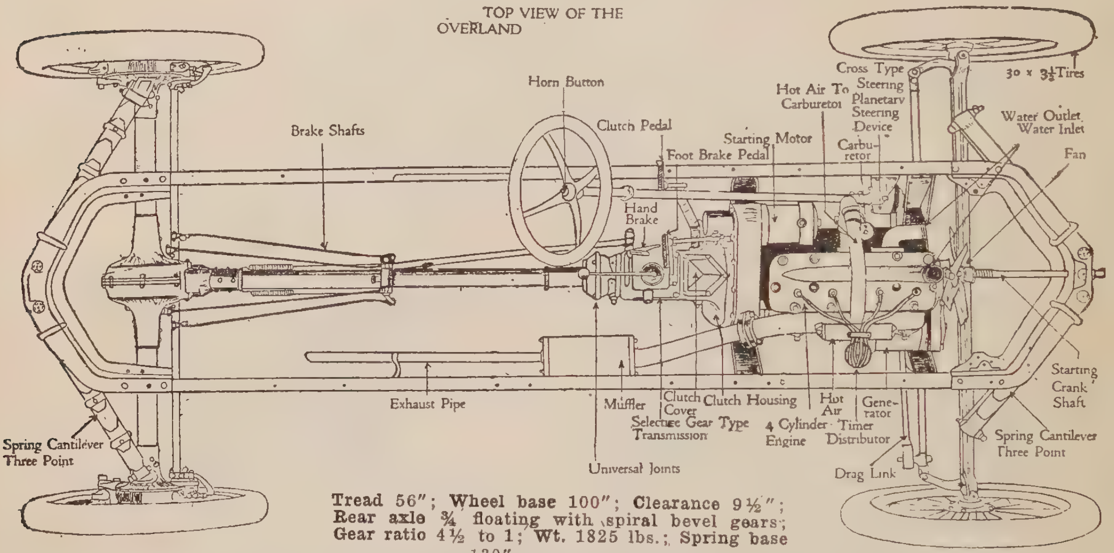
Adjustment of external brake is made at **F**, **G**, and **C**. Adjustment of the internal or hand brake is at **A**. It is turned up or lowered so as to have 1-64 inch clearance between the brake drum and brake.

The internal or hand brake formerly consisted of two shoes of metal, but the modern form is shown in Fig. 27. This is a double-acting, expanding type, and which acts internally against the inside of the drum. This brake shoe is lined with Raybestos, Thermoid or some similar material.

For the method of adjusting and relining brakes, see Index. This subject is treated in the Repair Section of this book.

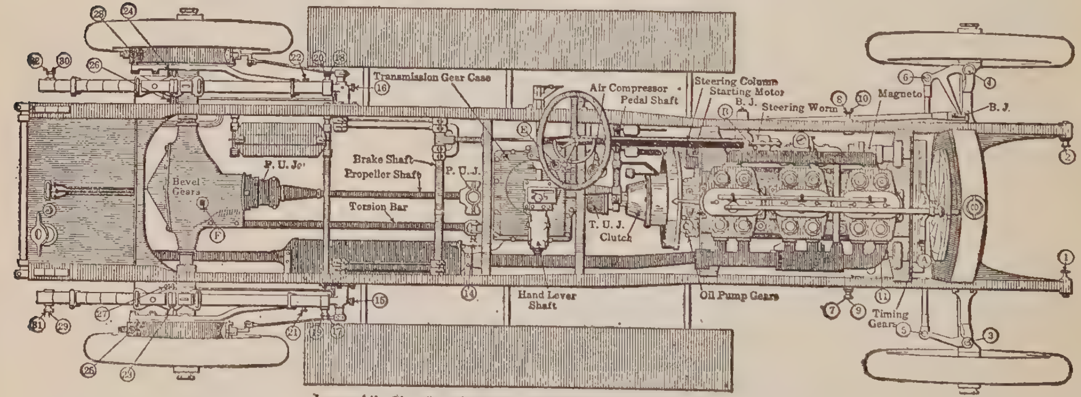
TYPICAL EXAMPLES OF A LIGHT CAR AND A HEAVY CAR

Illustrations and specifications of the two well-known cars shown below will give a comparison of the relative difference between a light car and a heavy car.



Tread 56"; Wheel base 100"; Clearance 9½"; Rear axle ¾ floating with spiral bevel gears; Gear ratio 4½ to 1; Wt. 1825 lbs.; Spring base 130"

Fig. 28. Example of a 4-cylinder car (Overland 4). Note the spring suspension used on this make of car, which is termed "triplex suspension," meaning that there are three points of contact on suspension. Engine, 4 cylinders; bore, 3-⅜", stroke 4"; actual h. p., 27; crank-shaft main bearing, 3; wheel base, 100"; tread, 56"; rear-axle ratio, 4½ to 1; rear-axle shafts, ¾ floating; transmission sliding gear, three speeds and reverse; clutch, lubricated single-plate type; unit power plant; tire sizes, 30" x 3½"; water capacity, 3¾ gal.; weight, approximately 1825 lbs.; clearance, 9½".



Locomobile Chassis. The "38" Type R-7. The "48" Type M-7

Fig. 29. Example of a 6-cylinder heavy car (Locomobile 48). Engine, 6-cylinder; bore, 4½"; stroke, 5½"; actual h. p.,90; crank-shaft main bearing, 5; wheelbase, 142"; tread, 56"; tire sizes, 37" x 5"; fuel capacity, 30 gal.; water capacity, 7¾ gal.; transmission, four speeds and reverse; clutch, multiple dry disk; rear axle, full floating.

INSTRUCTION No. 4

AXLES; DIFFERENTIALS; BEARINGS

FRONT AXLES

The front axle of a modern car carries about 80 per cent of the weight of the engine, and must at the same time withstand the shocks and jars that it receives through the steering wheels; it must therefore be strong and stiff. It also carries about 20 per cent to 40 per cent of the weight of the entire car.

Front axles are of two types: tubular and **solid** (Figs. **1** and 2). Formerly, axles were made of heavy steel tubes, but steel drop forgings with a cross-section of the form of the letter 1, are considered to give better results.

The center of the axle is usually bent down, so that it is the lowest point of the car except the wheels; this is done in order to protect the mechanism from being struck by high spots in the road. A rock or stump, standing up high enough to hit the fly wheel, will first strike the axle, which is strong enough to withstand a blow that could easily damage the engine.

The steering spindles are that part of the front axle on which the front wheels revolve and are made of nickel steel, heat treated. The steering spindles are sometimes fitted with either roller or ball bearings. The **steering knuckle** is that part which fits into the yoke of the axle. The **steering arm** of the device connects with the steering knuckle thrust arm, and the movement of the steering wheel guides the direction of the wheels. See page 910 for **types of front axle steering knuckles** (the **Elliott** and **Lemoine**).

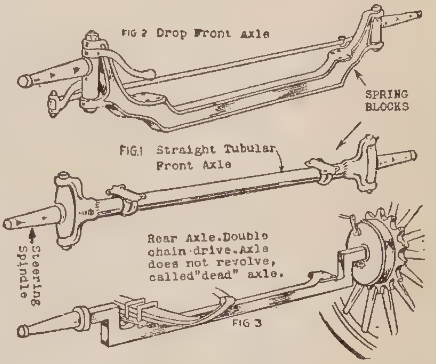


FIG 2 Drop Front Axle

FIG.1 Straight Tubular Front Axle

Rear Axle. Double chain drive. Axle does not revolve, called "dead" axle.

FIG 3

REAR AXLES

There are two types of rear axles: "dead axle" and "live axle." (Load is 60 to 80 per cent of car weight.)

Dead axles are stationary, with the wheels running free on the end of the axle, and are usually made as shown in Fig. 3. The wheels are usually revolved by chain and sprocket.

Live rear axles is the name given to axles that revolve with the wheels, and are known as "plain" live axle, "semi-floating" axle, "three-quarter floating" axle, "full-floating" axle.

The axle shafts on a live axle are in two sections (see **G**, **Fig. 7**, page 16). The inner end connects with the differential gears; the outer ends connect to the wheels. It is necessary to support the axle parts in a strong **housing** (**H**) and to brace it in order that the parts of the axle do not sag or get out of line.

Types of Live Rear Axles

There are **two types**: the "plain live rear axle" and the "floating live rear axle."

The plain live rear axle is the type where the **inner ends of the axle shafts support the differential.** See **Fig. 3A.** Note that the bearings are on the axle shafts; see also the Ford rear axle, page 1097. If the axle shafts are withdrawn the differential **would drop out of place.**

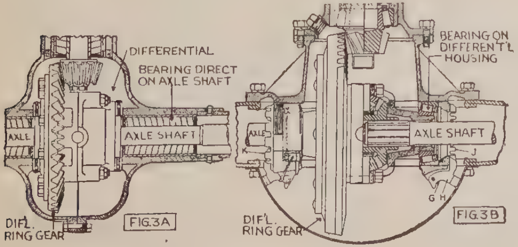

Fig. 3A. Plain live type of rear axle.
Fig. 3B. Floating type of rear axle.

To remove axle shafts the complete rear axle assembly must be removed from the car and the "divided housing" separated, as in Fig. 39, page 1096. See also pages 862, 863.

The floating rear axle is the type where **the differential supports the inner ends of the axle shafts.** See Fig. 3B. Note bearing is on outer ends of differential housing. If axle shafts are withdrawn differential **would not drop** out of place.

Types of Floating Rear Axles

There are **three types**, the "full-floating," "semi-floating," and the "three-quarter floating." The floating type is used more than the plain live type. See also page 863.

The type of floating axle is determined by: (1) whether or not the wheel bearing is on the outer end of the axle shaft or on the axle housing; (2) the location of the bearing or bearings; (3) the method of connecting the axle shaft with the wheel.

Full-floating type (Fig. 4). Two bearings in each rear wheel are mounted on the axle housing, placed on each side of the center of the wheel. Thus the wheels run on the housing and the housing supports the weight, not the axle shafts.

All of the bending stress due to weight or static force and to skidding force is carried by the housing.

The outer ends of **the axle shafts are not supported by the wheels** which do not depend upon the axle shafts for alignment. The wheel could run independently of the axle shaft in its bearings on the housing if necessary. Thus the axle shafts turn freely within the housing and bear only the torque (twisting effect) or stress of turning the wheels. The axle shafts are said to "float" within the housing.

The wheel can be driven by a jaw clutch or flange, but the true full-floating axle is driven by a jaw clutch (**D**, Figs. 4 and **4A**) which fits into notches in the driving flange (**F**). Note (**D**) is an integral part of the axle shaft.

Note: On some types of full-floating axles (see Fig. 35, page 877), the axle shaft is keyed (sometimes squared, or splined on others) to the flange and to remove the axle shaft the flange bolts are removed. This is termed a **"seven-eighths floating type."**

To remove axle shafts (Fig. 4), it is **not** necessary to remove wheels. Remove hub caps (not shown) and withdraw shafts (see also page 864). Technically speaking, the axle is not a true full-floating type if the shaft is keyed to the wheel.

FIG. 4 FIG. 5 FIG. 6

FIG 4A A TRUE FULL-FLOATING AXLE SHAFT FIG. 5A. A SEMI OR 3/4 FLOATING AXLE SHAFT

Semi-floating type (also called a "fixed-hub" type) is shown in Fig. 5. Outer ends of axle shafts are fixed, or keyed to the hubs of wheels, usually with keys (**F**) and nut (**N**).

The **bearings** (one on each outer end) are mounted directly on the axle shafts; thus the axle shafts support the weight, and carry the bending stress, torque, and the skidding and turning force.

To **remove axle shafts** (Fig. 5): The axle shafts on most semi-floating axles can be withdrawn from the axle housing without removing the entire rear axle, but it is necessary first to remove the wheels by loosening nuts (**N**) and draw the wheel off with a wheel puller; see pages 863, 864, 883 for further instructions.

For removing differential on different types of rear axles, see pages 863, 879.

The **three-quarter floating type,** also called the "flanged-hub" or "flanged-shaft" type, is shown in Fig. 6. The rear axle housing extends into the hubs of wheels as in the full-floating type. The outer ends of axle shafts fit into the hub flange and are splined as in Fig. 6 (could be keyed), and the flange is bolted to the wheel hub. Only one bearing is used on each wheel hub, usually placed directly under the center of the wheel and mounted on the axle housing (the two bearings in Fig. 6 are considered as one set of bearings).

The outer end of **axle shafts are supported by the wheels** which depend upon the axle shafts for alignment.

In the flanged-shaft axle, especially where only one bearing is used under the center of the wheel, the stresses (strains) are quite similar to those in the semi-floating type. The skidding force and that of turning corners is on the axle shafts.

To remove axle shafts (Fig. 6) it is not necessary to remove the wheel, but to remove the flange bolts and pull out the flange and axle shafts. See also pages 863, 868, and Fig. 27, page 921.

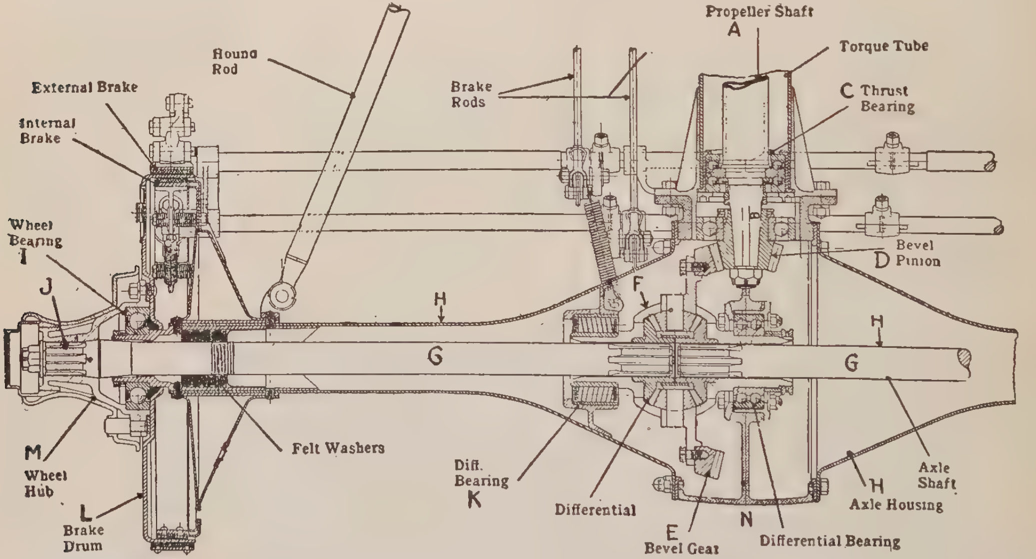

Fig. 7. Illustration of a three-quarter floating type of rear axle (Marmon as an example), complete with bevel driven gear (E). The driving axle shaft (G), does not support any dead weight. The road wheels run on ball bearings (I) carried on the outer sleeve or casing of the axle. The details are as follows: (**A**) propeller-shaft connection; (**B**) driving-pinion shaft; (**C**) ball-thrust bearings; (**D**) bevel-driving pinion; (**E**) large bevel; (**F**) differential gear; (**G**) half of driving axle; (**H**) tubular outer casing or sleeves (**I**) ball bearing for wheels; (**J**) driving ends of axle (squared or keyed); (**K**) roller bearings in differential case; (**L**) drum of internal and external brake; (**M**) hub of detachable wire wheel; (**N**) casing enclosing bevel gear and differential.

Note. The power is transmitted from the driving bevel (D) to large gear (E) this being bolted to the case of the differential (F), thence by the inside pinions to each half of the driving axle. It is usual to "anchor" the outer casing enclosing the differential gear to the chassis by means of torque tube or hound rods bolted to the upper and lower points of the gearcase which counteract the tendency for the whole casing to twist round from the reaction of the driving effort. On some cars the rear springs are made to serve as torque rods. The **thrust,** which is heavy between gears (D) and (E) is taken up by ball bearing (C).

TYPES OF REAR-AXLE DRIVE GEARING

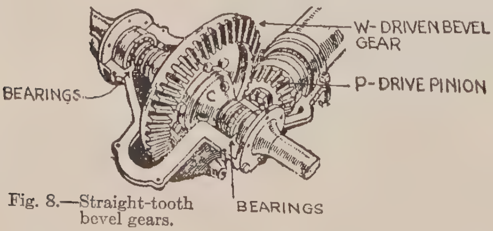

Fig. 8.—Straight-tooth bevel gears.

The power of the engine is transmitted at right angles to the rear axle and road wheels by means of bevel gears (P and W, Fig. 8), or by a worm and worm gear (Fig. 10). **Bevel gears are used on passenger cars** and the teeth are either **straight cut** (Fig. 8), or **spiral, or helical** (Fig. 9). The **ratio** of the diameter of these gears ranges from 3½ to 1, to 5 to 1, and the ratio determines the **high gear or direct drive** of the car.

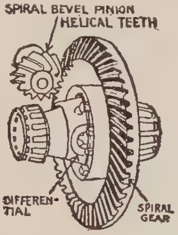

Fig. 9. Spiral or helical bevel gears.

The "spiral" or "helical tooth bevel gear" (Fig. 9), is a popular type of gear tooth used to a considerable extent. This type, if accurately made, is very silent.

In a straight-tooth bevel gear (Fig. 8), any given tooth goes in and out of mesh at one time along its entire length. In the helical bevel the meshing starts at one end of the given tooth and gradually moves towards the other end. Therefore, two helical teeth are in mesh at all times.

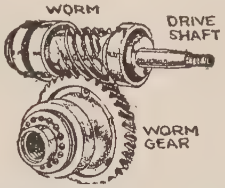

Fig. 10. The worm type of gear. The worm can be overhead or underneath the worm gear.

The "worm and worm gear" is used quite extensively on electric and commercial cars or trucks, where a large reduction of gearing is necessary. It is replacing the double-chain drive. It is made with the worm overhead, or underneath. The worm drive is very quiet and efficient.

The "single-chain drive" is now obsolete. It will not therefore be dealt with.

THE DIFFERENTIAL

Purpose of the differential: It is necessary to fit an automobile with **differential or compensation gears,** in order that the rear wheels may revolve at different speeds when the car turns a corner, while at the same time both are being driven by the engine. This gear is automatic, and operates according to the resistance of the road against the wheels.

Principle: There is more resistance to the turning of the inside wheel than the outside wheel when the car is turning; consequently the outside wheel may revolve faster. It is necessary for the outside wheel to revolve faster, because it has a longer distance to travel than the inside wheel. The same applies to a wagon, but the wagon wheels run free on the axle, therefore a compensating device is not necessary.

In illustration of this, see Fig. 12, and note that if the car is turning to the right, the wheel **A** must revolve faster than wheel **B.** Also refer to Fig. 11, and note that the axle shaft **A,** being attached to the wheel, must revolve faster than axle shaft **B,** when turning to the right and vice versa if turning to the left. Therefore, to compensate for this difference in speed of the two wheels and axle shafts, bevel gears (E) on the ends of the axle shafts (Fig. 11), mesh with the small bevel gears (D), called "compensating" or "differential gears," which are free in bearings on the housing or differential case attached to driven-ring gear **R.**

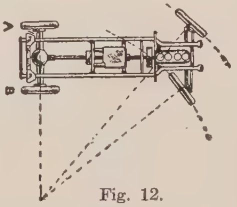

Fig. 12.

As long as the car travels straight ahead and the resistance of both rear wheels is the same, these gears (D) do not turn, but when the car turns, then greater resistance is offered to the inside wheel; therefore the compensating gears (D) with their spindles (DI), turn in their bearings, permitting the outside wheel to revolve faster than the inside wheel. In fact, the inside wheel could be stationary or revolve backwards if necessary.

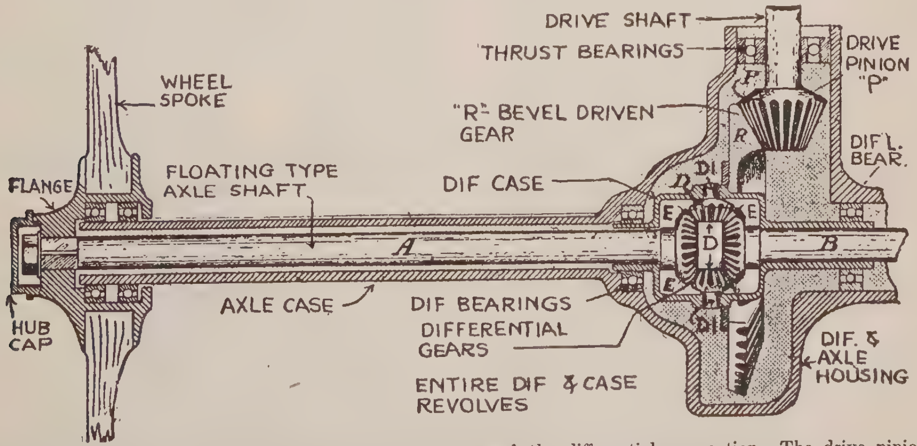

Fig. 11. Illustration explaining the rear-axle drive system and the differential-gear action. The drive pinion (P) on the end of the drive shaft drives the large bevel gear (R) which is connected to the differential case. Note that the entire differential case revolves on bearing. The power applied to the axle shafts (A and B) is then carried through the small bevel gears (D), which have spindles (DI) running free on bearings in the differential case. When the resistance is equal on both rear wheels and split-axle shafts (A and B), the gears (D) drive the bevel gears (E) on the end of the axle shafts, thus causing each axle shaft to revolve at the same speed. If resistance is greater on one axle shaft than on the other, the small bevel gears (D), with their spindles (DI), turn free in their bearings, thus permitting axle shafts (A and B) to turn at different speeds.

A study of Figs. 11, 12, 13, and 14 will make this principle clear. Note that the drive of the rear axle is through the drive pinion **P**, to gear **R**, thence through the differential case attached to it, then through the compensating gears **D**, to the bevel gears **E**, attached to the ends of the rear-axle shafts. You will observe that either axle shaft (**A** or **B**) could be held stationary, yet the other shaft could revolve.

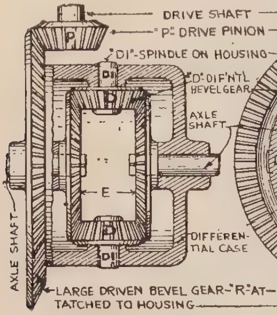

Fig. 13

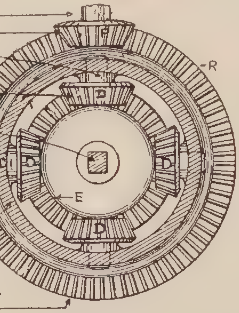

Fig. 14

Example of Differential Action

In order further to understand the action of the differential, refer to Fig. 11. Let us assume that the gear ratio of the rear axle is 4 to 1, which would mean that the ratio of bevel-driven gear (**R**) to drive pinion (**P**) would be 4 to 1. Consider that the engine is running at the rate of 1,000 r.p.m.

Consider gears (D) stationary, that is, we will assume, for the sake of explanation, that the spindles (**DI**) cannot turn on their bearings. Since the engine is running at 1,000 r.p.m., and the gear ratio is 4 to 1, the bevel-driven gear (**R**) would revolve 1,000÷4=250 r.p.m. Since the gear (**R**) is directly attached to the differential case, the latter will also revolve at the rate of 250 r.p.m. As we have considered the differential gears (**D**) as being stationary with respect to the differential case, they merely act as a direct connection between the differential case and the axle-shaft gears (**E**); consequently gears (**E**) will also revolve at 250 r.p.m., causing axle shafts (**A**) and (**B**) with their wheels to revolve at 250 r.p.m. This is exactly what happens when the car is traveling straight ahead, since there would be no effort exerted to cause gears (**D**) to revolve; consequently we can consider them stationary as assumed above.

Now consider gears (D) free to revolve, that is, we will permit the spindles to turn in their bearings. Now let us hold the axle shaft (**B**) stationary, and see what happens. The gear (**E**) attached to (**B**) will also remain stationary. The gear (**R**) and the differential case will still revolve at 250 r.p.m., thus causing the spindles (**DI**) to pass around the stationary gear (**E**) attached to (**B**) at the rate of 250 r.p.m. This would cause the gears (**D**) to revolve rapidly within the differential case as they rolled around the stationary gear (**E**) attached to (**B**). Now let us consider what happens to the gear (**E**) attached to the axle shaft (**A**). The motion of the differential case would tend to revolve (**A**) at 250 r.p.m. as explained above, but the rapid rotation of the gears (**D**) would also impart a further rotative effort to the gear (**E**) attached to (**A**), with the result that (**A**) would revolve faster than 250 r.p.m. This is exactly what would happen if the car was abruptly turned to the right, as (**B**) would then remain stationary.

The relative speed of (A) to (B) can easily be determined, because the sum of the speeds of (**A**) and (**B**) will always equal twice the speed of the driven bevel gear (**R**). Let us assume that (**R**) revolves at 250 r.p.m. as stated: then the sum of the speeds of (**A**) and (**B**) would be twice 250=500. If (**B**) is permitted to revolve at 250 r.p.m., then (**A**) will also revolve at 250 r.p.m., since their sum is 500. If (**B**) is only permitted to revolve at 100 r.p.m., then (**A**) will revolve at 400 r.p.m., since 100+400=500, or, in other words, 500−100=400. If (**B**) is permitted to revolve at 200 r.p.m., then (**A**) will revolve at 500−200=300 r.p.m.

Thus is seen the effect of the differential when the car is making a sharp or gradual turn. When making a gradual turn, (**B**) will revolve at nearly the same speed as (**A**), while, when making a sharp turn, there will be a great difference between the speeds of (**B**) and (**A**).

Q. 1: If the car was driven through mud, snow, sand, or on a greasy street, and the wheel attached to the axle shaft (**B**) (Fig. 11) should strike an obstruction that would cause that wheel to stop, describe what would happen.

Ans: Gear (**E**) attached to axle shaft (**B**) would also stop, thus causing the wheel attached to axle shaft (**A**) to spin, since it has slight traction on the slippery road.

Q. 2: Suppose you were starting from a standstill on a slippery road and one wheel should start to spin, and the car failed to move, what would be the reason and remedy?

Ans.: The wheel which is spinning would have no traction, that is it could not grip the road; thus it would spin and the other wheel, even though it had traction, would remain stationary. The remedy would be to put on skid chains, if available, or to tie a piece of rope around the tire, or to throw dry dirt or twigs under the wheel which spins, in order to give it traction or grip.

Q. 3: When the wheel spins, for example, the one attached to axle shaft (**B**) (Fig. 11), what action is taking place in the differential?

Ans.: The drive pinion (**P**) would be driving the driven bevel gear (**R**) thus causing the differential case to revolve with it. The axle shaft (**A**) with its gear (**E**) would remain stationary; the differential gears (**D**) would revolve rapidly around the stationary gear (**E**) attached to axle shaft (**A**). The motion of the differential case would tend to rotate gear (**E**) attached to (**B**) at the same speed as that at which the differential case is rotating, and the speed of (**B**) will be further increased by the fact that the gears (**D**) are revolving rapidly, as formerly explained.

When a double-chain drive is employed, the differential is placed on the jack shaft. The jack shaft is in two parts similar to a live axle.

Spur-gear differential: Most of the differential gears are of the bevel-tooth type. The spur-gear type (Fig. 15) is seldom used. Note that the illustration is that of a differential with a sprocket which was formerly used on a single-chain driven car.

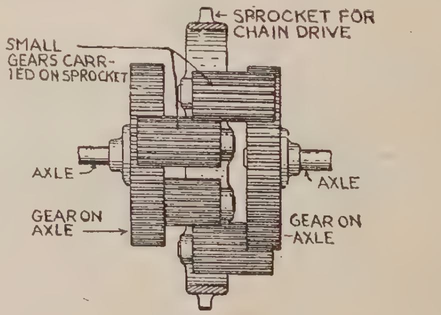

Fig. 15

BEARINGS

Every part of the car that moves with a rotary, sliding, or other motion is supported in bearings, which together with proper lubrication reduce wear and friction.

There are three different types of bearings in general use: the **plain, roller and ball bearings.**

Bearings are called upon to do two kinds of work: to take a **radial** load or a **thrust** load or a **combination** of both.

A radial load is a load or pressure perpendicular to the shaft supporting the load. For instance, the wheel bearings of an automobile, when running on a perfectly level road, are subject to radial loads.

Thrust load is a load or pressure parallel to or in direction of the shaft. When the automobile strikes a curve, a thrust load is imposed on the bearings in the wheels—that is, to the side, or endwise.

Fig. 16

Fig. 17

Fig 18

Fig. 16. Pure radial load.

Fig. 17. Combined radial and thrust load.

Fig. 18. An awkward way of resisting a combined end-thrust and radial load.

We might illustrate the relation between thrust and radial loads in this way: A man could be considered as being subjected to pure radial load when walking on an absolutely level surface (Fig. 16), but when this man walks along a hillside, without either ascending or descending the hill, as illustrated in Fig. 17, he is subjected to a combination of radial and thrust load; the thrust load having a tendency to push him down the hill.[1]

If a straight roller were called upon to take a thrust load as well as a radial load, it might be compared to the man in Fig. 18, he would need a crutch to prevent his toppling over. Therefore a ball-thrust bearing would be necessary at the end of the straight roller bearing (Fig. 22, below).

Plain bearings are usually on the main crank shaft, cam shaft, and connecting rods of an engine and take a radial load. Plain bearings can also be designed to take thrust loads.

Roller bearings are used in the wheels, rear axle, transmission, and other places and when straight, as in Fig. 19, they can only take a radial load. The roller itself runs over an inner race and inside of an outer race, case hardened.

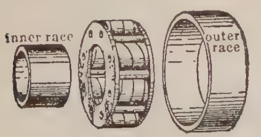

Fig. 19

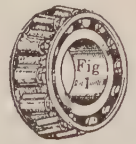

Fig. 20

When a roller is tapered, it runs over a cone-type hardened race (Fig. 20), and inside of an outer race, arranged as in Fig. 21. This type of roller bearing will take a radial and a thrust load without the use of a separate thrust bearing.

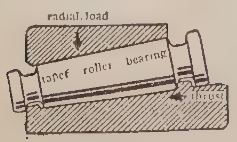

Fig. 21

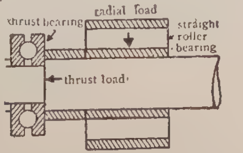

Fig. 22

The groove in the race and roller (Fig. 21) take the thrust load as well as the cone shape of race.

A straight roller bearing, to take a thrust load as well as a radial load, would require a separate thrust bearing (Fig. 22).

Ball bearings are also used on the wheels, rear axle, transmission and other places and are divided into three general classes; cup and cone, annular, and thrust.

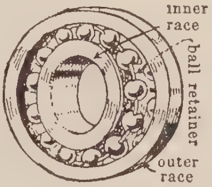

Fig. 23

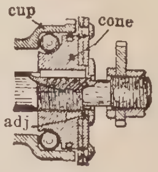

Fig. 24

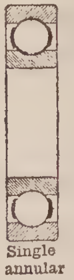

Fig. 25

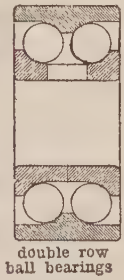

Fig. 26

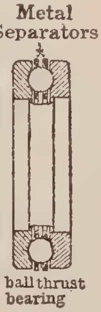

Fig. 27

The cup and cone bearing is shown in Fig. 24, and is used on many cars in the front wheels. This type of bearing is used extensively on bicycles. It is designed for radial loads, but is capable of withstanding considerable thrust also. It is adjustable.

The annular ball bearing is a bearing with an inner and outer race, which is grooved and hardened. They are not adjustable. This type can be a "single row" of balls (Figs. 23 and 25) or "double row" (Fig. 26). The single row takes a radial load.

The races of the double row are so shaped that it will withstand considerable thrust as well as a radial load. It is used where space would not permit the use of a separate radial and thrust bearing. This bearing is used extensively for supporting the drive pinion and taking the drive-shaft thrust in the rear axles.

The ball thrust bearing is shown in Fig. 27. This bearing can be used only where the load or stress is strictly a thrust or end-to-end load. This type is often used in clutches and is extensively used on the propeller shaft driving the propellers of motor boats.

The two parts the balls touch are called races. The one or two balls at the lower side support the entire weight and must be strong enough to hold up without being crushed. In automobiles, the balls are large and run in size up to 1 in. di. hardened and polished.

Sometimes balls wear flat or crack; if so a click will be heard and they must be replaced with perfect balls at once.

If one or more of the balls break in the annular self-contained bearing, pick out the pieces and run in on it and immediately secure another complete, or have it repaired by the manufacturer or a concern specializing in this work. If a ball breaks in a cone-type bearing it can be replaced.

INSTRUCTION No. 5

CLUTCHES: Principle and Construction

GENERAL EXPLANATION

Purpose of the Clutch

The word "clutch" as used in connection with automobiles, indicates a device attached to cars having change speed gears of the sliding type, which permits the engine to be connected with, or disconnected from, the transmission, so that the car may or may not move while the engine is running.

The clutch is connected and disconnected from fly wheel of the engine by a foot lever.

When disconnected from the flywheel of the engine there is then no connection between the engine and rear axle.

When the clutch is connected with the flywheel of the engine, the power of the engine is connected with a rear axle—if the gears of transmission are not in "neutral" position.

If gears are in neutral position, the power of the engine would end at the end of the secondary shaft of transmission.

While other types of transmissions require clutches, they are of special kinds, and will not be referred to in this instruction. (The Ford, for instance, uses a different principle.)

Because a steam engine has behind it the pressure of the boiler, it can be called on to supply much more than its regular horse power for short intervals. A gasoline engine has no reserve power to call on, and cannot deliver more than a fixed horse power.

When the gasoline engine is required to start the car, it must overcome the inertia of the car. This might be greater than the power of the engine could accomplish, and the engine might be stopped instead of the car being started.

If the clutch made an immediate connection between the engine and the drive, the power of the engine would have instantly to overcome the inertia of the standing car.

The power of the engine coming from the revolving of the fly wheel, and the explosion that might be occurring in one of the cylinders, it would probably be stopped instead of the car being started.

If, however, the clutch is made so that the engine takes hold gradually, the inertia of the car will be overcome, and it will move faster and faster as the clutch permits the engine to apply its power more and more.

This is done by making the clutch in such a way that when it is applied, it slips, instead of instantly making a connection between the engine and the drive.

When the clutch is "let in," it connects the crank shaft of the engine through the fly wheel with the transmission through the clutch shaft, and if the gears are in the "neutral" (gears out of mesh) position, the counter or secondary shaft in the gear case of transmission will revolve without moving the car.

If the clutch is "in" and the gears are meshed, the course of the power from the crank shaft of the engine (Fig. 1) will then be through clutch, through gears, through drive shaft, driving pinion, large bevel gear on differential, through differential gears to axle shafts and wheels.

Clutches have two chief parts: one part (usually the fly wheel) is attached to the crank shaft of the engine, the other part (cone or disk or plate) is attached to the clutch or main shaft of the transmission.

When the two parts are separated, that is to say when the "clutch is thrown out" by the clutch pedal, they are independent of each other and the engine can run without moving the car.

Fig. 1. Illustration explains how the power is transmitted from engine to clutch, thence to secondary or counter shaft. Note drive parts are fly wheel, clutch, clutch shaft, drive gear (O), secondary shaft gear (S), and gears on secondary shaft. The driven gears are the sliding gears (X) on the square shaft (T).

Note. This power to the rear axle is disconnected at point (P) when the clutch is "out," at which time the clutch and clutch shaft turn free from the fly wheel, and at (Z) when the drive and driven gears are in "neutral" or not in mesh. (This end of the square shaft (T) runs free in the end of the clutch shaft, and is not actually separated at (Z), as shown above.)

Clutch Action

Note in Fig. 1 the power from the engine is transmitted to the clutch shaft only through the clutch when in the rim of the fly wheel (if disk or plate type, then by the disks or plates as explained under that type of clutch).

Observe that the clutch shaft does not connect with the engine, but runs free at the end (Y), at all times in the hub of the fly wheel. The cone part of the clutch is connected with the clutch shaft so that when the cone turns, the clutch shaft must also turn. But observe that the cone slides on the square part of the clutch shaft so that it can be pushed out by the pedal or in by the spring. See also, Figs. 2 and 3.

When the friction part of the cone is out of the fly wheel, power ends at the fly wheel.

When the clutch is in, then power ends at the end of the secondary or countershaft, if gears are in neutral, in which position they are seen in Fig. 1.

When the two parts are connected, that is, when the clutch is "let in" by releasing the clutch pedal, the clutch cone on the clutch shaft is forced into frictional contact with the inside face of the fly wheel by means of a clutch spring and held there. The two parts being thus connected force the clutch shaft, gears (**O** and **S**) and secondary shaft to revolve with the engine, but do not drive the car unless the gears on the secondary shaft and the square shaft (**T**) are in mesh, or unless connection is closed at **Z** (Fig. 1) by dogs or an internal gear connection, which would be high speed.

When the clutch is "let in," the part on the fly wheel does not grip the part on the cone clutch immediately, unless they are moving at the same speed.

If they are moving at different speeds, which is usually the case, or when the part on the transmission is stationary, the two parts slip. This slipping continues until the two parts revolve at the same speed, when they bind together firmly. When "thrown out," they must separate instantly.

A disk or any other type of clutch used with the gear type of transmission is placed in the same relative position, back of the fly wheel, between the fly wheel and gear case. Although the construction may vary, the reader will note that the clutch is necessary on all cars.

Clutch pedals: The left-foot pedal on all cars of standard design is the "clutch pedal" and on the right the "foot brake pedal."

Types of Clutches

There are four types of clutches in general use: **the cone, disk, plate,** and **expanding type.**

The disk clutch (formerly called the "multiple disk") is a clutch with more than three disks and can be a **lubricated disk clutch** or **dry disk clutch.** A **plate clutch** is one wherein one plate is clamped between two others.

The Cone Clutch

This type of clutch is built into the fly wheel, and the fly wheel forms one of its parts. The rim of the fly wheel is broad, and the inside of the rim is made slightly funnel-shaped, forming the surface against which the cone part of the clutch presses (Fig. 2). The surface of the cone that bears against the fly wheel rim is often covered with leather. Some manufacturers use fabric material, running in oil. This part can be replaced.

CLUTCH SHAFT-SQUARE
CLUTCH SHAFT TURNS FREE IN FLY-WHEEL HUB—BALL BEARINGS ARE USUALLY PROVIDED

Fig. 2

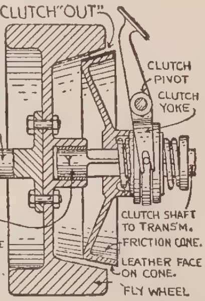

Fig. 3

The Disk Clutch

The disk clutch (formerly termed "multiple disk"), consists of a number of disks which are pressed together when the clutch is "in," the friction between them causing one to drive the other. This type of clutch is very compact, and is frequently built inside of a metal housing cast to the engine frame. See Fig 4, next page.

To illustrate the principle of the disk clutch place a silver dollar between two silver half-dollars, and squeeze them together between the thumb and forefinger of one hand. With the other hand, try to revolve the dollar, but not moving the halves. It requires only a slight squeeze to produce sufficient friction to make it impossible to move the dollar.

Multiple disk clutches are of two general types: those that operate in an oil bath and those that run dry; called **lubricated** and **dry** types.

The **lubricated** disk clutch **runs in oil**; its disks are usually alternate steel and bronze or all steel disks. The type that **runs dry** is usually composed of steel disks, one set of which is faced with a friction material of woven asbestos fabric.

Principle of the Lubricated Disk Type of Clutch

Parts: Fig. 5 shows the parts of the clutch separated from each other. The disks (**A**) are attached to the flange on the engine shaft; the smaller disks (**B**) are attached to the transmission shaft. The large disks (**A**) and small disks (**B**) are placed alternating.

The two flanges (**F** and **F1**) have pins extending from them, the disks (**A** and **B**) having holes so that they may be slipped on the pins or studs (**P, P1**).

The studs (**P1**) of the small disks (**B**) pass through the openings in the large disks. Thus the outer edges of the small disks come in contact with the inner edges of the large disks. All of the small disks (**B**) connect with flange **F1**, which has a square hole and slides on the clutch shaft by movement of the clutch pedal.

All the large disks (**A**) connect with the flange (**F**), which is connected to the engine shaft.

Assembled clutch: As will be seen from Fig. 4, which is the clutch assembled, the two flanges are connected only by the friction between the large and small disks, when the spring presses the parts together. The entire clutch is placed inside a casing, and runs in oil.

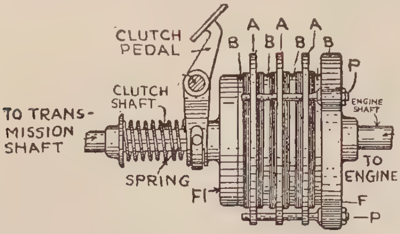

Fig. 4

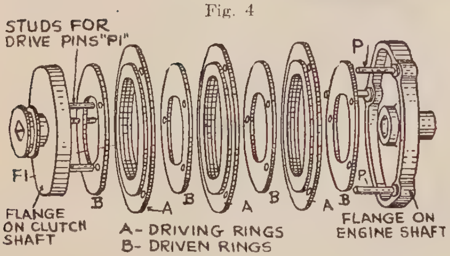

Fig. 5

When the clutch pedal is pressed forward, the clutch is "thrown out," the oil then flows between the disks and when the clutch is "in" and the spring presses the disks together, the oil is squeezed out from between them. While it is being squeezed out the clutch is slipping, and it begins to bind when the pressure has squeezed it out and the disks in consequence feel the effect of the friction. When the clutch is "thrown out," one set of disks may revolve independently of the other, for they are not connected in any way.

Hele-Shaw Lubricated Type of Disk Clutch

In the Hele-Shaw disk clutch (Fig. 6), a similar principle is adopted. The plates consist of a number of alternate bronze and steel disks much thinner. They are corrugated to increase the grip.

Half the plates are rotably connected by grooves with the driving member, and the alternate half with the driven member. When the clutch pedal is released, the clutch spring presses these disks together, and they all rotate as a solid mass. When the clutch pedal is depressed, the spring pressure is removed and the plates separated.

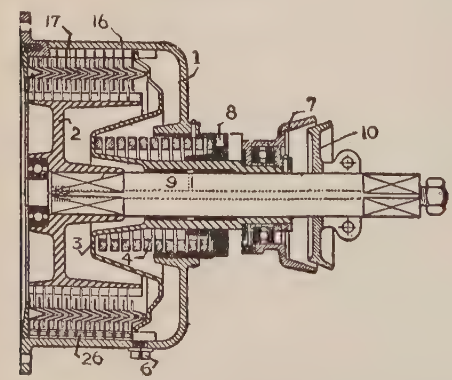

Fig. 6

Referring to the illustration (Fig. 6) the outer oil-tight case (1), to which the driving bronze plates (16) are keyed, is bolted to the fly wheel of the engine. The inner core (2) is keyed directly to the clutch shaft and to it are keyed driven steel plates (17).

The clutch is shown engaged as normally held by the spring (4) which actuates the ring (7) and the sliding presser (3). To facilitate quick disengagement, small springs (26) are fitted between the disks.

The case is oil-tight, provision being made for the replenishment of the oil through a plug (6) for the purpose.

Adjustments are made by means of an adjusting nut (8), and excessive spinning or dragging is prevented by a cone brake (10).

Principle of the Dry Disk Type of Clutch

Fig. 7 illustrates a dry disk type of clutch used on the Cadillac. The driving disks (**A**) are covered on both sides with a friction material, composed largely of asbestos, and are driven by six keys in the clutch ring (**H**) which is bolted to the engine fly wheel (**G**).

The driven disks (**B**) are not covered. These disks are carried on the clutch hub (**E**) and drive it through six keys on the hub. The clutch hub is keyed to the transmission shaft (**F**).

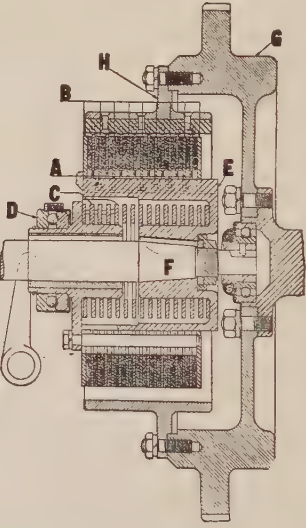

Fig. 7. The Cadillac disk clutch—dry type.

When the clutch is engaged by allowing the clutch pedal to come towards you, the spring (C) forces all of the disks together. The resulting friction between the disks (A) and (B) drives the clutch shaft (F) and the car, when the transmission control lever is in other than the neutral position.

There are no adjustments. The clutch pedal should be adjusted occasionally to compensate for wear on the facing of the clutch disks. There is one point (D) on the clutch for lubrication.

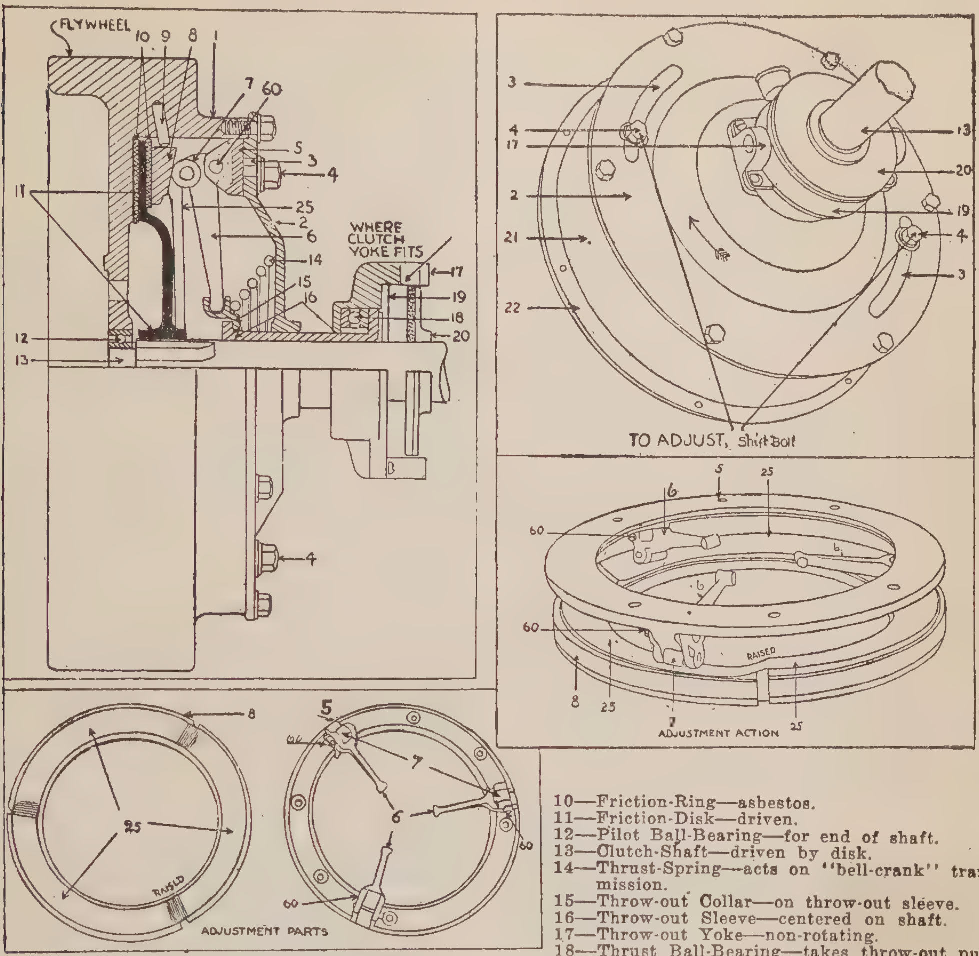
There are 17 steel plates, having 9 driven disks and 8 driving disks. The coil spring is held under 300 lbs. compression.

The Single-Plate Clutch

The S. A. E. term the disk clutch (formerly called the "multiple disk") a clutch with more than three disks.

The **single-plate clutch** is where one plate is clamped between two others. It is a popular type of clutch. It is a variation of the disk type, the latter comprising a large number of narrow disks, while the single-plate type usually consists of but three broad disks or plates, the ordinary type having two driving plates and one driven plate.

An example of a single-plate clutch is described in detail in the following matter. In this type, the clutch effect is created by wedging the plate. The type which will now be described is the Borg and Beck make, shown in Fig. 8, next page.



1—Clutch-Casing—cast with fly wheel.
2—Casing-Cover—carrying adjustment-ring.
3—Cover-Slot—for adjustment-bolt.
4—Adjustment-Bolt—for take-up action.
5—Adjustment-Ring—mounts thrust-levers.
6—Thrust-Lever (bell-crank)—mounts roller.
7—Thrust-Roller—acts against thrust-ring.
8—Thrust-Ring—acts against asbestos ring.
9—Driving-Pin—for thrust-ring.
10—Friction-Ring—asbestos.
11—Friction-Disk—driven.
12—Pilot Ball-Bearing—for end of shaft.
13—Clutch-Shaft—driven by disk.
14—Thrust-Spring—acts on "bell-crank" transmission.
15—Throw-out Collar—on throw-out sleeve.
16—Throw-out Sleeve—centered on shaft.
17—Throw-out Yoke—non-rotating.
18—Thrust Ball-Bearing—takes throw-out pull
19—Brake-Plate—rigid on throw-out yoke.
20—Brake-Collar—keyed on shaft.
21—Detachable-Casing—self-contained clutch.
22—Mounting-Flange—bolts against fly wheel.
23—Driving-Bolt—for thrust-ring (not shown).
24—Shaft, Brake and Universal Connection (not shown).
25—Adjustment-Incline—take-up seat for roller.
60—Bell-Crank Pivot—mounts thrust-lever.

Fig. 8

Borg & Beck Single-Plate Clutch

Principle: This type of clutch runs dry. The action is best understood when it is kept in mind that among the revolving parts, only the driven group: disk (11), shaft (13), and brake collar (20), can stand still when the fly wheel is running; all other parts being "anchored" to the fly wheel, must always revolve and drive with the latter.

When clutch is "in": The asbestos friction rings (10), though not positively attached to either the driving or the driven parts, will, in practice, "freeze" to the unpolished faces of the inner case of fly wheel and thrust-ring (8). They will thus always run bodily with the fly wheel.

When clutch is "out": The foot lever is applied which telescopes the coil spring (14) back, by action of the throw-out sleeve (16), which causes the roller (7) to withdraw a sufficient distance from the face of the thrust-ring (8), to permit the latter, with its companion friction-ring (10), to "back away" bodily, from friction-disk (11), thus releasing the disk from the friction-grip, and permitting it and other driven parts to come to a stop, while the fly wheel and parts anchored to it revolve.

Adjusting the Single-Plate Dry Clutch

Take-up action:[1] The roller-seat face of the thrust-ring (8) is formed on three, equal succeeding, take-up "inclines" (25); the ring being ¼-inch thicker, at the high end of each "incline" (25) than at the beginning, or low end. The three thrust-levers (6) are mounted upon, and equally spaced by, the adjustment ring (5); and this ring is adjustably mounted against the inner face of the cover (2), by means of the adjustment-bolts (4), of which there are two, through slots (3) in the cover.

When the bolts (4), are "slacked," and shifted in their cover-slots (3), they control and shift with them the ring (5), the latter carrying with it the levers and rollers (6 and 7), thus shifting all the rollers to new seats against the non-shifting thrust-ring; and, these seats being farther up the ring "inclines" (25). Where the inclines are thicker in cross-section, the ring is necessarily thrust so much farther toward the other friction parts, to compensate for any friction wear, and to maintain, at all times, a perfect friction grip.

---

[1] See also Index under "Borg & Beck clutch," which is also discussed in the Repair Section of this book.

Therefore to **adjust the clutch,** the clutch is held entirely out. With the clutch thus held "out," it is only necessary to "slack" the adjustment-bolts (4), tap either of them "clockwise," in the slot (3) on the cover, a quarter or half-inch or any other distance required, thus shifting the ring (5), and carrying the levers and rollers to new seats, upon thicker sections of the thrust-ring. This compensates for the friction wear which made the adjustment necessary.

If too much oil gets into the clutch and **causes slipping:** It will be necessary in this case to unscrew the bolts (4) about three turns, have someone hold ~~out~~ clutch, and let the oil drain out. It is also desirable to squirt gasoline into the interior of the clutch to wash out the oil. If slipping continues, the trouble is due to oil working into the clutch housing and it must be separated from the main oil supply of the oil pan of the engine.

Removing clutch: First remove the transmission. Mark the clutch cover that bolts to the fly wheel with a punch and place a corresponding mark on the fly wheel, in order that it may be put back in the same position. The cover plate must not be turned.

Replacing clutch: There are two asbestos fabric rings; one lies against the face of the fly wheel (10), next to this comes the driven plate (11), then another friction washer (10). The cast thrust ring (8) comes next, but before installing, make sure that the driving pins (9) are in place in the inside of the fly-wheel rim. Drop the thrust ring (8) in position, so that the three slots fit over the pins (9). The adjustment ring (5), with its parts assembled to it, should not be installed. The adjusting ring (5) fastened to the cover plate by means of two cap screws and cover plate bolts to the fly wheel.

A clutch brake is provided, and this comes into action when the clutch pedal is pushed all the way down. The purpose is to stop the transmission gears from spinning when the clutch is disengaged. The throw-out collar (15) presses against the brake collar (20). The clutch brake is mounted on the transmission shaft and is faced with asbestos fabric.

If the clutch is worn, trouble will be experienced when shifting gears into first speed when car is standing. The clutch will appear to drag and will continue to drive the transmission gears when fully disengaged, so it will be difficult to mesh the gears. To remedy this remove the oil pan; have someone hold out the clutch, while the throw-out clutch and collar are examined to see if the collar (20) actually touches the brake or not. If it does not, the transmission should be removed, and if the brake-friction facing is in good condition, there is no need of installing a new one. See that the throw-out is not coming in contact with the brake flange and ascertain if it should be adjusted so that these two points form a contact.

Note. Always remember to drive with the foot off the clutch pedal. Make sure that the clutch pedal does not strike or press against the toe board. See also, Index under "Adjusting clutches."

UNIVERSAL JOINTS

A universal joint is a flexible connection between two shafts, which permits one to drive the other, although they may not be in line. Refer to Figs. 9, 10, and 11 and study the principle. Universal joints are usually placed forward and rear of the drive shaft. They are also termed "cardan joints."

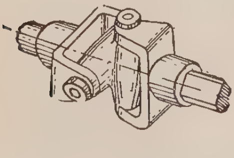


Fig. 9. Universal joint in a straight line.

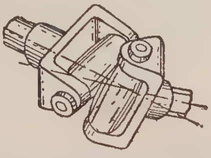

Fig. 10. Out of line.

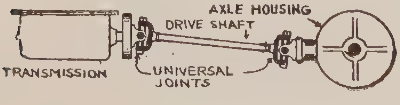

Fig. 11. Angular drive.

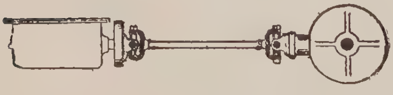

Fig. 12. Straight-line drive.

Universal joints are necessary on automobiles with shaft drive, for while one end of the driving shaft is attached to the transmission shaft, which is on the frame, the other end is connected to the axle, and is constantly moving up and down as the wheels follow the roughness of the road. If no universal joints were used, the shaft would jam in its bearings from the up and down movement of one end of it.

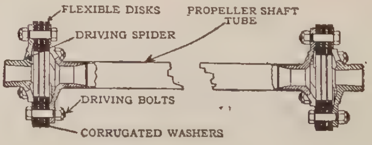

Fig. 13

Another type of universal joint is the flexible Thermoid-Hardy (Fig. 13). This joint is used only on "straight-line" drive. It consists of flexible discs secured to spiders on the ends of the shaft by means of bolts and corrugated washers. This assembly is bolted between a spider on the rear of the transmission and another on the front of the pinion shaft. The only attention these joints require is to see that all bolts are kept tight.

See Index for "Universal joints, adjusting," etc.

Angular and Straight-Line Drive

The angular drive is where the transmission is above the axle, as in Fig. 11.

The straight-line drive (Fig. 12) is where the drive shaft is in line when the car is carrying an average load, and is thrown out of line only to the extent that the chassis moves up and down on the springs. The variation is as great in one direction as another, but on the angular type, the shafts are never in alignment and the universals are required to act through a considerable angle.

INSTRUCTION No. 6

TRANSMISSION: Principle and Construction; Gear Shifts

GENERAL EXPLANATION

Purpose of a Transmission

When a bicyclist wants to race on a level track, he gears up his wheel with a larger sprocket, so that one revolution of the crank takes him farther. Yet if he takes his wheel, with this large sprocket on the pedal shaft, out on the road where there are hills, he must get off and walk or exert an extra lot of power. This clearly shows that if a bicyclist wants to speed while on the level, and yet take all hills, he must change the drive sprocket.

The same principle applies to the automobile. For this reason the automobile is provided not only with two changes of gears (instead of sprockets), but sometimes with three and even four changes of gears. These gears are contained in a gear-box usually placed back of the clutch.

The principle upon which all change-speed gears work is the fact that when two gear-wheels or spur-gears are meshed together the larger wheel turns more slowly than the smaller wheel.

As an example, a gear-wheel with 10 teeth, in mesh with a second wheel having 20, would revolve twice as fast as the latter, the explanation being that when the 10-tooth gears of the smaller wheel have moved round once they will have engaged with only 10 teeth of the larger wheel, and therefore will have turned the larger wheel through only half a revolution; that is, it will be necessary for the smaller wheel to revolve twice in order that the larger one may revolve once.

With this piece of elementary information, we will observe that in the gear-box (see below) there are two shafts—the upper one coming from the engine through the clutch, and the lower one continuing to the back axle.

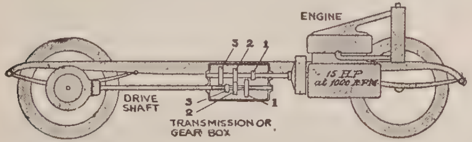

Fig. 1. This illustration is intended to simplify the explanation. In actual practice the arrangement is slightly different.

Each shaft is fitted with three different sized gear-wheels numbered in the illustration, 1, 2, and 3. Those on the upper shaft are fixed to the shaft itself, but those on the lower shaft are able to slide on a keyway, to right and left along the shaft. The shaft is not round like the upper one, but is squared, so that although the sleeve of the gear-wheels can slide backward and forward, they cannot revolve independently of the lower shaft.

In order now to vary the speed of the car, it is only necessary to slide the gear-wheels along the lower shaft until the correct two gears come into mesh to form the gearing required.

The illustration, for instance, shows the intermediate speed-gear in mesh, but were we to move the gears to the right so that wheels 1 and 1 come into mesh, we should put the car on its first speed, that is its lowest speed, so that, with the engine running normally, the car would be moving very slowly, the driving gear being much smaller than the driven gear.

When, however, the sleeve is moved to the left, so that gears 3 and 3 mesh, the effect is reversed. Now we have the driving gear much larger than that driven, and the result will be that when the engine runs normally the car will be traveling at a very high speed.

The sides of the teeth of the gears are usually made like the point of a chisel, so that when two gears are brought together they will mesh easily. (To "mesh" means that the teeth of two gear-wheels become engaged.)

Types of Transmissions

There are three types: the **sliding-gear, planetary,** and **friction-disk** type.

The **planetary** type used on the Ford (Fig. 8), is explained in the Ford Instruction. The **friction-disk** type (Fig. 9) is now seldom used.

There are two types of **sliding-gear** systems: the old-style **progressive** type (Fig. 2) and the modern **selective** gear type, pages 27 and 28.

The **progressive** type was discarded because it was necessary to pass one gear through another which made a clashing noise and was difficult at times to operate.

With the **selective** type it is not necessary for the sliding gear to pass through another gear. It is easier and quicker to operate and considerably less noisy. It is with this type that we shall deal.

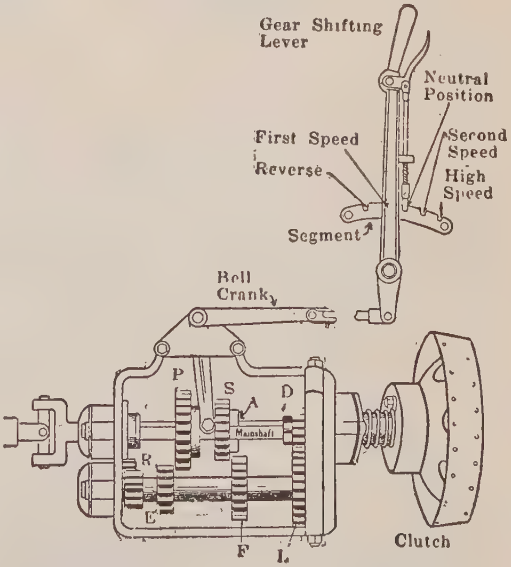

Fig. 2. A three-speed progressive type of transmission, showing the lever and gears in "neutral" position; an obsolete method. Note, in order for dog (A) to reach dog (D), which would be high gear or direct drive, it would be necessary for the sliding gear (S) to pass through gear (F); or to reach reverse, by gear (P) being meshed with (R), it would be necessary for gear (P) to pass through gear (E).

Location of the Transmission

The location of the transmission on the modern type of car is where the transmission and clutch are connected to the engine in one unit, termed a "unit power plant" (Fig. 3).

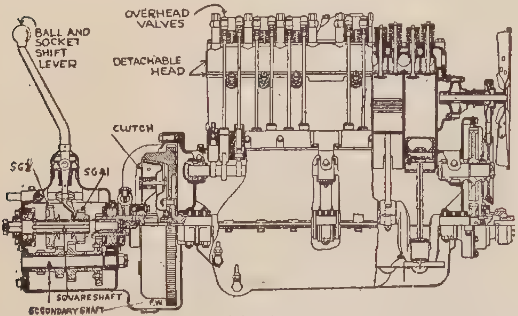

Fig. 3

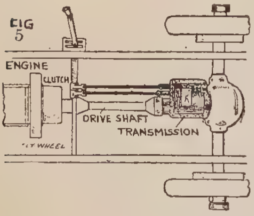
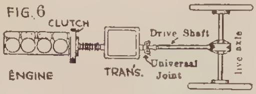
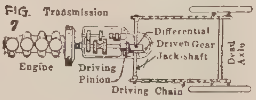
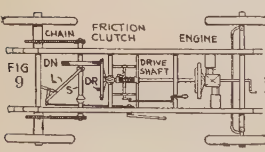
On some of the earlier type of cars the transmission was placed adjoining the rear axle housing (Fig. 5).









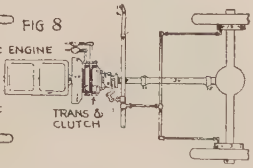


Fig. 6 shows the transmission separated from the engine. This method is used on the Locomobile.

Fig. 7 shows the location of the transmission when used with a double-chain drive and a dead rear axle.

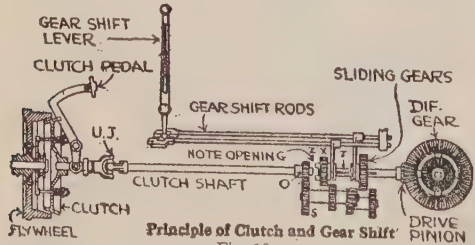
Fig. 8 is the Ford planetary transmission location, explained under Ford Instructions.

Fig. 9 is a friction-disk type of transmission, used on cars of the early period. The drive disk (DR) connected to the drive shaft transmits the power through the driven disk (DN) to the jack shaft, thence by sprockets and chain to the dead rear axle.

The change of speeds is obtained by sliding the driven disk (DN) on the keyed shaft (S) by the lever (L). By this means several ratios of speeds could be obtained. The disadvantage, however, was due to slipping. This type is now seldom used.

The Selective-Gear Type of Transmission

This type is preferable, because of the absence of noise from the gears and because of the ease of operation. The gear-change ratio, or gear desired, is "selected" by movement of the gear-shift lever, and the shift can be made without one gear passing through another.



Principle of Clutch and Gear Shift
Fig. 10

The relation of the gears to the clutch is shown in Fig. 10. The principle of the selective type of transmission is shown on pages 27 and 28.

Referring again to Fig. 10, note that the power is transmitted from the fly wheel to the clutch, thence from the clutch shaft to gear (O and S), through the sliding gear for first or second speed. For high speed, small dog-clutches on the sliding gear (X), on the square shaft (T), mesh with dogs on gear (O), which makes the drive direct to the rear axle. See also Fig. 12.

Relation of Parts

How the change of gears is obtained. Note, in Fig. 12, the square shaft (130) is independent of the clutch shaft (134). Also note, in Fig. 11, that the gear (128) and the driven gear on the countershaft, as well as the countershaft itself (129), always turn together. Thus power from the engine would end at shaft (129), providing sliding gears (SG-1 and SG-2) were in the position shown, which is "neutral" position.

Fig. 11.

Neutral position means the sliding gear is not in mesh with the gear that drives it. Therefore, with the position illustrated in Fig. 11, we could not drive the rear axle, even though the engine was running and the clutch "in."

First or low speed would be obtained by shifting gear (SG-2) in mesh with countershaft low-speed gear. **Second speed,** would be obtained by shifting sliding gear (SG-1) in mesh with countershaft second-speed gear. **Third or high speed,** would be obtained by shifting (SG-1) forward so that dogs (139) would grip; then the drive would be direct to the rear axle, but the countershaft and its gears would also turn, but not being in mesh with the

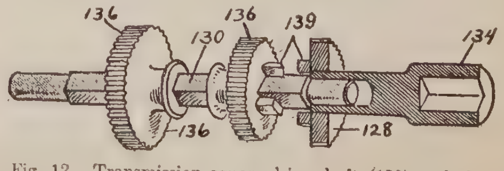

Fig. 12. Transmission square drive shaft (130) and sliding gears (136).

driven gears it would make no difference. **Reverse** would be obtained by shifting (SG-2) back until it meshes with the idler gear, which would reverse the direction of drive shaft (130).

Remember—gears cannot be shifted until the lever is brought to "neutral" position.

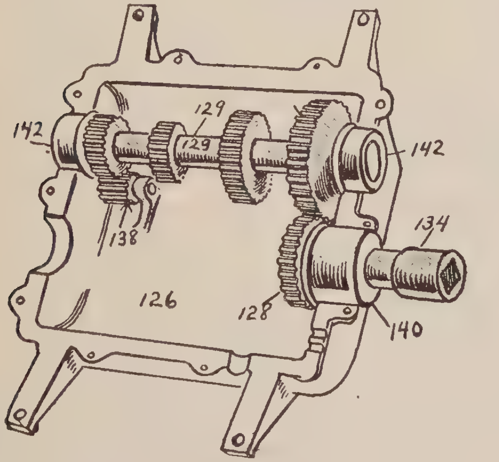

Fig. 13. The lower half of transmission with countershaft (129) and its gears which are permanently attached thereto. Idler gear (138), clutch or main drive gear (128), and clutch shaft (134) are also illustrated.

A Modern Selective-Gear Type of Transmission

The transmission in Figs. 11, 12 and 13 gives a clear explanation of the relation of one part to another.

The modern transmission now uses internal gears instead of "dogs." For instance, see Fig. 18, page 28. Note that instead of "dogs" (139, Fig. 12), the gear (8, Fig. 18) has internal teeth which mesh with a smaller gear on the side of gear (9).

The transmission (Fig. 18) is connected to the engine. It is therefore termed a "unit power plant." There are three speeds forward and one reverse.

Operation of the Gear-Shift Lever

There are two types of gear shift levers: the "**gate**" principle and the "**ball-and-socket**" type. The latter is used more than any other type.

The gate type: The gate type is shown in Figs. 14 and 15. A simplified explanation as to how the shift lever operates in relation to the shift bars (146 and 147) and shifting or sliding gears (SG-1 and SG-2) will be made clear by referring to Figs. 11 and 14.

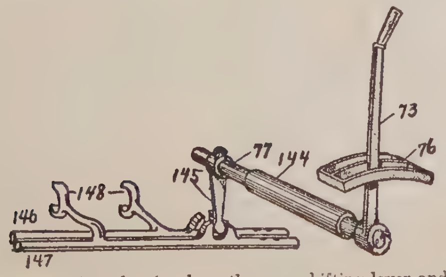

Fig. 14. View showing how the gear-shifting lever and the selector connect with the shifting bars. The lever is now in "neutral" position, but if pushed to the inside gate or selector, it would shift the inside bar (146); if pushed to the outside gate position it would shift the outside bars (147). Note, that the lever moves sidewise as well as forward and backward.

The movement of the gear-shift lever for different speeds varies on different cars. For instance, in

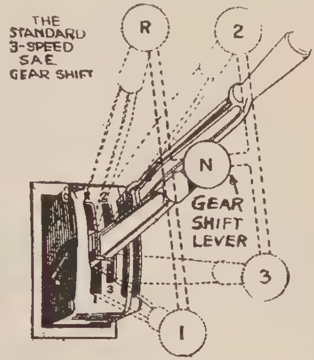

Fig. 15

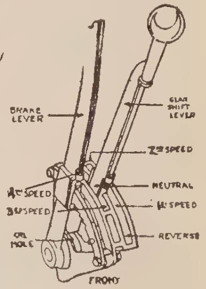

Fig. 16

Fig. 15. A three-speed forward and reverse gate type gear shift.

Fig. 16. A four-speed forward and reverse gate type gear shift.

Fig. 15, to obtain **first or low speed,** the gear-shift lever, which is now neutral (**N**), is moved sidewise to the left and then back. To obtain **second speed,** it is moved sidewise to the right and then forward; for **third, or high speed,** to the right and back; for **reverse,** to the left and forward.

The four-speed gate type of gear-shift (Fig. 16) corresponds with that shown in Fig. 20, page 29.

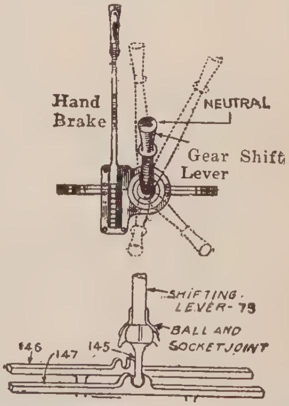

Fig. 17. Ball-and-socket type of gear-shift lever, with three speeds forward and reverse. The gear-shift lever (73) is now upright in the center of the socket and is in "neutral" position.

The ball-and-socket type of gear shift shows almost identically the same principle as the gate type, except the movement of lever (73), (Fig. 17), is in a "ball and socket" instead of a "gate." Note that arm (145) serves the same purpose as arm (145) (Fig. 14). This is the type in general use.

S. A. E. Standard Gear-Shift Movements[1]

The gear shifts as recommended by the Society of Automotive Engineers are illustrated on page 29.

The transmission, giving three forward speeds and one reverse speed (or gear changes) is in general use. On some few large cars, and also on most types of trucks, the four-speed transmission is used. Fig. 19, page 29, illustrates the gear shift in general use. The selector can be of the "gate" or "ball-and-socket" type, usually the latter.

---

[1] See Index for "S. A. E. standard four-speed truck gear shift."

Clutch shaft (19) is permanently connected with the main drive or clutch gear (9) or the transmission. The other end (CE) works free in a ball bearing in the fly wheel, but does not connect with the fly wheel.

FIG. 18

When the clutch is "in," a spring (16) presses against flange (T) of a sleeve, causing the three fingers working on pivots (F) to apply pressure through pressure plate (R) (a ring); this in turn applies pressure against the single plate. The single plate (13) is fitted with Raybestos riveted on each side. This friction material clutches the fly wheel. The drive is then through driven plate (13) to plate hub (D), then a square section of the clutch shaft (CS) to the main drive gear (9). Note (CS) part of clutch shaft is squared and clutch plate hub (D) slides thereon.

When the clutch is "out," the pedal (11) is pressed; this causes the yoke collar to press against flange (17) of the sleeve. This action causes flange (T) on the other end of the sleeve to relieve the pressure against fingers (F). This releases the pressure against the single plate (13).

The adjustment of fingers (F) or pressure against the plate is at (A). This type of clutch runs without oil.

Note. Figures in the squares at the end of the wording of Fig. 18 compare with reference figures on transmission on page 26 (Fig. 11).

Fig. 21. Four-speed; same as Fig. 20, except that the reverse (R) is in a separate slot, to the side of the first speed (1).

Example of Gear Shifts

The gear-shift principle (Fig. 22) is the "ball-and-socket" type and standard S. A. E. movement, as shown in Fig. 19. The transmission is of the "selective-gear" type, three speeds forward and one reverse. (Studebaker model "EJ" is used as an example.) Note that the gear-shift lever (1) is now upright and in neutral (N) position. If shifted according to the movements, first, second, third and R, the various transmission-gear ratios will be selected as shown in Fig. 22 below.

Remarks Relative to Changing Gears

To start the engine: See that the gear-shift lever is in neutral position. The clutch is then in, but the car will not move. Turn on the ignition switch and crank the engine.

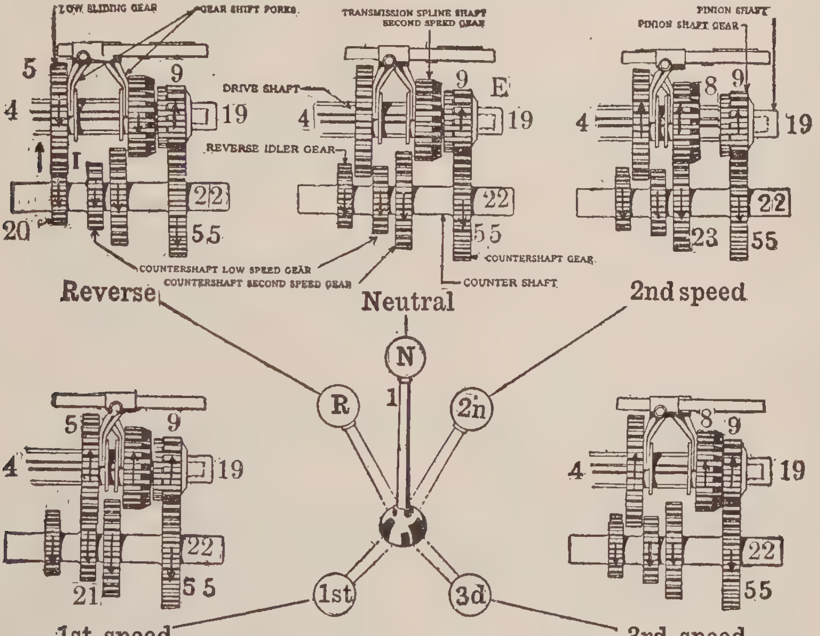

Fig. 22. **First speed:** The drive is from (19) to (9), to (55), to (21), to (5), to the transmission square shaft (4), to the rear axle. (Arrows on the gears indicate the direction in which the gears turn.)

Second speed: (19) to (9), to (55), to (23), to (8), through square shaft (4), to the rear axle.

Third speed, or high gear on direct drive: (19) to (9), to (8), through the transmission square shaft (4), to the rear axle. Note: Gear (8) fits over teeth at the side of gear (9); thus the drive is direct through shaft (4). The shaft (22) and its gears revolve, but no power is transmitted through them.

Reverse: (19) to (9), to (55), to (20), to the free-running idler gear (I) (directly back of an in-mesh with gear 20), to (5) to the transmission square shaft (4), to the rear axle. This idler gear, interposed between (20) and (5), gives a reverse motion to shaft (4)

To start the car: Speed up the engine slightly. Throw out the clutch by pressing the left foot pedal. Shift the gear-shift lever to first speed. Let in the clutch. Speed up the engine to give momentum to the car, and if on a level road, you can then throw out the clutch, quickly shift to third speed, and then let the clutch in. If on a hill, go to second speed instead of third, and then shift to third speed after the car is well under way.

To stop the car: Throw out the clutch, apply the foot brake, and slow the engine down. After the car stops, shift gears to neutral, then let clutch in. In order then to stop the engine, turn off the ignition switch.

Changing gears from a higher to a lower speed, when the car is running, is seldom done, as the speed of the engine is controlled instead, unless in a congested district it is necessary to run very slow, or if taking a hill and the engine pounds. This indicates that the hill is too steep for the power of the engine, and a change to a lower gear should be made at once by throwing out the clutch and shifting the gear lever.

Never shift to a lower gear when running at a fast speed, as there is danger of stripping the teeth from the gears.

Never shift to reverse gear unless the car is at a dead standstill.

Note. The shift gears by shifting ought to be made without a particle of noise if the clutch is thrown out when shifting. If there is noise, then it is usually due to the clutch not being fully thrown out or dragging or spinning, or to the transmission shaft, or to the fact that the transmission shaft is out of line owing to worn bearings.

INSTRUCTION No. 7

THE GASOLINE ENGINE: Principle and Construction

GENERAL EXPLANATION

There are three motive powers for automobiles: (1) The **gasoline engine,** also called an **internal combustion type of engine** because the fuel combusts, or, in other words, the burning of the fuel takes place inside the engine cylinder, between cylinder head and piston, or, in the combustion chamber. This type of engine could use either gasoline, kerosene, or alcohol, but in this treatise we will deal with gasoline as a fuel. (2) The **steam engine is an external combustion type,** the combustion taking place under the boiler, separate from the engine. (3) The **electric motor** derives its power from an electric storage battery.

Fig. 1. The gasoline engine: an internal combustion type.

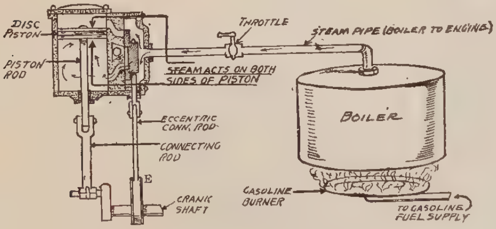

Fig. 2. Steam engine: an external combustion type.

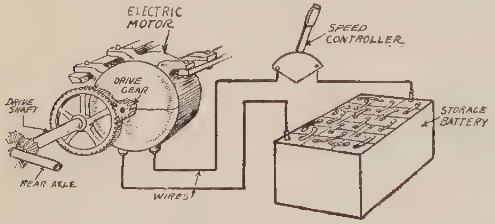

Fig. 3. The electric motor and its source of electric supply: the storage battery.

We shall deal with the gasoline type of automobile. The gasoline engine furnishes the motive power to drive the automobile.

Note. The word motor is often used to designate the engine but if one wishes to be technical and correct it should always be referred to as engine. The word "motor," however (owing to the popular practice), is used in many instances in the book.

Engines for small cars are sometimes made with but one, or perhaps two cylinders (now obsolete). A few motor cars formerly had engines of three cylinders. The majority have four, six and eight. Five-cylinder engines hardly exist. Seven-cylinder engines exist in a special form for flying machine, as the Gnome revolving cylinder type. The twelve-cylinder engine is also coming into prominence; motor boats indulge in engines with as many as twelve to twenty-four cylinders. But whether the engine has one or twenty-four cylinders, the explanation of how it works, or the principle, always remains the same.

All gasoline engines work on practically the same principle. It must be a four-cycle or a two-cycle type (the four-cycle type is dealt with in this instruction). The valve arrangement may be different, but we describe the various types of valves farther on in this instruction. The ignition may be different, but we shall discuss all forms of ignition. We mention this so that when you see an engine with a different ignition or a different valve arrangement, remember the principle is just the same on all engines (except the two-cycle type, which have no valves. The principle of combustion and ignition is similar, however).

When a compressed mixture or charge of gasoline vapor and air is set on fire, it burns with great rapidity and produces intense heat, which **causes the gases to expand and thus** develops the pressure against the head of the piston, which operates the crankshaft of the engine. This combustion is so rapid that it is usually spoken of as an "explosion"; this word is often used, although the word "combustion" is more correct. The intensity of the pressure decreases as the piston travels downward on power stroke, due to the expansion of the gases having more space in which to expand.

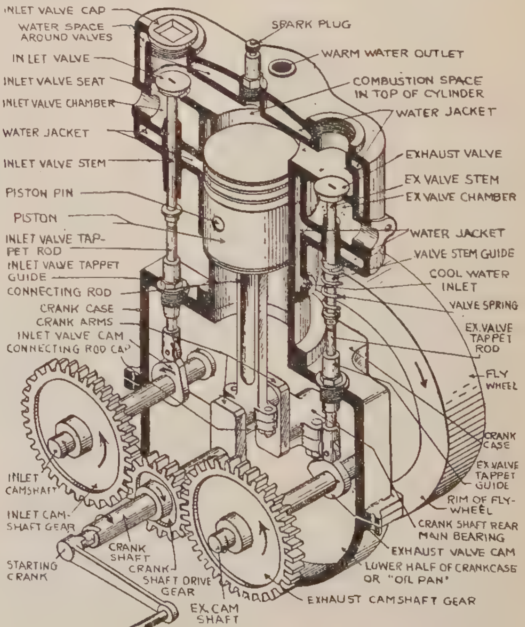

Fig. 4. Parts of a gasoline engine. Cylinder is a "T-head" type with inlet valves on one side and exhaust valves on the other. The inlet valves do not necessarily have to be on the right side. Some cars, for instance, the Locomobile six-cylinder T-head engine, have the inlet valves on the left and the exhaust on the right; whereas the Pierce-Arrow T-head six-cylinder engine is the reverse.

The difference is that an explosion is instantaneous, while the combustion of gasoline vapor and air, although very rapid, is not instantaneous. The combustion takes place within the cylinder of the engine.

One end of the cylinder is **closed,** and the other is **open,** the closed end being called the **cylinder head.** Within the cylinder is a **piston,** sliding back and forth.

The space between the piston and the cylinder head is called the **combustion chamber.**

The back-and-forth motion of the piston in the cylinder is called **reciprocating motion.** In order that it may turn the wheels, this reciprocating motion must be changed to the motion of a wheel revolving on its axle, which is called **rotary motion.** The reciprocating motion of the piston is changed to the rotary motion of the wheels by means of a crank shaft.

The piston is connected to the crank shaft by a connecting rod, so that it moves in and out as the crank shaft revolves. One complete turn of the crank shaft, by which the piston is moved from one end of the cylinder to the other, and back again, is called a "revolution." One-half of a revolution of the crank shaft moves the piston from one end of the cylinder to the other, and this is called a "stroke."

It must be remembered that there are two strokes of the piston to every revolution of the crank shaft: one down-stroke and one up-stroke.

A steam engine is called "double-acting," because the pressure of the steam acts on both sides of the piston.

A gasoline engine is called "single acting," because the pressure acts on only one side of the piston: on the top or side nearest to the cylinder head.

The combustion that causes the pressure or expansion that operates the engine takes place between the cylinder head and the piston, in the combustion chamber. The combustion should be timed to occur so that the greatest pressure is exerted when the piston is nearest the cylinder head. The pressure causes the piston to slide the length of the cylinder, from the head toward the open end.

In a steam engine, the pressure of the steam forces the piston to slide first one way and then the other.

In a gasoline automobile engine the pressure from the combustion acts on only one side of the piston, forcing it to slide only one way. After being forced downward, the piston must be brought upward again, and this is done by a fly wheel attached to the crank shaft. With the downward motion of the piston, the fly wheel starts revolving. When once started, the fly wheel continues to revolve until friction or some other resistance stops it, but before this can happen the pressure from another combustion is again exerted, keeping it going.

The fly wheel being attached to the crank shaft, they revolve together, and because the piston is connected to the crank shaft by the connecting rod it moves with them. The piston, moved downward by the pressure, starts the crank shaft and fly wheel, and then the fly wheel in continuing to revolve moves the crank shaft and piston. Since a gasoline engine does not operate with continuous pressure during its action, the piston first moves the crank shaft and fly wheel, and then the fly wheel and crank shaft move the piston.

Note. Larger fly wheels are used on single-cylinder engines than on multiple-cylinder engines, because there are not as many firing impulses to two revolutions of the crank shaft on a single-cylinder engine. The fly wheel is usually fitted securely to the tapered end of the crank shaft and flange. It must be secure, otherwise a knock would occur.

The fact that the crank shaft of a gasoline engine must first be turned by hand or by an electric motor or mechanical device, in order to start the engine, is due to the fact that a charge of gas must first be drawn into the cylinder by the suction stroke, and then compressed. After the gas is once ignited, then the force of the power stroke, and momentum of the fly wheel will carry the crank shaft and piston through the other three strokes until the power stroke occurs again.

Before there can be a combustion of mixture in the cylinder, the mixture must be drawn into the cylinder, through the inlet valve.

When in the cylinder, the mixture must be prepared, so that it ignites, burns and expands with the greatest possible rapidity and heat.

After the mixture has been burned, the useless gases must be removed, or exhausted from the cylinder, to make room for a fresh charge of the mixture.

These successive events must occur in their proper order, for if any one of them fails, or it is not performed properly, the succeeding event cannot occur, and the engine will stop running. **These events are called a cycle.**

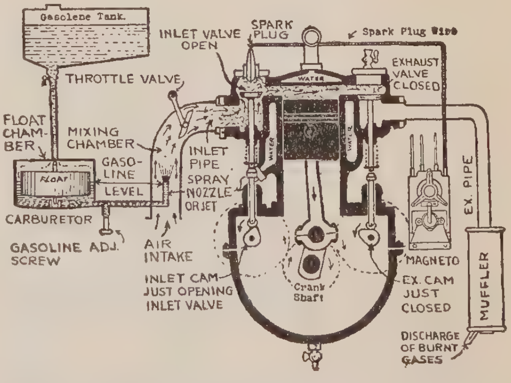

Fig. 5. In this view we are looking at the end of the engine. The illustration is exaggerated in order to simplify the explanation. Imagine the end cylinder cut in half. The object is to illustrate how the gasoline from the tank flows to the carburetor and fills the float chamber until the float needle cuts off the flow. The gas mixed with air, is then drawn into the cylinder by the suction of the piston on the **suction stroke.** During this suction the intake valve must be opened by a cam (the nose-shaped affair at the bottom of the valve lifter) to permit gas to enter the cylinder.

After the cylinder is filled with gas, which is the purpose of the suction stroke, the intake and exhaust valves are closed and the piston, on its up stroke (**compression stroke**), compresses the gas. At the highest point of compression, the gas is ignited by the spark at the points of the spark plug and the piston is forced down with considerable force; this is called the **explosion stroke.** As the piston travels up again the burnt gas is expelled through the exhaust valve which should open at this time and permit the burnt gas to pass out through the exhaust pipe and muffler. This fourth and last stroke, which completes the operation is called the **exhaust stroke.**

The Four-Cycle Principle

There are two distinct cycle principles; generally spoken of as **"four-stroke cycle"** and **"two-stroke** cycle" principles. The two-cycle engine is generally a small marine type of engine and will be dealt with farther on.

The four-cycle engine is the type used for automobile work. Therefore we still deal with this type throughout the automobile instruction.

The cycle is thus composed of: (1) the drawing into the cylinder of the mixture (Fig. 6) below; (2) the compression of the mixture (Fig. 7); (3) the burning or ignition of the mixture and the forcing downward of the piston by the pressure produced by the burning of the mixture (Fig. 8); (4) the removal of the burned and useless gases left after the combustion (Fig. 9).

The cycle is performed during two revolutions of the crank shaft, or, what is the same thing, four strokes of the piston.

The first event occurs while the piston makes a **downward stroke,** during which the cylinder is sucked full of the mixture, just as a similar stroke of a pump or syringe sucks in a liquid. This is called the **inlet stroke or suction stroke.**

The next stroke of the piston is an **upward stroke,** during which the mixture sucked into the cylinder is prepared by being compressed, and at the end or top of this stroke it is set on fire, or ignited. This is called the **compression stroke.**

When the compressed gas is ignited, the pressure from the combustion forces the piston to make a downward stroke. This is called the **power stroke.**

The next upward movement of the piston pushes the burned and useless gases out of the cylinder. This is called the **exhaust stroke.**

These four strokes occur in each cylinder during two revolutions of the crank shaft and are repeated over and over again in each cylinder as long as the engine continues to run.

On a six, eight, and twelve-cylinder engine, in order that the four events occur in each cylinder during the four strokes they "lap" one into the other. Thus we have two cylinders on power for certain periods of time.

In principle the gasoline engine is like a gun. In a gun the shot is fired by exploding powder behind it. In a gasoline engine we explode gasoline behind the piston in exactly the same way.

There are some differences, of course. The charge goes out of the gun, and that is the end of it. But in a gasoline engine, after the explosion drives the piston before it, in order to get any work out of the machine, this piston must come back and a new charge must be exploded behind it. The burned gases and heat must be disposed of, and all of these things must be done over and over again very quickly, at exactly the right time.

Explanation of the Four Strokes

Valves are arranged to open and close at the proper time to admit fresh gas and to let out the burned gas, and the positions of the piston, valves, and cams for each function are shown in Figs. 6 to 9. Note the direction in which the cams (1 and 2, Fig. 6) are turned by the cam gears, which are driven by the crank-shaft gear.

Cams on a gasoline engine are for the same purpose as an eccentric (E), (Fig. 2, page 30), on a steam engine—to open and close the valves.

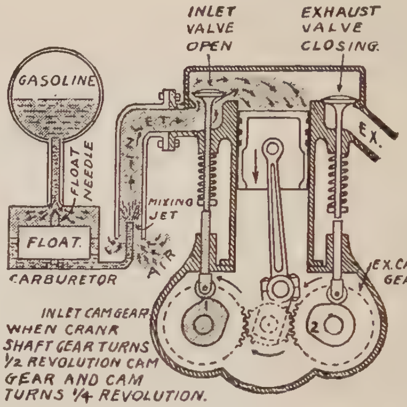

Fig. 6. Showing the suction stroke—down. The charge of gas is being taken into cylinder from the carburetor by the suction of the piston through the open inlet valve.

Note that the inlet valve is opened by inlet cam. Note direction of travel of cam. This stroke is also called "admission" or "inlet" stroke.

Note. The figures on the cams correspond to the figures on the cams in Fig. 10, which are intended to show the movement in degrees at each stroke of the piston.

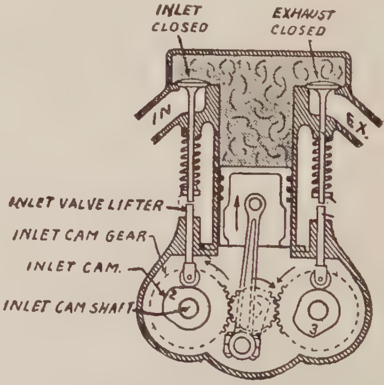

Fig. 7. Compression stroke—up. Both valves are closed because the nose of the cam is not raising either of the valves. Gas is being compressed as the piston travels up. Note the direction of travel of the cam.

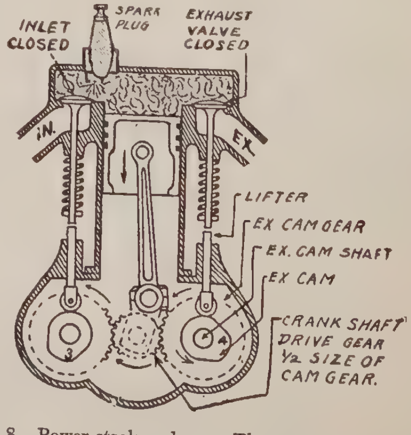

Fig. 8. Power stroke—down. The spark is now occurring, therefore the compressed gas is combusting and expansion force is being exerted against the piston head, thus forcing it down with great pressure. In actual practice, the spark occurs before combustion takes place. Both valves are closed. This stroke is also called the "explosion" or "working" stroke.

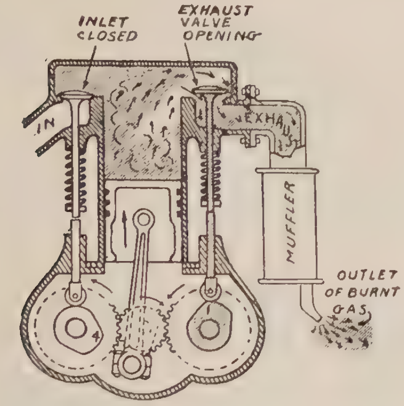

Fig. 9. Exhaust stroke—up. The exhaust-valve cam is now raising the exhaust valve which is open, thus permitting the burned gas to be forced out of the exhaust pipe through the muffler.

When the piston reaches the top of the exhaust stroke the piston will have completed the four strokes, or two crank-shaft revolutions, and the cam-shaft one revolution.

The next stroke is the suction stroke again. These four strokes are repeated over and over again as long as the engine runs.

The above explanation of the four strokes is based on a T-head type of engine, supposed to be cut in half.

The "L" head uses but one cam shaft. The view is from the front of the engine. Thus there is but one inlet and one exhaust cam for each cylinder, just the same as a T- or "round"-head cylinder or any type of four-cycle engine. The principle is identically the same.

Note. A "dual-valve" engine has four valves per cylinder. This is explained farther on.

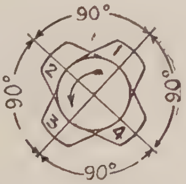

Fig. 10. Illustrates the movement of the cam. Note that the cam moves 90 degrees, or one-fourth revolution each time the crank moves 180 degrees, or one-half revolution.

When the crank shaft makes two revolutions, or 720 degrees to complete the four-cycle revolution, then the cam shaft and cam would be making one revolution, or 360 degrees, because the driven cam gears are twice the size of the driving crank-shaft gear.

The figures 1, 2, 3, 4 on the cams correspond to the cams in Figs. 6 to 9, and are intended to represent the movement in degrees at each stroke of the piston.

Control of Speed of Engine

After the engine is started with the starting crank (self-starters will be explained farther on), the speed of the engine is controlled by opening and closing the butterfly throttle valve of the carburetor which, when opened, admits gas to the cylinder. The more gas admitted, the stronger the compression, therefore the greater the explosive force, and hence more speed. Closing this valve reduces the speed. The gas, of course, is admitted through the inlet valve during the suction stroke.

The opening and closing of the throttle is regulated by hand (Fig. 11), by means of the throttle lever on the steering wheel, or by a foot pedal connected with the same throttle lever, and called an "accelerator."

The carburetor is connected to the inlet manifold by the inlet pipe, and the gasoline flows to the carburetor from the supply tank through a small brass or copper pipe, called the **fuel pipe.**

Fig. 11. Illustrating the principle of opening and closing the throttle valve in the carburetor by the throttle lever on the steering wheel.

Pure gasoline vapor will not burn, but must be mixed with air before it can be used to develop pressure. The mixing of gasoline vapor and air in the proper proportions is called "carburetion." To give the best results, the mixture of gasoline vapor and air must always be in correct proportion. (This is explained in the carburetor instruction.)

There is a passage through the carburetor into which the air is drawn as the piston makes the suction stroke. The liquid flows to the carburetor and is brought into contact with the current of air. The gasoline turns to vapor, and is absorbed by the air, the mixture being sucked into the cylinder on the suction stroke.

The quantity of mixture that is drawn into the cylinder during one suction stroke is called the **charge.**

If the speed of the engine is governed by the amount of gas drawn into the cylinder through the butterfly throttle valve of the carburetor and the inlet valve on the engine, it is clear that if high speed or more power is desired, it is necessary that all of the mixture possible be drawn into the cylinder through the inlet valve, and that the inlet valve must open at the exact time and open wide enough to permit a full charge being drawn in.

As the inlet valve is mechanically operated, the cam must be adjusted (by having the inlet cam gear properly meshed with the crank-shaft gear) so that it will open the valve promptly as soon as the sucking action of the piston commences, which it is just beginning to do in Fig. 6. Note that the cam is just starting to raise the inlet valve.

If the inlet valve does not open soon enough, the piston will have made part of its stroke before the charge begins to enter; if it opens too soon, part of the burned gases from the previous power stroke will be pushed into the carburetor. If it closes too soon, the cylinder will not get a full charge; if it closes too late, part of the mixture will be pushed out of the cylinder on the compression stroke.

The setting of the cam gear (which controls the position of the cams) with the crank-shaft drive gear, is termed **valve timing** and is treated more fully under the instruction on that subject.

If all the openings into the cylinder, such as the exhaust valve, the spark plug, piston rings, relief cock, etc., are not tight, air or gas will be sucked into the cylinder through them at the same time that the charge enters through the inlet valve, and this would destroy the proportions of the mixture.

As the piston travels up on compression stroke, the gas is tightly compressed until it occupies only the space between the inside of the cylinder and the head of the piston, and it is the force or expansion from this compressed gas, when ignited, at the highest point of compression, that the power of a gasoline engine depends upon.

If the valves are not closed tight, or if there are any leaks by which this gas can escape, it is clear that the gas will not be compressed as much as if there were no leaks. The result is a weaker power stroke.

When an engine is running with the throttle wide open, as, for instance, on a steep hill, the compression is greater, because more gas is drawn into the cylinders.

If the engine is running on a level, with the throttle partially open, then the compression is less.

Thus it is clear that if the space between the cylinder and piston head is, say, one inch, the more gas that is compressed in this space, the greater the pressure.

The greatest power is obtained from a given volume of compressed gas when it is ignited at its highest point of compression, which is at the top of the compression stroke and just at the moment when the piston is over center in the direction of rotation.

It is the expansion force of the ignited gases, caused by the heat when combustion takes place, that produces the pressure against the head of the piston. It is, therefore, clear that as the piston travels down on the power stroke, this expansion force becomes less and less, because it has more space in which to expand. Hence the importance of having the spark occur at the correct time and also of having the valves open and close at the proper time.

Toward the end of the power stroke, and usually before the piston reaches the bottom of its power stroke, the **exhaust valve is set to open.** There is still pressure in the cylinder, and when the **exhaust valve is open,** this pressure will cause the gases to begin to escape.

As the exhaust stroke is an **upward stroke** of the piston, the piston will push out through the exhaust valve all of the burned gases that do not escape by their own pressure.

If all the burned gases are not pushed out of the cylinder, it will prevent a full charge of fresh gas from being drawn in, which will cause a weak mixture and a weak explosion.

The exhaust valve closes as the piston reaches its upmost point, or a little after, the inlet valve opening as the exhaust valve closes.

Back pressure, caused by the muffler or obstructions in the exhaust pipe, will prevent the burned gases from escaping as freely as they otherwise would, and all may not be pushed out by the time that the exhaust valve closes.

The exhaust valve and its seat are exposed to the full heat and flame of the burning mixture, and are more liable to warp or pit than the inlet valve. It must be watched, and if there does not seem to be perfect compression when the engine is cranked, the probability is that it needs grinding to seat it properly. The exhaust valve thus requires more grinding than the inlet valve.

A proper mixture will be entirely burned before the exhaust valve opens. An **improper mixture** that burns slowly may still be burning when the exhaust valve opens, and will heat the exhaust pipe and muffler so that the pipe may become red hot. Such a mixture wastes fuel, and may result in a fire. It may be corrected by making a correct adjustment of the carburetor and spark, which will be explained later on.

Ignition: When the throttle is being opened and the engine begins to speed up, it is necessary also to "advance" the time of ignition; in other words, to cause the spark to occur earlier than if engine is running slow.

Fig. 12

A spark lever is usually placed on the steering wheel along side of the throttle lever, which is connected by a rod and bell crank to the contact-breaker box on the magneto, or, if a coil and timer is used, to the commutator or interrupter.

When the spark lever is moved, it also moves the contact-breaker box on magneto, or commutator, which causes the spark to occur "late" or "early," according to the movement of this lever.

The proper time for the ignition of the mixture is at the top of the **compression stroke**—when the gas is compressed to the highest point.

Up to this point we have supposed that the spark occurs exactly at the moment when the piston reaches the top of the compression stroke. Now, this would be, in fact, the correct time, were it not for the fact that the gas takes quite an appreciable time to combust and expand after being ignited, an interval, let us say of a fraction of a second. Thus before the gas has had time to burst into a full combustion and expansion, the piston, on account of its great speed (suppose it is traveling at 1,500 revolutions per minute), will have traveled part of the way down the cylinder before being affected by it. This means part of every power stroke wasted.

The advance of spark: The remedy for this is to make the spark occur earlier; that is, to make it occur just before the piston has completed, or reached the top of the compression stroke, so that the full burst of explosion and the piston arrive simultaneously at the top of the stroke, or just as the piston is slightly over the top of "dead center." This is called "advancing the spark."

The retard of spark: Suppose the engine is now running at only half the speed, say 700 revolutions per minute. During the exploding or igniting period, which we assumed to be a fraction of a second, and which remains the same, the piston, with its speed now reduced, has not time to travel so far, and the spark therefore need not be so much advanced.

Again, when the engine runs dead slow, say at 100 revolutions per minute, which is slow for an automobile engine, the spark requires hardly any advance at all. So that we see, at once, that the **faster** the engine runs the more the spark must be **advanced,** and that the **slower** the engine runs the less it need be advanced, or, to express it in a more usual way, the more the spark must be **retarded.**

To "advance" or "retard" the spark, means that the spark is made to occur earlier or later relative to the position of the piston. It does not mean that the spark is made to occur more frequently or less frequently. (This subject is treated more fully under "Ignition Timing.")

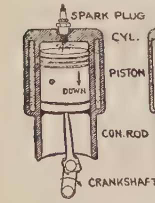

Fig. 13

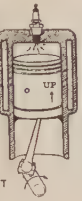

Fig. 14

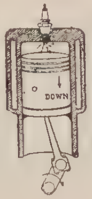

Fig. 15

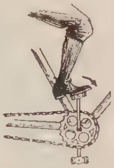

Fig. 16

Fig. 13. Here the explosion is occurring at just the right time, at the moment when the piston starts downward, securing the full length of the power stroke.

Fig. 14. Here the explosion is occurring too early, causing the piston to push backward on the crank shaft, applying power in the wrong direction. While a single-cylinder engine would "kick back" and stop, in a four-cylinder engine the remaining three cylinders would have this resistance to overcome.

Fig. 15. Here the spark is occurring too late, wasting the top or best part of the power stroke.

Fig. 16. The piston is like the pedal of the bicycle. It should receive the push when it first starts downward. (Illustration through courtesy of K. W. Ignition Co.)

The point to bear in mind is that the spark must be made to occur so that the greatest expansion takes place just the moment the piston is over the top of dead center. In order to give the gas sufficient time to ignite, so that complete combustion will occur at this point, the spark is "advanced" or "retarded," according to the speed of the engine, as explained above.

Another factor to be considered is the electrical apparatus producing the spark. For instance, an ignition system using a vibrator coil would require more advance than a closed-circuit type of interrupter, because the action of the vibrator-coil system is slower. This condition is termed "electrical lag."

If the spark is advanced too much, all of the mixture will have been burned before the piston reaches its upmost point, so that it will be necessary for the fly wheel to force the piston upward against the pressure until it gets to its upmost point. This strains the engine, and causes a sound that is called an **"ignition knock"**; a hard, metallic sound.

The knocking is not always detected easily by the novice, who will probably confuse it with other sounds on the car, but when once it has made itself evident, the **spark should instantly be retarded** until the knocking ceases. The strains set up in an engine which is allowed to knock may seriously damage connecting rods and cranks.

It will be seen from the foregoing that in addition to controlling the speed of the engine through the gas throttle lever, it may also be controlled by advancing or retarding the spark, the speed of the car changing accordingly.

An engine should not be slowed by retarding the spark. If it has appeared to the reader in the last few paragraphs that it is possible to slow an engine by retarding the spark, let him at once understand that this is the last method by which it ought ever to be done. It is not only unscientific, but is also wasteful of fuel and produces extra heat, and causes rapid pitting of the exhaust valves, the gases passing through them in an incandescent form.

The correct method of slowing down or increasing the engine speed is to shut or open the throttle valve, which is situated between the carburetor and the inlet valve, by which the amount of fuel supplied to the engine may be regulated. Then as the engine varies its speed, slower or faster, the spark should be retarded or advanced accordingly.

The rule, therefore, is to let the engine speed follow the throttle and to make the spark follow the engine speed; or, to put it in another way, in order to drive economically, the throttle valve must be kept closed as much as possible and the spark advanced as far as possible, short of knocking or of a tendency to knock.

Such subjects as ignition, carburetion, cooling, fuel systems, lubrication, etc., will be taken up farther on under their respective headings. We are still dealing with engine construction, and must, for the present, adhere to this branch of the subject.

INSTRUCTION No. 8

ENGINE PARTS: Assembly; Types

ASSEMBLY OF PARTS

The stationary parts are: crank case, upper and lower half, bearings, cylinders, exhaust and inlet ports, valve caps, compression or relief cocks, water-cooling pipes, carburetion and part of the ignition systems, exhaust and inlet manifolds.

The moving parts are: crank shaft, connecting rods, pistons, piston rings, piston pin or wrist pins, cams, cam shaft, timing gears, crank-shaft gear, valves, valve plungers or tappets or lifters, fly wheel.

In order to enable the reader thoroughly to grasp the meaning and purpose of the parts, we will build up a four-cylinder T-head type of engine as shown below. The illustrations are not drawn to scale, nor are they technically correct, but will serve the purpose of explaining the location of the parts of an engine.

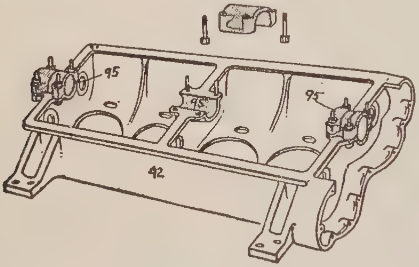

Fig. 1. Main bearings. Upper half of crank case upside down.

Crank case: A reference to Fig. 1 will show an aluminum crank case, upper-half part, which we lay on the floor, upside down, so that we can see the bearings (95).

Note. The S. A. E. designates the lower part of the crank case as the "oil pan" when containing no bearings. If it contains bearings, it is termed the lower crank case. The S. A. E. further designates crank cases as of the "split type" and the "barrel type." In the barrel type the crank shaft is removed from one end of the crank case, the bearing caps being removed through hand-hole plates. The type shown here, and most used, is the "split type" with the bearings in the upper half.

The main bearings are made in halves and are usually made of bronze or white metal and are termed "bushings," instead of bearings, when removable or renewable. The bushings are fitted into bearing caps and the upper part of the bearing.

Shims (thin paper or metal strips) are placed between the two halves of the bearing, so that when wear occurs, a "shim" can be taken out and the lost motion taken up. See Index, under "Shims."

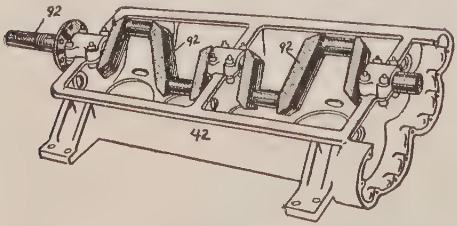

Fig. 2. Crank shaft. Upper half of crank case upside down.

The crank shaft (92) (Fig. 2) will now be fitted in the bearings. The bearing caps are placed over the bearing surface of the crank shaft, and the bearing cap nuts are tightened.

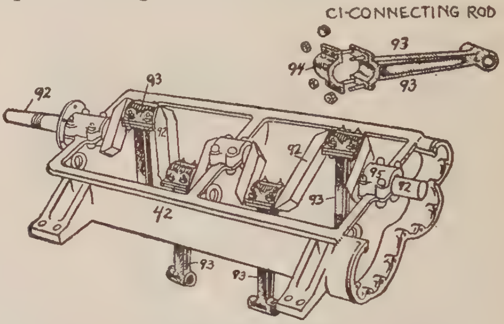

Fig. 3. Connecting rods fitted to crank shaft.

The connecting rods (93) (Fig. 3) are now fitted to the crank shaft. The lower half of the large end of the connecting rod, called the connecting-rod cap (94), is removed, so that it can be fitted to the crank shaft. Shims are inserted, so that it works free on the crank shaft. Then the nuts are drawn good and tight, so that there will be no lost motion. If there was lost motion a knock or pound, which would cause wear, would result.

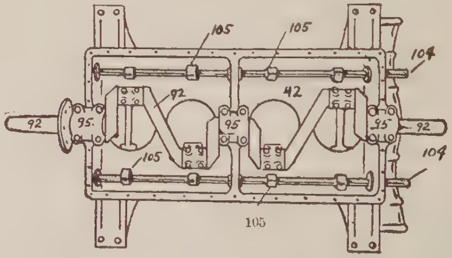

Fig. 4. Cam shafts.

The cam shaft (104) (Fig. 4) with the four cams (105, nose-shaped) is now fitted to its bearings. In this engine there are two cam shafts: one with four cams for raising the four inlet valves, and the other, with its four cams (105), to raise the four exhaust valves.

The cams are placed with their noses equi-distant, so that when they revolve they will raise the valves, by pushing them up with their nose, at a given time. The timing gears which operate the cam shafts will be explained farther on.

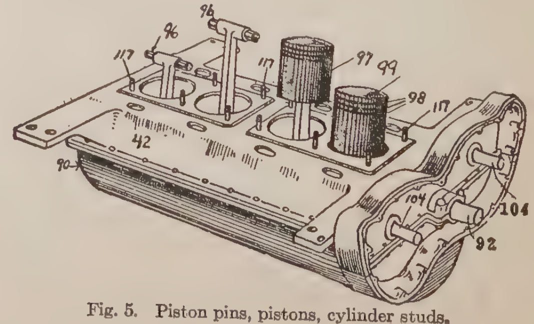

Fig. 5. Piston pins, pistons, cylinder studs.

The crank case is now turned right side up, after having fitted to it the lower half of the crank case (90). This lower half holds the oil, which the crank shaft splashes in and is called the oil pan (lubrication systems explained farther on).

The piston or wrist pin (96) (Fig. 5) in the small end of the connecting rod is shown here. This holds the piston to the end of the connecting rod (details of each part will be explained farther on).

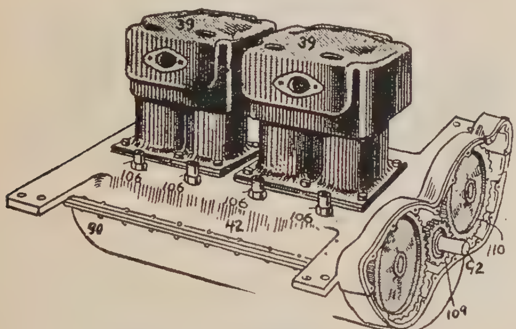

Fig. 6. Cylinders, valve-plunger guides, timing gears.

After the four pistons are fitted to the connecting rods, the cylinders (39) (Fig. 6) are fitted down over the pistons, care being taken not to break the piston rings.

The cylinders (39) are held to the crank case by nuts fastening to **studs** (117) (Fig. 5).

The valve-lifter guides (106) (Fig. 6) are fitted in holes in each side of the crank case so that they will come in line with the exhaust valves on one side of the cylinders, and with the inlet valves on the other side.

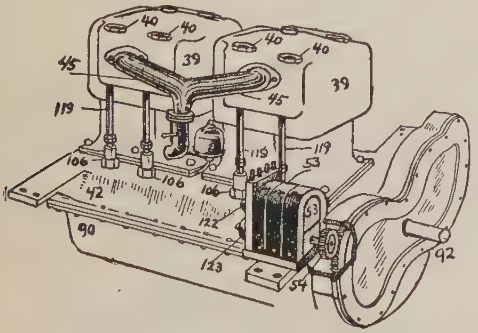

Fig. 7. Inlet valves, inlet manifold, carburetor, magneto.

Valve lifters, or tappets, are now fitted through these valve-lifter guides which raise the valves through the action of the cams.

The gear for driving the timing gears, called the **crank-shaft timing gear** (109) (Fig. 6), is keyed or threaded to the end of the crank shaft (92); this gear drives the two timing gears (110 and 111).

The cam-shaft timing gears are keyed to the cam shaft (104) (Fig. 4); one gear and shaft to operate the inlet valves (119) (Fig. 7), and the other gear and shaft to operate the exhaust valves (120) (Fig. 8). The gear-case cover is placed over the gears.

The inlet valves (119) are placed in their seat by passing them through the inlet valve-cap holes (40) (Fig. 7).

The exhaust valves are placed in position, on the opposite side of the cylinders, in the same manner.

The inlet manifold (45) is now bolted to the inlet-valve side of the cylinders, and the carburetor is connected to it.

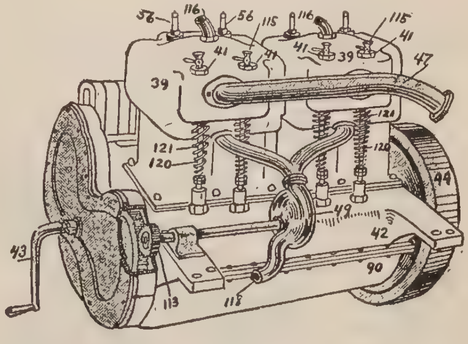

Fig. 8. Exhaust valves, manifold, fly wheel, pump, etc.

The exhaust manifold (47) (Fig. 8) is bolted to the exhaust side of the cylinders, and is connected with the muffler at the rear of the car, by the exhaust pipe (47).

The exhaust-valve caps (41) and the inlet-valve caps on the opposite side are now screwed in place—tightly.

The priming cups, also known as "compression" or "relief cocks" (115), are screwed into the exhaust-valve caps.

The spark plugs (56) are screwed into the inlet-valve caps or in the center of each cylinder, but usually over the inlet valves.

The fly wheel (44) and **starting crank** (43) are fitted to opposite ends of the crank shaft. By referring to Fig. 3 (92), the reader will note that the end of the crank shaft tapers, and a flange is also turned on this crank shaft. The fly wheel fits to this taper and bolts to the flange, as there must positively be no lost motion.

The magneto (53) (Fig. 7) (a high-tension magneto is used for ignition in this example), is bolted in place on a brass base provided for it, on the side of the engine. An extra gear (which will be explained farther on) is operated by the cam shaft and drives the magneto, which generates electricity. The electricity is distributed to the four spark plugs (56) at certain periodical times by the distributor on the magneto (122) (Fig. 7).

Wires are now connected through a switch to the magneto. This switch is to control the ignition circuit.

The circulating pump (49) is connected to the water jacket of the cylinders. The gear (113), driven by the cam gear, drives the pump, and keeps the water in constant circulation, which keeps the cylinders from getting too hot (not over 170 to 180 degrees Fahr.). We now connect rubber hose to metal pipes on the radiator and also to our pump (49), and belt up our fan, which is run from the same shaft. The radiator is filled with water by unscrewing the radiator cap.

The gasoline fuel pipe from the gasoline or fuel tank is now connected with the carburetor.

TYPES OF ENGINES

As previously mentioned, there are several types of engines, all of which work on the four-cycle principle. In order that the reader may more clearly understand, we will give an outline illustration of some of the different types of engines in general use.

The type of engine used more than any other for automobile work is the four and six, and the eight and twelve "V"-cylinder type of engine.

Fig. 9. A single-cylinder vertical type of engine, with air-cooled cylinder. Valves are both on the side and mechanically operated. There are two flywheels with a crank pin between them. The flywheels run inside of the aluminum crank case. This type of engine is used on motorcycles, cycle cars, and railroad light cars.

Fig. 10. A single-cylinder horizontal type of engine, with water-cooled cylinder. Formerly used on light-weight automobiles. Seldom used; valves mechanically operated.

Fig. 11. A double-cylinder opposed type of engine, with water-cooled cylinders and mechanically operated valves. Note that the cylinders are 180° apart. Cylinders are of the "L"-type. The crank shaft is also of the 180° type.

Fig. 12. A twin-cylinder "V"-type of engine, with cylinders placed 45° apart. Cylinders are air-cooled. Valves are mechanically operated from overhead. The cylinder is of the "round" type. This type of engine is used on motorcycles and cycle cars.

Fig. 13. A four-cylinder, vertical type of engine, with transmission and clutch in one housing joined to the engine—called a "unit power plant." This engine is suspended in a frame at three points; it would therefore be called a "three-point suspension" type of power plant. Valves are all on one side of the "L"-type cylinders.

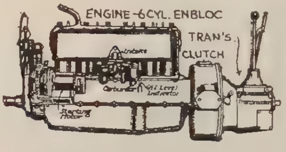

Fig. 14

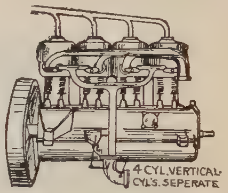

Fig. 15

Fig. 14. A six-cylinder "unit power plant." Transmission and clutch case join the engine. Cylinders are cast together, or "in block."

Fig. 15. A four-cylinder engine with cylinders cast separate. All valves are on one side; hence "L"-type cylinders.

CAM
GEAR
CRANK GEAR

Fig. 16. Eight-cylinder "V"-type engine, with cylinders placed at an angle of 90° apart. One cam gear operates the valves on both sides of the "L"-shaped cylinders. There are four cylinders on each side, usually "in block." The crank shaft is a four-cylinder type (180°) between crank throws, with two connecting rods to each crank pin.

THE AUTOMOBILE, TRUCK, AND TRACTOR ENGINE[1]

The Automobile Engine

The 4, 6, 8, and 12-cylinder engine is used for automobile work. The "four" and "six" are used most.

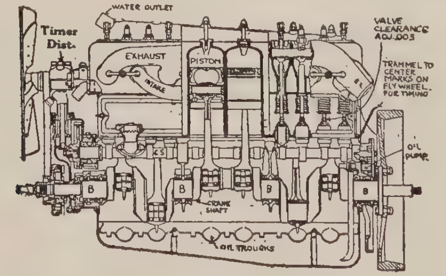

Fig. 17

Valves are placed on the side or overhead. **Ignition** is usually coil and battery, using an interrupter and distributor. A **generator** supplies current for charging the battery, also for lights and ignition. A **battery** supplies current for lights, ignition, and starting the motor. **Speed** of automobile engines varies from 150 to 2,000 r. p. m. On some few engines the speed is as high as 3,000 r.p.m. The engine shown in Fig. 17 is a 6-cylinder engine with a 3⅞″ bore by a 5″ stroke, with valves on the side. **Control of speed** is by a hand-throttle lever and foot accelerator. A governor is never used.

The Truck Engine

Usually a 4-cylinder engine is used on trucks, for reasons stated in the instruction on "Trucks." **Valves** are usually on the side. **Ignition** is usually a high-tension magneto. On the Buda truck engine (Figs. 18, 19), the Eisemann magneto with automatic advance is used. The speed of the engine is comparatively slow (950 to 1,000 r.p.m.). Speed is governed by McCann or Pierce governor on this

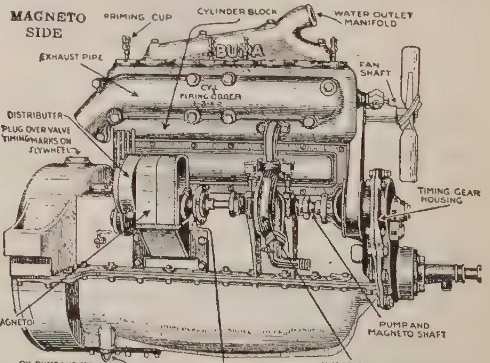

Fig. 18. Magneto side.

---

[1] The truck and tractor engine is further explained under the "Truck and Tractor" Instruction.

engine (see Index under "Governors"). The **stroke of the piston** is usually long, and in this instance, the bore is 4½" by 6" stroke or 32.4 H.P. (S.A.E.), or 52 actual H. P. **Truck speed** is from 9 to 17 m.p.h. **Starting** is usually by hand-crank in connection with an "impulse starter" (see Index). **Control of speed** is by hand throttle and accelerator.

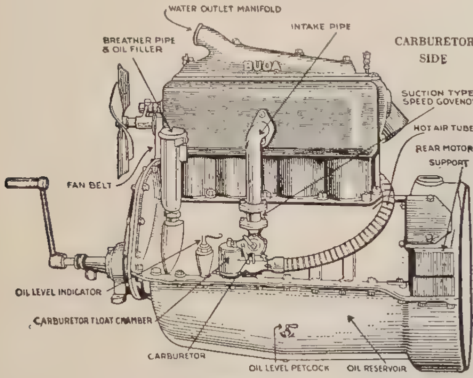

Fig. 19. Carburetor side.

Airplane Engine

Many airplane engines are 8 or 12-cylinder, "V"-type, and in most instances use the overhead type of valves. The "V"-type cylinders give a maximum of power at a minimum weight. **Ignition** is by means of a high-tension magneto or coil-and-battery ignition. The **speed of the engine** at flying speed is 1,400 to 1,700 r. p. m.

The Tractor Engine

Usually a 4-cylinder engine is used on tractors, for reasons stated in the instruction on "Tractors." **Valves** are overhead or on the side, and some use the overhead "dual" valve system. The **stroke** is usually long, the average being 6" stroke by 4½" bore. The speed of the engine is controlled by a **governor** (Fig. 20), which is a centrifugal ball-type, operating through levers to the carburetor throttle (T). The governor is used to maintain a uniform speed and to prevent the engine from "racing" if the load is suddenly released, or from "stalling," if the load is suddenly applied. **Speed of the engine** is usually 950 r. p. m., which is usually maintained for long periods of time while working. The **speed of a tractor** is very slow, the average being about 2½ or 3 miles per hour on high speed.

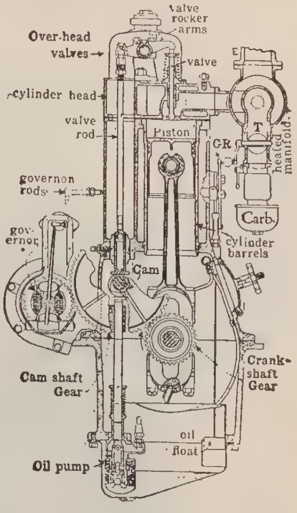

Fig. 20

Ignition is usually provided by means of a high-tension magneto, in connection with an "impulse-starter," which is used to facilitate starting when cranking the engine.

Carburetion is secured by means of gasoline to start with and kerosene to run on after the engine is heated up. The heating of fuel around the intake manifold from exhaust gases is very important when using kerosene.

Cylinder sleeves, or barrels, are used on many tractor engines. They consist of removable sleeves or barrels (Fig. 20) placed in cylinder blocks, which, in case of wear or accident, can easily be replaced with new ones. See also, Index, under "Cylinder sleeves."

The reader can now compare the relative difference between the four engines and thus note, that while the construction may vary, the same underlying principles apply to each.

TWO EXAMPLES OF AUTOMOBILE ENGINES

An example of an engine with valves-on-the-side operated by one cam shaft on the side is the Overland "4," as shown in Fig. 21.

An example of an engine with valves-in-the-head operated by one cam shaft on the side is to be seen in Fig. 22, showing a cross-sectional front view of the Nash model 681, 1919, six-cylinder engine.

The clutch and transmission (not shown) are mounted with the engine as a single-unit power plant.

Specifications of the Nash engine (Fig. 22) are as follows:

Engine: 6-cylinder, in-block, high-speed, valve-in-head type, operated by push rods on the side.

Cylinder bore, 3¼", stroke, 5".

Main bearings are die-cast babbitt, brass backed; three in number; diameter and length: front, 2¼" x 2¾"; center, 2¼" x 2¾"; rear, 2¼" x 2¼".

Crank shaft, forging steel, double-heat treated, 2¼" diameter.

Lubrication, gear pump, driven by spiral gears from cam shaft. Circulating splash system and force feed to main bearings, oil fed to oil pans, in which the lower ends of the connecting rods dip. On later models of this engine a "force"-lubrication system is used.

Valve adjustment: The clearance for valve adjustment is made between the valve stem and its point of contact with the rocker arm. The clearance is adjusted to .015". Loosen the push-rod lock nut and move the ball-adjusting nut either up or down until the correct clearance is obtained.

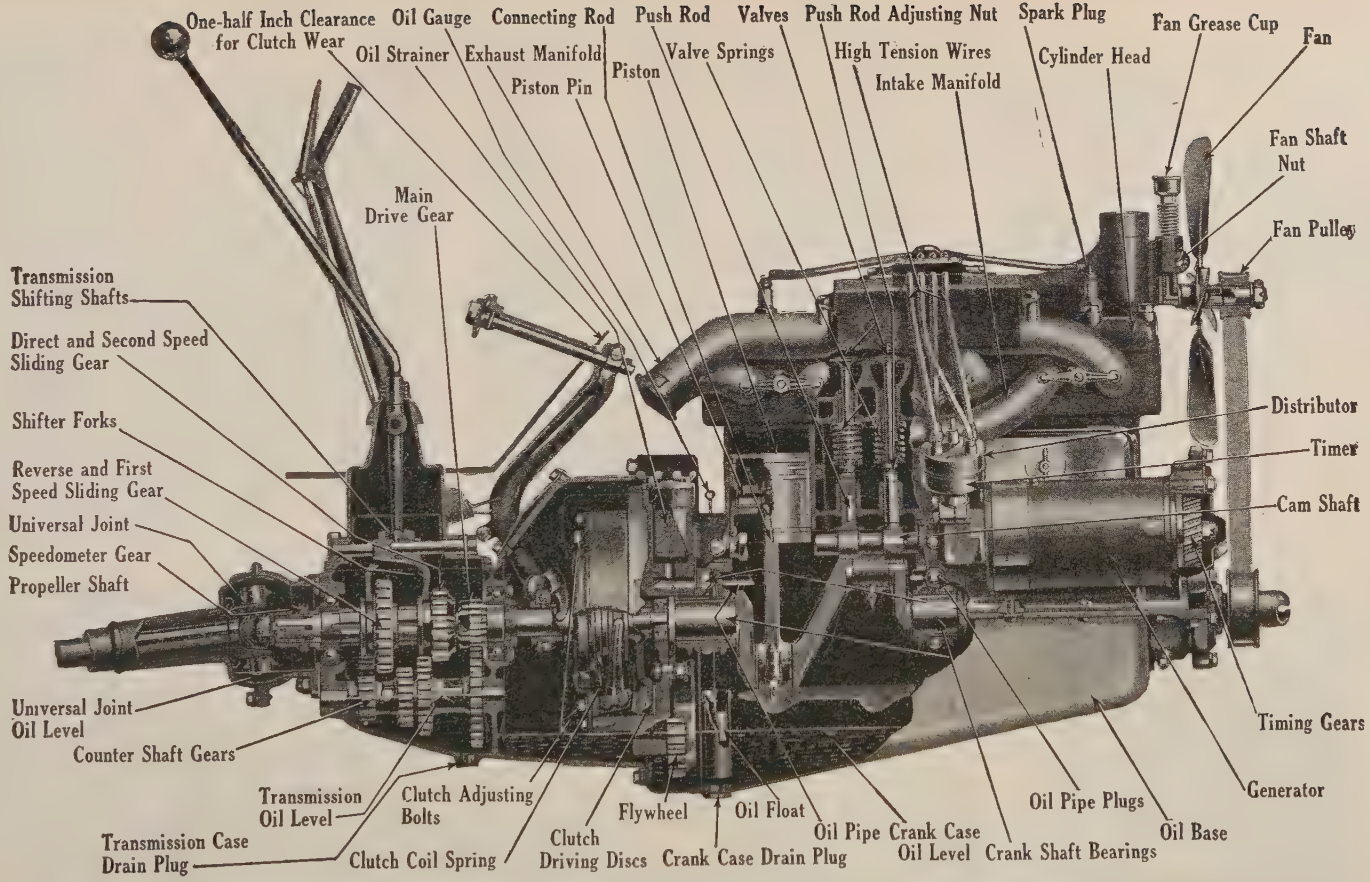

Fig. 21. Example of an Engine with Valves on the Side Operated by One Cam Shaft on the Side. Cross-section of engine, clutch, transmission and universal joint, or the unit power plant of the "Overland 4" L-type mono-block engine, with valves on the side.

Specifications

Engine: 4 cyl. 3 3/8″ bore x 4″ stroke; S. A. E. h.p. 18, actual 27; three bearings; lubrication, splash, and centrifugal force; oil thrown from periphery of fly wheel which feeds under this pressure to crank shaft bearings; monobloc (meaning all four cylinders cast in one block); L-type cylinders with separate head; helical timing gears; unit power plant.

Valves on the side: size 1 9/16″ di. head; 3/8″ di. stem; 1 3/8″ di. in clear; 45° seat; 7/32″ lift; cast-iron head welded to steel stem. Rings: 3, and are 3 3/8″ di. x 3/16″ wide.

Valve timing (measurements on flywheel): Inlet opens 31/32″ past upper d.c.; inlet closes 2 53/64″ past lower d.c.; exhaust opens 3 41/64″ before bottom and closes 13/16″ past top d.c. This is the distance laid out on the periphery of the flywheel.

Valve timing by degrees: Inlet opens 12° past upper d.c.; inlet closes 35° past lower d.c.; exhaust opens 45° before bottom d.c.; exhaust closes 10° past top d.c. (measurements on flywheel).

Valve timing by piston travel: This measurement means the distance the piston travels from its highest or lowest position. Inlet opens 1/16″ past upper d.c.; inlet closes 9/32″ past lower d.c.; exhaust opens 29/64″ before bottom d.c.; exhaust closes 1/64″ past top d.c.

Cooling: Thermo-syphon. Capacity of radiator 3 3/4 gal.

Carburetor: Tillotson 3/4″ special. See discussion of "Carburetion."

Electric system: see Index on "Overland 4" electric system.

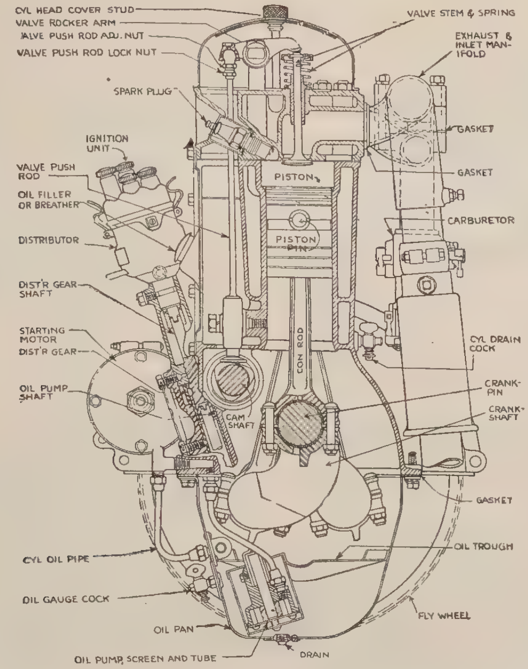

Fig. 22. Sectional end-view of the Nash automobile engine with valves-in-the-head. Specifications are given on page 39.

ENGINE PARTS

Crank Case

The difference, or variation in construction of the various parts of an engine will now be taken up.

The adjustments and repairs of the various parts are treated farther on in the "Repair Section" of the book.

The cylinder is attached at its open end to the crank case, which forms a box around the crank shaft.

The crank case is of irregular shape, so that while there is plenty of room for the cranks and connecting rods to operate, there is little waste space. It contains the crank-shaft bearings, and forms the bed-plate, or foundation, for the engine.

It is often made in two parts: an upper part bolted to the cylinder and containing the crank-shaft bearings, and a lower part enclosing the crank shaft, and which is called the "oil pan."

As the lower crank-shaft case is intended to contain lubricating oil, it is tight so that there may be no leakage. Usually the lower part of the crank case can be removed for adjustment of bearings.

The crank case is usually made of aluminum alloy, or, if in two pieces, the upper may be made of iron, and the lower of aluminum and sometimes of cast iron.

The crank case is used to support the cylinders and the various parts of the mechanism, such as the pump, magneto, etc.

The S. A. E. designates two types of crank cases: the "split type," where the lower part is separate and contains no bearings. The lower part is then called the "oil pan." The "barrel type" is when the lower part is permanently attached and has a hand-hole plate for reaching the bearings, and the crank shaft is removed from the end of the crank case with the removal of the crank-case head.

The arms for supporting the crank case on the chassis are sometimes made short to bolt to a sub-frame, while other manufacturers make longer arms to extend and bolt to the main frame.

A "three-point suspension" is where the power plant is suspended in the frame at three points of contact. **"Four-point suspension"** is where the power plant is suspended at four points.

A "unit power plant" is where the engine clutch and transmission are in one unit, as in Fig. 21.

Engine Bearings

The engine crank-shaft bearings are known as "main bearings." Most of the manufacturers make four-cylinder engines with three main bearings for the crank shaft. Some are made with five bearings, but these are usually very large engines. On six-cylinder crank shafts there are as many as seven main bearings, the majority of smaller engines using three.

The Marmon "34" uses four main bearings; Pierce-Arrow uses seven bearings on the six-cylinder passenger-car engine and three on the four-cylinder truck engine; Hudson model "O" uses four; Packard "six" has seven and Packard "twelve" ("twin-six") three; and Locomobile "five." If the six cylinders are cast "single," which is unusual, usually five bearings, two ends and three inside, are used. If the cylinders are cast in "pairs," there are usually five bearings, two ends and three inside. If the cylinders are cast "in-block," small six-cylinder engines use three bearings and large engines, four or five. If ball bearings are used, there are usually two bearings.

Crank-shaft main bearings are usually in two parts: the upper and lower halves (Fig. 24). Both parts constitute the bearing.

The upper half is supported by the upper part of the crank case, and the lower half in a bearing cap.

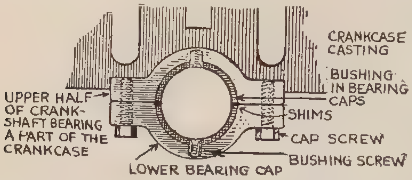

Fig. 24. Construction of a crank-shaft main bearing.

The bearing cap is fastened to the upper half of the bearing with cap screws.

On some engines, babbitt metal is cast into the bearing halves, and then dressed down, scraped and run-in.

On others, the upper half is cast and the lower half is in the form of a bushing which can be renewed when worn, by screwing a new bushing in place in the lower bearing cap.

Most of the wear is on the lower half of the bearing, because it supports the weight of the crank shaft and receives the thrust of the power impulses. Therefore it can be taken up by removing the lower bearing cap and the "shims," which are usually placed between the two halves, or by dressing the sides of the lower cap down to a proper fit, thus drawing the cap tighter around the shaft. After a long period of time and after the lower half has been taken up two or three times, the upper half will have to be cast again. On some engines the upper and lower half can be fitted with bushings, which are detachable and are held in place with a countersunk screw. Thus new bushings can be replaced and run-in.

A bearing bushing is that part of a plain bearing that the shaft comes in contact with. They are usually made of babbitt, phosphor bronze, or white metal. The phosphor bronze is very hard and lasts a long time, but is somewhat liable to "seize," if run without oil.

A white metal bushing consists of a layer of white metal, run (when in a molten state) into a channel in the bearing. It then hardens and is scraped and polished. White metal has the virtue of not seizing or doing much damage if ill treated, but if it is run for a long time a knock will result. There are many different alloys used for bushings, some being faced with brass. Bushings can be purchased ready for application. **If a bushing is burned or cut** from lack of oil, it can be scraped and "spotted up" to a fit, if the cut is not too deep, or a new bushing may be put in place and burned and run-in. These subjects will be treated farther on under the subject of "Repairs."

All ordinary wear in engine bearings can be taken up by removing shims and drawing to a tighter fit, termed "taking-up-on-the-bearings." The rear main bearing is usually the bearing which wears first, because it supports the weight of the fly wheel.

Connecting-Rod Bearings

Probably the **first bearings to require renewal** are those of the connecting rod.

The big end of the **connecting rod** is attached to the crank pin, and a bushing of bronze or white metal or other metal (with a melting point lower than that of cast iron) in the form of a shell, surrounding the crank pin, is secured in it.

The bushing is split lengthways into two halves, like the bearing of the crank shaft, one part being set in the connecting rod and the other being held in place by the **connecting rod cap.**

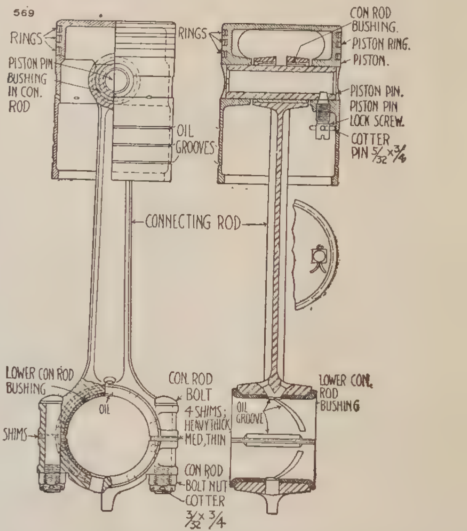

Fig. 25. A connecting rod showing piston-pin bushing and crank-pin bearing and cap. The bearing is in the small end of connecting rod for the piston pin. The piston pin is stationary.

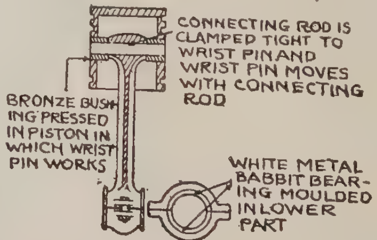
The small or upper end of the connecting rod contains a solid bronze bushing (Fig. 25) that forms the **wrist or piston pin bearing.**

Because of the small space in the piston, it is not possible to have this bushing split and held in place by a cap. The bushing is therefore set in the connecting rod, and the piston pin pushed through it. The wear of the piston-pin bushing is slight, and if it should wear loose, a new bronze bushing is driven into the connecting rod.

The **piston pin** is passed through the piston, and secured so that it cannot move. It is usually case hardened. This type is termed a "stationary piston pin."



CONNECTING ROD IS CLAMPED TIGHT TO WRIST PIN AND WRIST PIN MOVES WITH CONNECTING ROD
BRONZE BUSHING PRESSED IN PISTON IN WHICH WRIST PIN WORKS
WHITE METAL BABBIT BEARING MOULDED IN LOWER PART

Fig. 26. Note that in this type (Ford) the piston pin moves with the upper end of the connecting rod, and the bearings are in the piston bosses.

On the Ford (Fig. 26), the piston pin moves with the motion of the connecting rod, the small end of the connecting rod being clamped to it. The piston pin moves in bronze bushings fitted in the piston. This type is termed an "oscillating-type piston pin."

Through the connecting rod the piston transmits the pressure of the explosions to the crank shaft and fly wheel. In order that it may withstand the heavy shocks of the explosions, the connecting rod must have great strength. It is made of drop-forged carbon steel, heat treated, and, in rare instances, is of bronze. A straight I-beam type is used almost universally.

Bronze is used extensively on large, slow-speed engines, but would be too heavy for automobile work, as the high-speed engine requires light-weight reciprocating parts. Each connecting rod should weigh the same.

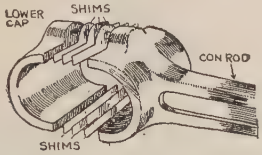


Fig. 27. Connecting-rod bearing end with cap removed to show shims.

Most connecting rods and main bearings are fitted with "shims" as in Fig. 27. When the bearing wears, a shim can be removed, thus drawing the lower cap tighter around the shaft. Shims are made of thin layers of metal .001″ to .005″ thick. The thinnest shim is usually placed at the bottom. Sometimes shims are made of paper.

Shims are used on the lower end of nearly all connecting rods, except in those engines using oil pressure in a hollow crank shaft which is cross-drilled to supply oil to the connecting-rod bearing. If shims were used with this type, they would allow oil to escape so rapidly that the oil gauge would show little or no pressure. The lower half of the connecting-rod bearing face is lapped off until an amount of metal representing the thickness of a shim has been removed.

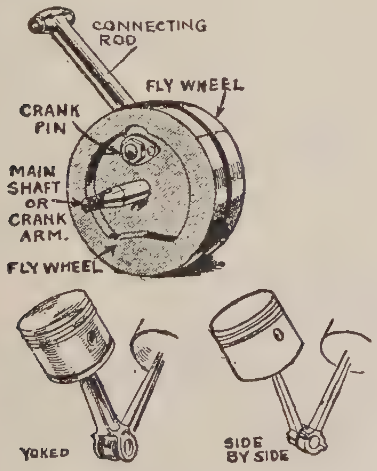

Fig. 28. Upper illustration shows a connecting rod, a crank pin, and a crank arm on a single-cylinder motorcycle or cycle-car engine. Note that a crank pin is between the two fly wheels which are placed in the crank case. The lower illustrations explain two methods of connecting two connecting rods to one crank pin on a "V"-type engine.

The connecting rod on a crank shaft of a "V"-type engine can be placed either "yoked" or "side by side," as shown in Fig. 28. When they are yoked, the cylinders would be "in line"; if side by side the cylinders would be "staggered," or slightly out of line.

The Piston

The piston of a gasoline engine is called a "trunk piston," to distinguish it from the "disk piston" of a steam engine.

A trunk piston is longer than its diameter, and is hollow, with one closed end. The closed end is toward the combustion space, and it is against the closed end that the force of the explosion acts.

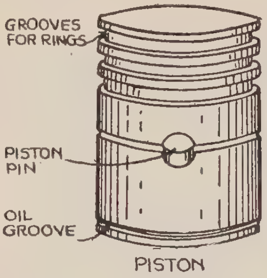

Fig. 29

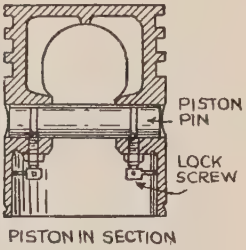

Fig. 30

Fig. 29. A trunk type of piston.

Fig. 30. Sectional view of piston. Note piston pin is stationary.

The piston pin passes through the piston, usually about the middle or a little nearer the top (depending on the stroke).

The open end of the piston permits the connecting rod to swing from side to side.

The piston does not fit the cylinder tightly, for a tight fit would cause friction and wear. This space is called **piston clearance** (see Index). The piston is usually slightly smaller at the top than at the bottom, because the heat is more intense at the top and expansion must be allowed for.

A piston is usually measured at the skirt, or below the piston pin. Pistons are made of cast iron, and when heated they expand. The usual clearance between the cast-iron piston and cylinder wall is about .001″ to each inch of piston diameter.

Meaning of "piston clearance": Let us take, as an example, a Continental Model N engine which is 3¾″ bore. In decimals, therefore, its bore would be 3.750 (three inches and seven hundred and fifty thousandths of an inch).

Suppose the clearance of the piston was .003 (three thousandths of an inch), which would mean the piston diameter should be .003 less than the bore, then 3.750 (the bore) minus .003 (the clearance) would equal 3.747 (three inches and seven hundred and forty-seven thousandths), which would represent the diameter of the piston for a clearance of .003 for this engine.

Pistons are usually marked on top and in decimals. The diameter is that of the skirt. The **bore of a cylinder** is usually stamped on the lower machined face of the cylinder block.

Aluminum alloy pistons are used to a certain extent instead of cast iron.

Advantage: They are about one-third lighter; thus the inertia of the reciprocating piston is reduced considerably, and consequently the side-pressure or thrust on the walls of the cylinders is lessened. The great heat conductivity of aluminum alloy lessens the carbon deposit on the piston head and the deposit is more easily removed. In case of extreme heat, if the piston should "seize," the cylinder is not damaged by aluminum because it is softer than the cylinder.

Disadvantage: Aluminum alloy pistons expand twice as much as cast iron, and therefore when the engine is cold the clearance between the piston and cylinder wall being twice as great as normally, raw gasoline is drawn into the cylinder which passes down to the crank case and thins the lubricating oil and washes off all of the lubrication on the cylinder walls. A "piston-slap" is also produced, due to the great clearance, until the pistons are heated up, at which time they expand and the piston-slap noise should cease.

On one model of the Franklin, the shallow, square groove of screw-thread form was turned at the bottom of the skirt of the piston just beneath the lower ring. This held oil and permitted a smaller clearance.

Pistons and connecting rods for high-speed work should be made very light. In some instances, where cast iron is used, the piston is made lighter by making the skirts thinner and the piston pin-boss lighter. On some high-speed engines the piston skirt is sometimes drilled with large holes for the sake of lightness.

Piston Rings

The pressure from the explosion is prevented from escaping between the piston and the cylinder wall by **piston rings.**

The piston rings fit in the groove around the upper end of the piston, and there may be from two to five of them, usually three. The rings fit the groove snugly, but not so tight that they may not move freely.

They are cut crossways, so that they may be sprung open. When closed, so that ends touch, the rings are a trifle smaller than the diameter of the cylinder.

When sprung open, they are larger than the diameter, or bore of the cylinder. They are so made that they always stand a little open.

The rings are slipped into the grooves by springing them open, and sliding them over the piston.

When a piston is to be placed in a cylinder, the rings are drawn together, so that they will slide in easily. The piston with its rings fits the cylinder snugly, and the elasticity of the rings keeps them pressed against the cylinder wall, making a fit that keeps the pressure from escaping.

Since none of the pressure of the explosion is able to escape, it is all exerted against the closed end of the piston, or **piston head.**

The rings must be placed on the piston so that the ends are not one over the other, for if they were in line the pressure might escape through them (see Fig. 31).

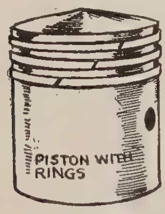

Fig. 31

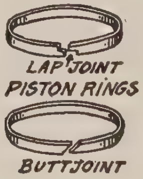

Fig. 32

Fig. 31. In order to prevent compression passing through the joints of rings they are placed as illustrated.

Fig. 32. Two standard types of piston-ring joints.

The rings are prevented from moving around the piston by **pins** placed between the ends (although this is not the case on all pistons). The only motion they have is the spring in and out.

The ends of the rings are beveled, or made with a joint (as in Fig. 32), so that the gas will not leak through the joint. Two of the usual types of piston rings are shown in Fig. 32. Piston rings are made of cast iron of a slightly softer grade than the cylinder.

There are many improved types of piston rings which the manufacturers claim will not leak; usually three rings are placed on a piston. Two rings are often used for high-speed work, whereas, for average automobile engines, three rings are generally used. This subject is fully treated in the "Repair Section" of this book.

Piston rings are measured according to the bore of the cylinder and the width of the ring groove.

The Crank Shaft

The crank-shaft-throw changes the reciprocating motion of the piston to the rotary motion necessary to turn the wheels. It rests in bearings that hold it in a fixed position, but permit it to revolve.

The crank pin must be rigidly attached to the crank shaft, and to secure this rigidity, it is usually made in one piece, solid as in Fig. 33, and is usually made of chrome nickel steel.

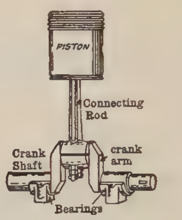

Fig. 33. A single-throw crank shaft. Crank is set at 360°.

The crank projects from the crank shaft, and when the shaft revolves, the crank makes circles around it. A crank is one of the most common mechanical devices. The crank pin is that part to which the connecting rod fits and is also called the "**throw**" of the crank. A windlass is turned with a crank; a bucket or chain pump is operated with a crank; the pedals of a bicycle form cranks.

In a bicycle, the crank arms are attached at their inner end to the crank shaft, and to their outer ends the pedals are attached. When riding a bicycle, the feet press on the pedals at the ends of the crank arms, and make the crank shaft revolve. The feet describe circles around the crank shaft. Each crank arm and pedal form a crank, and there is only one arm to a crank.

In a gasoline engine, two arms are necessary, for the reason that the cranks are not at the ends of the shaft. There are therefore **two arms** to each crank or "throw." (Fig. 33.)

The outer ends of the crank arms are connected by the **crank pin.** The crank pin corresponds to the pedal of a bicycle. A gasoline engine has as many cranks as it has cylinders.

Degrees as Used with a Crank Shaft

The position of a crank on a crank shaft in relation to other cranks on the same shaft is expressed in degrees of a circle.

A degree is designated with a small ° at the right of the figure. For instance, a crank shaft with throws of 360 degrees, would be designated as 360°. See Index, explaining the meaning of "degree."

If the cranks project from the same side of the shaft, as in Fig. 33, so that the crank pins are in line, it is called a 360-degree (360°) crank shaft.

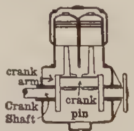

Fig. 34. A two-cylinder vertical engine with a 360-degree crank shaft; both connecting rods on one crank pin.

When the two crank pins on a crank shaft project in the same direction, as in Fig. 34, both connecting rods drive as one crank. This type of engine, however, is not used on account of its vibration. An engine with a crank shaft as shown in Fig. 36 would be more balanced. See Index under "Firing order" of cylinders.

If a crank shaft has two crank arms projecting in opposite directions, as in Figs. 35, 36, and 38, it is called a 180-degree (180°) crank shaft.

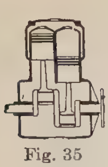

Fig. 35

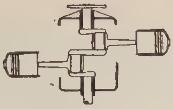

Fig. 36

Fig. 35. A two-throw crank shaft for a two-cylinder vertical engine; crank set 180 degrees.

Fig. 36. A two-cylinder opposed type of engine with crank shaft set 180 degrees. Cylinders are also 180 degrees apart.

The engine in Fig. 36 is **a two-cylinder opposed type of engine.** It was formerly used to a great extent on small cars, and is still used on trucks and tractors for heavy work. The cylinders are placed 180 degrees apart. The crank shaft is also 180 degrees.

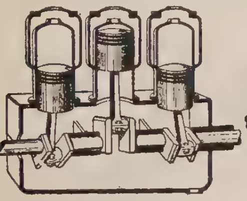

Fig. 37

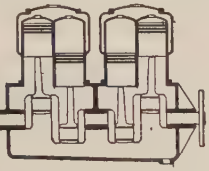

Fig. 38

Fig. 37. A three-cylinder ~~vertical~~ type of engine with cranks set at 120 degrees. Note No. 2 piston is up. No. 3 (right) would be 120 degrees or one-third of a revolution; No. 1 would be 120 degrees, or one-third revolution from No. 3, or two-thirds from No. 2.

Fig. 38. A four-cylinder vertical engine with crank shaft set 180 degrees. Note piston No. 1 and 4, and 2 and 3 are always in line.

The four-cylinder engine (Fig. 38) employs a 180-degree crank shaft. Note the "throws," or crank pins, of the crank shaft on cylinders 1 and 2 are 180 degrees apart and on 3 and 4 are 180 degrees apart. Therefore, pistons on cylinders 1 and 4 always move up or down together, and 2 and 3 move up or down together. In other words, these crank throws are in line.

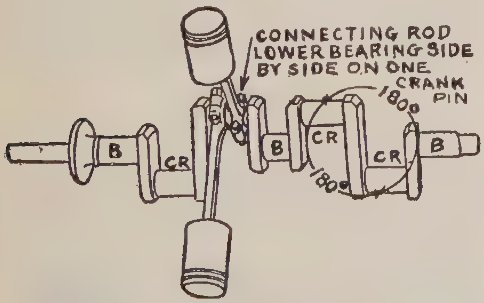

Fig. 39. A regular four-cylinder type, 180° crank shaft is used on the eight-cylinder "V" type of engine. Two connecting rods are placed on one crank pin, either side by side, or yoked (see Fig. 28).

The eight-cylinder "V"-type engine would in reality be nothing more than two four-cylinder engines with cylinders set "V" shape, the angle of the cylinders usually being 90 degrees, or one-half of the 180 degrees of the crank shaft. The same four-cylinder 180-degree crank shaft is employed. There are **two connecting rods to** each throw of the crank, which can be placed "side by side" (Fig. 39), or "yoked."

When connecting rods are placed side by side, as shown in Fig. 39, it is necessary to "stagger" the cylinders by setting them out of line with each other. If "yoked," the cylinders would be in line.

A three-cylinder engine must have a crank shaft with the three crank pins placed in three positions, or one-third of a revolution apart; this would be placing them 120 degrees apart (see Fig. 37).

A six-cylinder engine would have a crank shaft with six crank pins or crank "throws" placed in thirds, or 120 degrees apart. There would be three pairs in line (see Fig. 40).

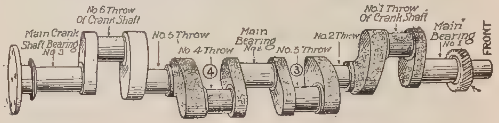

Fig. 40. A solid crank shaft, with three main bearings; six cylinder.

A twelve or twin-six-cylinder "V"-type engine would use the same type of six-cylinder crank shaft, but with two connecting rods to each crank pin. The cylinders would be placed 60 degrees apart, or one-half of the 120-degree crank shaft.

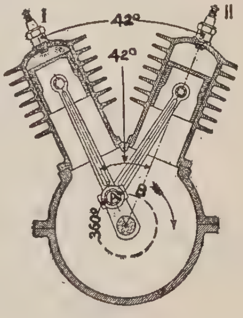

Fig. 41. A two-cylinder twin type of engine used on motorcycles and light cars. Note the 360-degree crank. Cylinders are at a 42° angle.

The twin-cylinder "V" type of engine used on a cycle car and motorcycle would use a 360-degree crank or one crank pin, with connecting rods "yoked." Cylinders on this type of engine are usually placed at an angle of from 42 to 45 degrees apart.

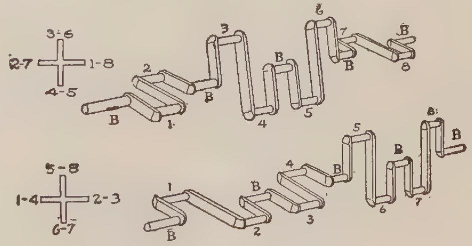

Fig. 42 (lower); Fig. 43 (upper).

Two methods of placing the crank throws on a "straight-eight" cylinder engine, where the eight cylinders are all in line are shown in Figs. 42 and 43. (B) are bearings and (1) to (8) are the crank pins.

The Duesenberg arrangement where two four-cylinder crank shafts are placed end to end, one of them being given a twist so that its "throws" are 90 degrees to the throws of the other is shown in Fig. 42. This crank shaft is made from a solid piece of steel. Counterweights not shown in the illustration are integral with the shaft. Fig. 43 shows another arrangement, which would give a different firing order. The advantage claimed in using the "straight eight" is a better balance than any other eight-cylinder engine of the "V" type.

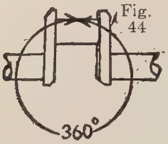

Fig. 44

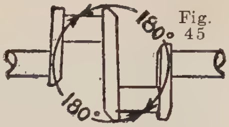

Fig. 45

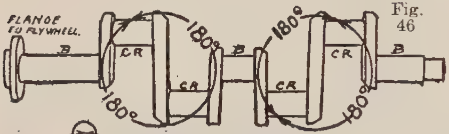

Fig. 46

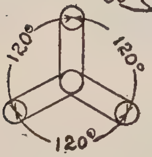

Fig. 47

Figs. 44–47. In the illustrations above, the idea is to explain the term "degree" used in connection with crank shafts. Any perfect circle is 360°. If the circle is divided into quarters, each quarter would be 90°; half of the circle 180°; a third 120°.

Fig. 44. Note one crank pin—hence 360° crank.

Fig. 45. From center of one crank pin to center of another is half a circle, or 180°.

Fig. 46. Here we have two pairs of crank pins as shown in Fig. 45. Each pair of crank pins is placed 180° to each other.

Fig. 47. End view of a three or six-cylinder crank shaft. Note that crank arms are one-third apart, or 120°.

Construction of Crank Shafts

There are two kinds of crank shafts, one known as the **"solid crank shaft"** and the other as the **"built-up crank shaft."**

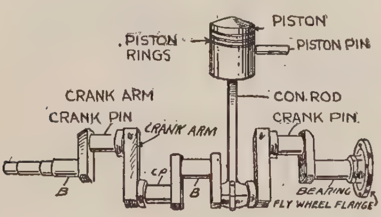

Fig. 48. A solid type of crank shaft—three-bearing type, four-cylinder.

The solid crank shaft is by far the most commonly used. It is made from one piece of steel, which is forged to shape and then turned up in a lathe, the workmanship in many cases being accurate to a ten-thousandth part of an inch.

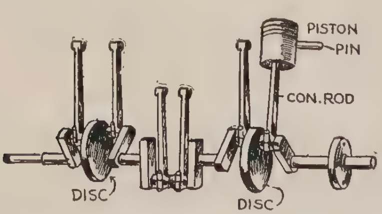

Fig. 49. A built-up type of crank shaft (seldom used). The above is a six-cylinder crank, with four bearings. Note that it is built-up to disks.

The built-up crank shaft (Fig. 49) has each of its parts made separately and then fixed strongly together, and quite often fitted with ball bearings. Ball bearings can be fitted only to a built-up type if there are more than two bearings.

An advantage of the built-up crank is that the crank-shaft bearings could be fitted with ball bearings, as shown in Fig. 50. However, built-up shafts of this kind are not usual, and in the case of powerful engines, only the strongest solid crank shafts are ever used.

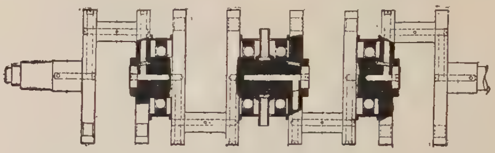

Fig. 50. A ball-bearing, built-up type of crank shaft with three bearings for a four-cylinder racing engine. With three or more bearings it is necessary to have a built-up crank shaft in order to mount the ball bearings. On the **Autocar truck** engine there are two ball bearings placed on the outer bearing ends of the crank shaft. Thus a solid ball-bearing crank shaft can be used. See Index under "Autocar truck engine"; and under "White ¾-ton truck."

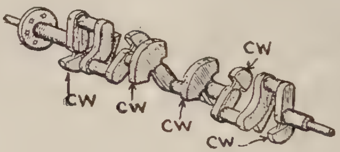

Fig. 51. Counterbalance weights applied to a six-cylinder crank shaft.

The counterbalanced crank shaft (Fig. 51), with counterweights (CW) electrically welded to the crank shaft and an integral part of the crank shaft, as illustrated, is becoming popular. It permits high speeds to be obtained without detrimental vibration, and relieves the tendency to "whipping" of the crank shaft and "slapping" of the pistons at high speeds.

Whipping of crank shaft is more pronounced where there are very long weak crank shafts with great distance between bearings. Vibration of an engine can also be due to forces being out of balance or unequal; for instance, engine loose on frame; uneven compression; weak explosion in one or more cylinders due to leaky rings or valves, or too much oil in that particular cylinder; defective spark or plug; sprung crank shaft; clutch out of balance; new full-size bearing and shims on one crank throw, and the old worn or lighter bearing with shims or liners removed on the other crank throw; different weight pistons; front wheels out of true, rim out of plane with spokes.

Cylinders

The cylinder of a gasoline engine is made of cast iron or twenty per cent semi-steel, and the water jackets are generally cast in one piece with it. The cylinder of a gasoline engine is cast with **water jackets** surrounding it and in one piece (Fig. 52).

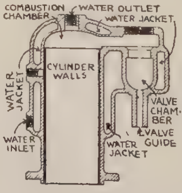

Fig. 52

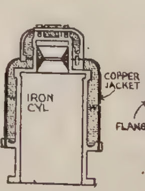

Fig. 53

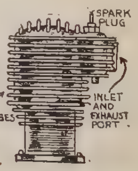

Fig. 54

Fig. 52. A single cylinder with water jacket cast around it.

Fig. 53. A single cylinder with a copper water jacket placed around it. An obsolete design.

Fig. 54. Air-cooled, flanged type cylinder.

On some of the early-model engines, such as the Pope Toledo and the 1914 Cadillac, the water jacket was formed by surrounding the upper part of the cylinder with sheet copper as in Fig. 53. This method is now obsolete.

The portion of the cylinder in which the piston moves should be a true circle, and as smooth as possible. In the better grade of cars the **cylinder walls** are ground to a smooth finish so that there may be as little friction as possible. Any roughness of the walls will cause wear, which comes in the form of cuts and scratches lengthways, and permit the pressure to escape around the piston.

Cylinder heads may be cast **solid** or with **detachable head** (see Fig. 62). The detachable head is very popular, especially where cylinders are cast "in-block." It permits easy access to the valves, and for removing carbon and removing pistons, and is also good manufacturing practice because it makes the grinding of cylinders easier. Where cylinders, on a **multiple-cylinder engine,** are cast singly or in pairs, the heads are usually solid and the entire cylinder is removed from the crank case when work is to be done inside.

Cylinders for **gasoline engines** are made in several **different shapes** and are usually made of cast iron. Some of the **airplane engines** have cylinders made of steel, and some of the engines used on trucks and tractors have **inner sleeves** which are removed and replaced with new sleeves when worn. The Marmon "34" passenger car automobile engine uses cylinder sleeves. See Index under "Cylinder sleeves." The type used most for automobile work is the **cast-iron cylinder** with a water jacket cast around it.

Cylinder Designs

The "T"-head type of cylinder is made so that the exhaust valves are on one side and the inlet valves are on the other side. Note the "T" shape in Fig. 55.

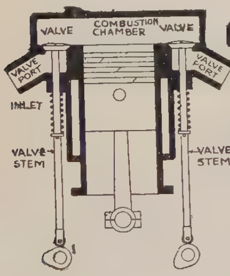

Fig. 55

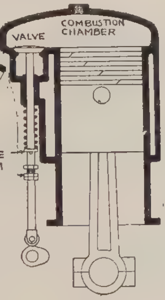

Fig. 56

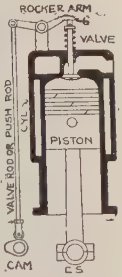

Fig. 57

The "L"-head type of cylinder is made so that the exhaust and inlet valves are all on one side of the cylinder. Note the "L" shape in Fig. 56 (if turned up-side-down).

The "I"-head type of cylinder is made so that the valves are placed in the top of the head of the cylinder (Fig. 57), and is termed the "valve-in-the-head" type.

The "F"-head type of cylinder is made so that one valve is in the head, usually the inlet, and the exhaust is on the side.

How Cylinders Are Cast

When an engine has **more than one cylinder,** the cylinders can be cast singly, in pairs, or in-block, and can be of either the "T," "L," round or "I"-head type. Sometimes multiple cylinder engines have all cylinders cast singly. They can be of the "T," "L," or "I"-head type.

Cylinders cast singly, as applied to a four-cylinder engine, are shown in Fig. 58.

The term **Cylinders cast** in-block means that the multiple cylinders are all cast in one piece. They can also be of the "T" or "L"-head construction.

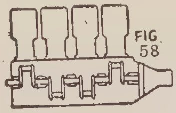

FIG. 58

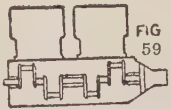

FIG 59

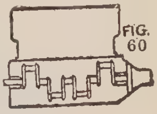

FIG. 60

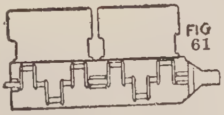

FIG 61

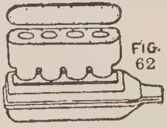

FIG. 62

Note in Fig. 60 that the cylinders are in-block and the **head is solid,** whereas in Fig. 62, the **head is detachable.** The term "mono-block" is also often used where all cylinders are cast in one block. **Cylinders cast in pairs** are shown in Fig. 59. The engine is a four-cylinder type. **Cylinders cast in triplets** are shown in Fig. 61. The engine is a six-cylinder. The cylinders could be cast in-block, or in pairs, triplets, or singly. The Locomobile six-cylinder engines have the cylinders cast in pairs and the majority of other six-cylinder engines have cylinders cast in-block.

Cylinders on the **six-cylinder engines** are usually of the "L"-type, except the Pierce-Arrow and Locomobile, which are "T"-type.

Cylinders on **eight-cylinder "V"-type engines** are usually cast "in-block" and are placed 90 degrees[1] apart, and on a twin-six-cylinder engine, 60 degrees[2] apart (see Fig. 63). On a **twin "V"-cycle car or motorcycle engine,** the cylinders are usually 42° to 45° apart.

CAM
GEAR
CRANK GEAR

Fig. 63. A "V"-type eight-cylinder engine. A 180-degree four-cylinder type of crank shaft is used with two connecting rods on one crank pin.

Cylinders on a **two-cylinder engine with cylinders placed opposite** are shown in Fig. 64. Note that the cylinders are placed 180 degrees apart and are in a horizontal position. This is termed an "opposed-cylinder" engine.

The offset cylinder with an offset crank shaft or offset cylinders, or with Des Axe crank shaft setting, as you choose to say, is represented in Fig. 66. The line **A**, which passes through the center of the cylinder, is some distance to one side of the line **B**, which passes through the center of the crank shaft. Some of the advantages claimed for the offset crank shaft are less liability of a back-kick, reduced wear on the bearing surface of the cylinder walls, connecting rods, and crank shaft, less liability of the engine to be stalled when the car is running slowly on a high gear, and other construction facilities. The cylinder **set central** over the crank shaft, as in Fig. 65, is the type in general use. See page 61; "Effect of offset cylinders."

---

[1] Lincoln and Wills-Saint Claire eight-cylinder "V"-type of engines have cylinders set 60° apart.

[2] On the Liberty, twelve-cylinder "V"-type of engine, the cylinders are set 45° instead of 60° apart.

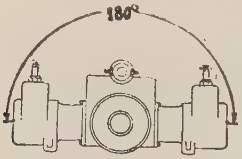

Fig. 64. Two-cylinder opposed type engines.

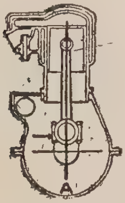

Fig. 65

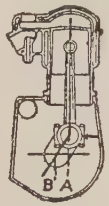

Fig. 66

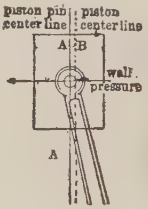

Fig. 67

An **offset piston** is shown in Fig. 67. Note that the piston center line is not in line with the wrist, or piston-pin center line. The reason for the offset of the piston is to compensate for the reaction of the side thrust of the piston during the power stroke. When the piston is part way down on its power stroke all of the power or pressure on the piston is transmitted to the connecting rod at an angle, which reacts against the piston wall in proportion to the angle at that moment, mounting to a maximum at 45 deg. The greater portion of this area is below the wrist pin, so by placing the largest area on the left side, the tendency is to tip the piston against the side-thrust pressure and thus give a better equalized pressure. The Buick engine has the piston slightly offset.

Meaning of Bore and Stroke

The stroke is the length or distance the piston travels up and down inside of cylinder. **The bore** of a cylinder is its inside diameter.

Square stroke. When the piston travel in a cylinder has the same length as the bore in diameter, it is called a square stroke and bore.

Long stroke. When the piston travel is much more than the bore diameter, then it is called a long stroke. For instance, an engine with a piston of 4″ diameter, with a stroke of 4″, is called "square-stroke" engine. The case of a cylinder whose bore is, say, 4″ and the stroke 5½″, would be called a "long stroke."

The valve chamber is that part surrounding the valve. The **valve port** is the opening for the intake or outlet of gas.

The combustion chamber is the inside upper portion of the cylinder, above piston, when the piston is at the top of its stroke.

Inlet and Exhaust Manifold

The **inlet manifold** is the part which connects to the inlet port openings in cylinders, from the carburetor. If there is only one connection to the cylinder, as on a single-cylinder engine, then it is called an **inlet pipe.**

When the valves are all placed on one side of the engine, as in the "L"-head type of cylinder, then the inlet and exhaust manifold are both on the same side of the cylinder.

When the inlet valves are on one side and the exhaust valves on the other side, as in a "T"-head cylinder, then the inlet manifold is generally on one side and the exhaust manifold on the other side.

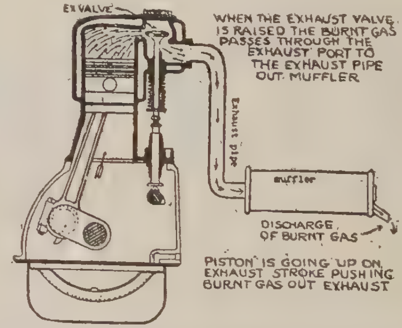
The **exhaust pipe** leads from the exhaust manifold to the muffler. If the engine is an eight or twelve "V"-type, there are usually two exhaust pipes and two mufflers. In order that the exhaust manifold may be cooled as rapidly as possible, the exhaust manifold and pipe, connecting the exhaust valve chamber to the muffler, are exposed to the air.

The **connection from exhaust manifold to exhaust pipe** is usually made with a flange connection, with asbestos packing between.

The muffler and exhaust pipe should be made so that there is as little **back pressure** as possible. Back pressure is caused by anything that prevents the free escape of the gas. Therefore sharp bends should be avoided, otherwise the incoming fresh mixture becomes mixed with that part of the burned gas left from the previous charge, and the power of the engine is cut down accordingly.

The Muffler—also Called "Silencer"

Purpose: If the exhaust valve opened directly into the open air, the noise of the combusted gases escaping through the exhaust port during the exhaust stroke would sound like the firing of a gun.



EX VALVE
WHEN THE EXHAUST VALVE IS RAISED THE BURNT GAS PASSES THROUGH THE EXHAUST PORT TO THE EXHAUST PIPE OUT MUFFLER

muffler
DISCHARGE OF BURNT GAS
PISTON IS GOING UP ON EXHAUST STROKE PUSHING BURNT GAS OUT EXHAUST

Fig. 68. Illustrating how the exhaust gases pass from the cylinder, through the open exhaust valve, to the muffler.

This noise is due to the pressure in the cylinder being much higher than the pressure of the air, and a sudden change from one to the other produces a loud report. The more sudden the change and the greater the difference in the pressure, the sharper will be the noise. For instance, the noise would be greater if climbing a hill with an open throttle, than if running on a level with a partially closed throttle.

To silence the noise, a muffler is connected to the end of the exhaust pipe, which is connected to the exhaust manifold (Fig. 68). The exhaust manifold is connected to the exhaust valve ports.

Construction: The muffler is usually made of iron pipe, like a stove pipe, with cast-iron heads, as in Fig. 69. The exhaust gases (when the exhaust valves are opened) pass through the exhaust pipe into the chamber (C), as shown by the arrow marks; then through openings in rear of (C), passing into chamber (B), then through openings in front of (B), into (A), then through (A) to the open air.

If the muffler is not designed properly and is too small, or if it becomes clogged with soot, then the burned gases cannot be expelled as rapidly as they should be. The result is **back-pressure,** or a tendency for the gases to work back against the outcoming exhaust, and also a retention of heat, thus causing overheating of engine and a slight loss of power, due to the back-pressure.

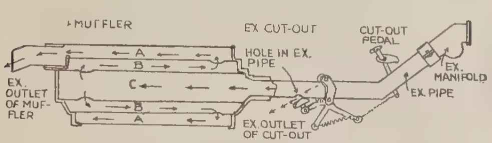

Fig. 69. Sectional view of a muffler also showing how a "cut-out" is placed on the exhaust pipe.

The Exhaust Cut-Out

The exhaust cut-out is a device which can be placed on the exhaust pipe, between the engine and muffler (Fig. 69). It is arranged so that it can be opened by a foot pedal, thus permitting the exhaust gases to pass into the open air instead of the muffler.

The cut-out is now seldom used, except on speed cars or for hill climbing, because of the noise, and also because of the fact that mufflers are now designed so that there is only a slight back-pressure. The cut-out was used extensively during the early days, because engines were minus power and mufflers were not properly designed.

Inlet Manifold Construction

In the simplified illustrations below are shown different constructions, in order to give the reader an idea of the different methods which are and have been used.

With the **inlet manifold,** the design should be such that there may be as little resistance as possible to the flow of the mixture. This manifold should be as straight as the position of the carburetor will permit. There should be no sharp angle-bends, the bends being as flat and easy as possible and the distance from carburetor to inlet ports as short as possible to prevent condensation.

When more than one cylinder is supplied from one carburetor, the distance from the carburetor to each valve should be the same. The inside of the inlet manifold must be smooth and clear so that there is no obstruction offered to the flow of gas.

In those illustrations marked "incorrect," the distance from the carburetor to the inlet valves is not equal, and consequently the valves nearest the carburetor will get more of the mixture than those farther away.

In the arrangement marked "good form," the distances are almost equal, and consequently the valves get equal quantities of mixture, and the engine will run more evenly than if the cylinders received different amounts.

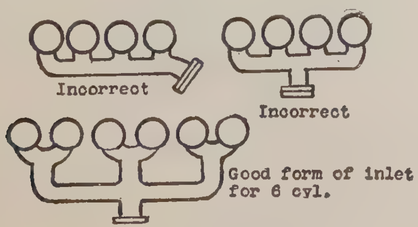

Fig. 70. Inlet manifolds.

Inlet manifolds are usually provided with **means for heating,** so that the gas mixture when passing through the manifold is vaporized. A hot-water jacketed manifold is shown in Fig. 71. The water connections are made with the circulating pump.

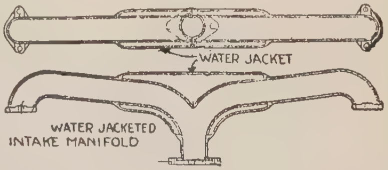

Fig. 71. Top and side view of a water-jacketed inlet manifold.

Most inlet manifolds are heated by a part of the exhaust gases passing through a jacket which surrounds part of the manifold.

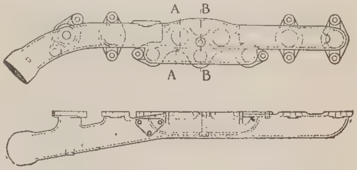

Fig. 72. Top and side view of an exhaust-heated intake manifold.

The "hot-spot" manifold is so arranged that the exhaust manifold surrounds part of the inlet manifold. Thus the exhaust gases pass over a portion of the inlet manifold which shortens the warming-up period with present-day fuel, and thus vaporizes the heavier particles of fuel more quickly. (See Fig. 72.)

This subject is also treated under the general subject, "Carburetion," in the discussion of "Heating the mixture."

Exhaust Manifold Construction

Sharp bends in the exhaust manifold or pipe cause back pressure, and should be avoided. Dirt in the pipe, or muffler, as well as soot in the muffler, has the same effect. In other words, the idea is to have the exhaust pipes offer the least resistance possible to the burned gases passing from the exhaust ports, otherwise part of the burned gases remain in the cylinder, mix with the fresh gases drawn in, and thus affect the mixture.

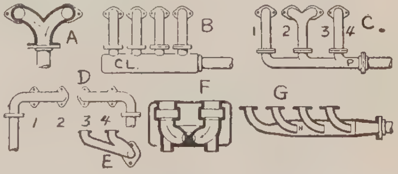

Fig. 73. Exhaust manifolds: A good method of exhaust outlet for a 2- or 4-cylinder vertical engine is shown in Fig. 73 at **A.**

B is a simple manifold in which an individual pipe from each cylinder exhausts directly into the large collector chamber **CL.** In this manifold the collector tube is made sufficiently large so that when the exhaust valve closes, the pressure in it is less than that in the cylinder at the valve, and thus there is no danger of back pressure.

C shows an arragement in which the pipes 2 and 3 for the middle chambers are formed in one, whereas they are separate for cylinders 1 and 4. This works satisfactorily in that cylinders 2 and 3 never fire consecutively, and the one pipe is capable of taking care of the exhaust of the two.

D is quite similar to the case shown in C, excepting that there are individual pipes for cylinders 1 and 2, and 3 and 4. This is bad construction, in that 4 fires immediately after 3, and 1 immediately after 2.

As the direction of the exhaust leaving the cylinders is the same, it is very easy to make a manifold in which the exhaust pipes, instead of having a tendency to obstruct one another, assist the other cylinders to exhaust.

In engines which have their inlet and exhaust valves opposite, frequently all four of the exhaust valves are connected through one manifold with a single orifice. F is one example of an arrangement where it is possible to make the two passages unite. This is suitable for engines with cylinders cast in pairs.

The defects of A and D can readily occur in this one; if makers were considering loss of power, they would not use this one, but they want only to save space.

For the best design, illustration G offers a reasonable solution. In this illustration there is an individual pipe from each cylinder to the large collector. At the end, each individual pipe projects into the collector tube and curves in the direction of the exit for this collector tube.

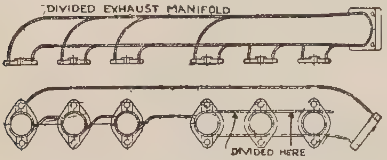

Fig. 74. Two views of a divided exhaust manifold.

The divided exhaust (Fig. 74) is used on several six-cylinder engines with cylinders cast in two blocks of three cylinders to a block. It is claimed for this design that it prevents overlapping and refilling of the cylinders with burned gases.

Valve Caps

Where valves are on the side and the head is cast integrally with the cylinders, **valve caps are screwed over the valves** in the cylinder. By removing these caps the valves can be lifted from their seat and ground. There are two valve caps to each cylinder; an **inlet-valve cap** and an **exhaust-valve cap.**

Compression or Relief Cocks, or Priming Cups

They consist of small **pet cocks** screwed into the exhaust valve caps. By opening them when the engine is running, it is possible to see if any of the cylinders are missing fire. A flame will shoot out if firing. They are also used for injecting gasoline when the engine is cold and hard to start. The S. A. E. now terms this a "priming cup."

Cams and Cam Shafts

A cam is a device that produces intermittent motion. When an object is in motion part of the time and at rest between motions, its action is said to be "intermittent." A cam may best be described as a wheel with a hump or nose on one side (Figs. 75 and 76); in other words, it is a piece of metal revolving with a shaft, part of its circumference being farther from the shaft than the rest. The part of the cam that projects is called the **nose.** Anything resting against the cam will be moved only when the nose comes around to it; otherwise it remains stationary.

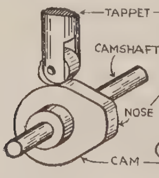

Fig. 75

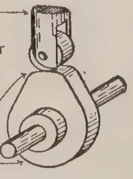

Fig. 76

Fig. 75. Showing the nose of cam.

Fig. 76. Nose of cam raising valve plunger or tappet, which raises valve.

For a four-cylinder engine, four cams on the inlet cam shaft are shown in Fig. 77. Four more cams on an exhaust cam shaft are provided on the opposite side of this engine, because it has "T"-head cylinders. The cams are divided in four positions on the cam shafts, and are made in one piece or integral with the cam shaft. If the cylinder is the "L"-type, then all cams would be on the one cam shaft (see Fig. 79).

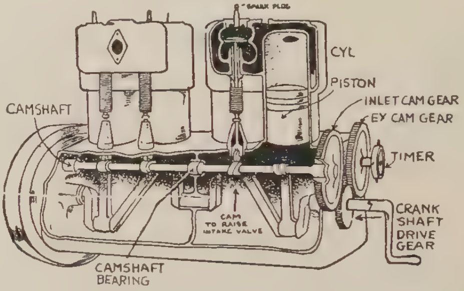

Fig. 77. Illustrating how the cam shaft on a four-cylinder engine is operated by timing gears; also how the nose of the cams raises the valves. There are two cam shafts placed opposite, therefore it is a "T"-head type.

For each cylinder there is one inlet cam and one exhaust cam. The **exhaust cam** usually has a **broader nose** because it must hold the valve open longer.

The **cam shaft,** also called the "secondary" or "half-time shaft," has a cog wheel or gear, called a "timing gear," on one end, which meshes with the **drive-shaft-gear** on the crank shaft. The cam shaft gear is also often driven by a **silent chain.**

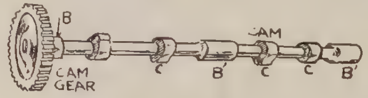

Fig. 78

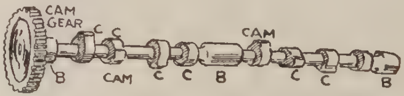

Fig. 79

Fig. 78. The cam shaft as used with a four-cylinder "T"-head type cylinder. There are two shafts, an intake cam shaft and an exhaust cam shaft—one on each side of the cylinder as shown in Fig. 80. There are four cams on each shaft. The noses of the cams are placed at different positions, so that the valves will be raised at a certain time. **C** are the cams. **B** are the bearings for the cam shaft.

Fig. 79. The cam shaft as used with a four-cylinder, "L"-head type of cylinder. There is but one cam shaft in this type because all of the inlet and all of the exhaust valves are on the "L"-side of the cylinder (see Fig. 81). There are eight cams on the cam shaft.

When the crank shaft revolves, the **drive gear on the crank shaft** drives the **timing gears,** which drive the cam shaft and thereby rotate the cams (see Figs. 80 and 81).

The **nose of the cam** raises a valve lifter or **tappet,** which plunges against the end of the valves and raises them from their seat. When the nose of the cam is under the roller or valve lifter, the valve is held open; the valve is closed after the nose passes, by the action of a strong spring.

The **valve stem,** being held in a **valve guide,** cannot move in any direction but up and down. Thus the steady **rotary** motion of the **cam** is changed to the **intermittent** motion of the **valve.**

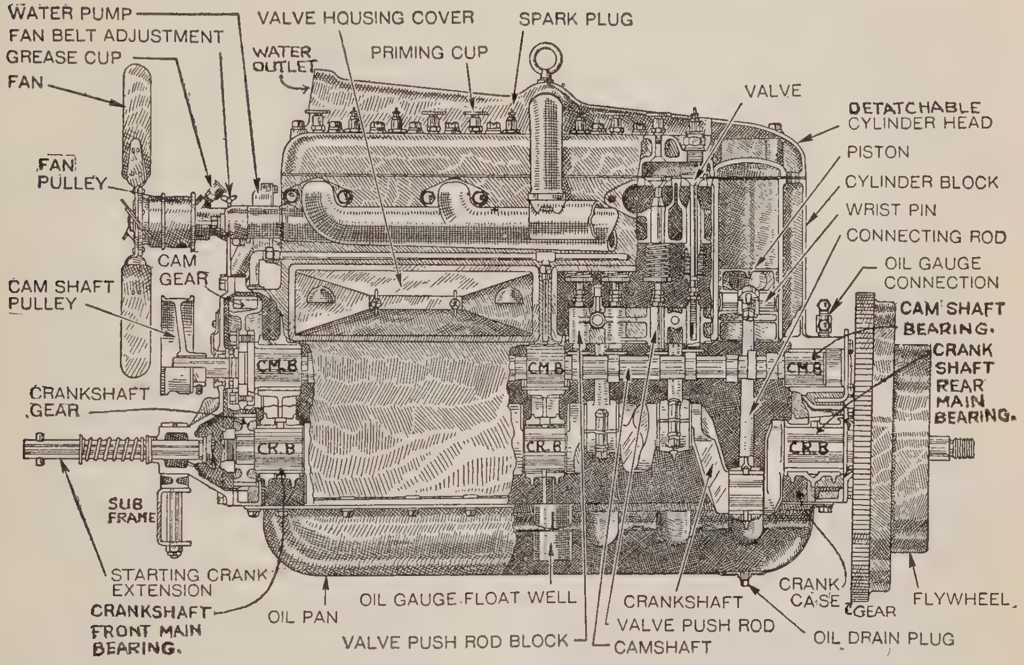

Fig. 83. Top view of the Mitchell model "F" six-cylinder engine. The illustration shows how the cam shaft is driven by gears. The crank-shaft gear drives the cam gear, which is attached to the cam shaft. The one cam shaft operates all valves (inlet and exhaust) from the one side of the engine.

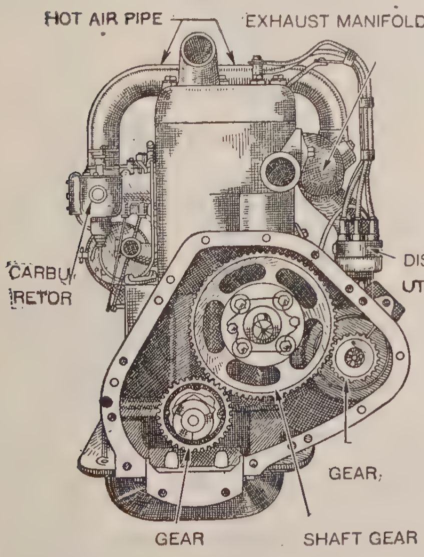

Fig. 83A

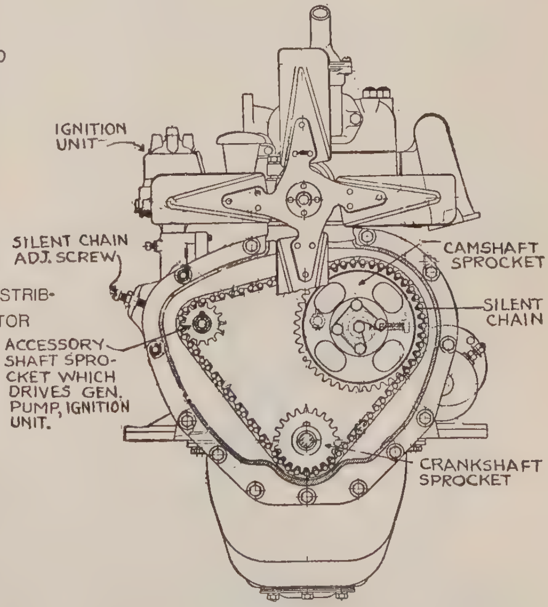

Fig. 84

Fig. 83A. End view of the Mitchell engine. Note that the crank-shaft gear (lower one) drives the cam-shaft gear (large one). The cam-shaft gear then drives the generator gear (on the right).

Fig. 84. Front view of the Studebaker model "EJ" six-cylinder engine. The cam shaft is driven by a silent chain.

As has been shown on four-cycle engines, each valve opens only once while the crank shaft makes two revolutions. Therefore the cam shaft should revolve only once while the crank shaft revolves twice.

The cams are an integral part of the cam shaft and one cam cannot be moved one way or the other unless all move together. There are **two types of cam shafts,** those operating from the **side** of the cylinder and those operating **overhead,** or above the cylinder.

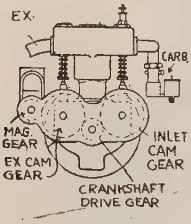

Fig. 80

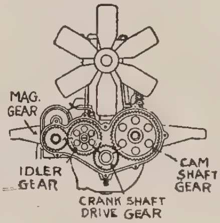

Fig. 81

Fig. 80. Showing method of driving the two cam shafts and magneto on a "T"-head engine. Note the two cam gears and shafts.

Fig. 81. Method of driving the one cam shaft. An idler gear is provided to drive the magneto gear. "L"-head type of cylinder engine. Note the one cam gear and shaft.

Gear-Driven Cam Shafts

The crank shaft drive gear and cam gears are called **timing gears.** If two gears running together (or in other words, in "mesh"), have the same number of teeth they will make the same number of revolutions.

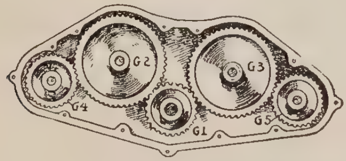

Fig. 82. End view of the cam gears and drive gear. The two cam gears (G2, G3) are called "half-time" gears, because they revolve just one-half the time, or revolutions, that the drive gear (G1) revolves. G1 is drive gear on crank shaft. G3 is cam gear for inlet cam shaft. G2 is cam gear for exhaust cam shaft. G4 and G5 are extra gears to drive the magneto and generator ("T"-head engine).

If the **driven gear** has twice as many teeth as the **drive gear,** it will revolve only once while the other revolves twice. This is called a "two-to-one" or "half-time" gear.

Because the cam shaft must revolve only once while the crank shaft revolves twice, the cam-shaft gear has twice as many teeth as the crank-shaft drive gear (see Fig. 82).

The **cam shaft revolves in the opposite direction to the crank shaft** when driven by gears without an idler and in the **same direction** when driven by a silent chain or an idler. The crank shaft and fly wheel of all gasoline engines revolve **clockwise,** or to the **right,** when facing the front of the engine. Thus gear (G1) (Fig. 82) would revolve clockwise.

The **wide-faced helical gear** is the popular type of gear for the timing gears because they make less noise than a straight-tooth spur gear. Special materials, such as fabroil, micarta, and other compressed materials, are used by many as material for making gears which are silent. Drop-forged gears are also used, so also is steel for the crankshaft gear and cast iron for the cam gear.

Silent-Chain-Driven Cam Shaft

The **silent chain** for driving the generator is quite popular, and it is also being used to a great extent for driving the cam shaft. The object is to obtain quieter running. This type of chain must not be confused with the ordinary roller type as used on chain-driven trucks. The silent chain is more positive in action, otherwise the timing would be thrown out of adjustment. The **teeth on a sprocket** used for a silent chain are very close together and are accurately made. The **silent chain,** as its name indicates, is silent, but requires taking-up occasionally. After a certain period new links, or a new chain, is required. See Index under "Silent chains, adjusting of."

ENGINE VALVES

Purpose of valves: There are two valves to each cylinder of all four-cycle gasoline engines: an **inlet** valve and an **exhaust** valve.

Note. The "dual-valve" engine has four valves to each cylinder; two inlet and two exhaust valves. This subject will be treated later.

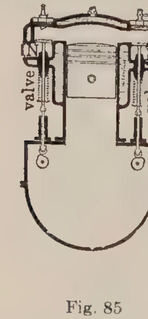

Fig. 85

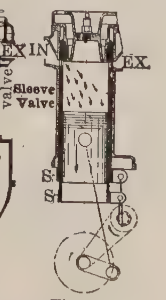

Fig. 86

Fig. 85. Poppet type of valve: so named because the valve pops up and down. Poppet valves are used on "L," "T," "I" or "F"-head type of cylinders, and are always mechanically operated.

Fig. 86. The sleeve type of valve. There are two sleeves (S),—with openings at upper end. When these openings are together, the fresh gas is admitted or the burned gas is discharged. Mechanically operated. "IN" means inlet, and "EX," exhaust.

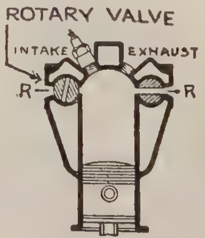

Fig. 87

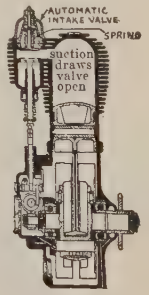

Fig. 88

Fig. 87. The rotary valve.

Fig. 88. Automatic inlet valve. Suction of piston draws the valve open against the tension of spring. Exhaust valve mechanically operated.

Types of valves: There are three types in general use: the "poppet," the "sleeve," and the "rotary," (see Figs. 85 to 88), the poppet type being used almost exclusively.

The inlet valve admits fresh gas to the cylinder. As fresh gas is going into the cylinder during only one stroke in every four, the inlet valve is opened during only one stroke in every four, in other words, during one stroke in every two revolutions of the crank shaft.

The exhaust valve permits the burned and useless gas to escape. It is opened and held open by a cam on the cam shaft. It is thus described as "mechanically" operated.

Mechanically operated valves are opened and held open by means of cams and closed by means of a strong spring. The **exhaust valve** is always mechanically operated.

Inlet valves are generally mechanically operated, but some of the old and motorcycle type of engines have the inlet valves of the "automatic" type.

The **automatically operated inlet valve** is held against its seat by a light spring (see Fig. 88). During the suction stroke, the sucking action of the piston, as it travels downward in the cylinder, draws the valve open. At the end of the suction stroke, when the suction ceases, the spring forces the valve disk back to its seat, and the gas is prevented from escaping through the valve.

It must be understood that the valves of a gasoline engine always open in such a direction that the pressure from power and compression strokes tends to keep them firmly on their seats.

Valve Operation and Location

The **"mechanically"** operated **"poppet"** type valve is the type in general use, therefore we shall confine our attention to this type.

Valves are operated, or opened, by the intermittent motion of a cam and are closed by a strong spring.

The **location of the valves** may be overhead or on the side, or a combination of both.

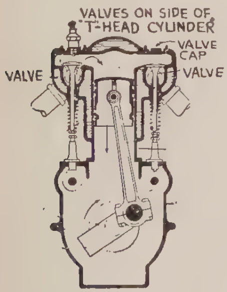

Fig. 89

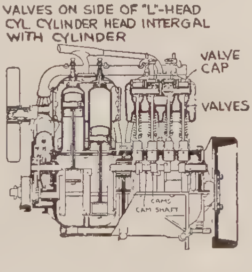

VALVES ON SIDE OF "L"-HEAD CYL CYLINDER HEAD INTERGAL WITH CYLINDER
VALVE CAP
VALVES
CAMS
CAM SHAFT

Fig. 90

Valves-on-the-side may be placed on opposite sides of the cylinder, as in the "T"-head cylinder type of engine (Fig. 89), or all on one side, as in the "L"-head cylinder type of engine (Fig. 90). Valves are operated by a cam shaft on the side.

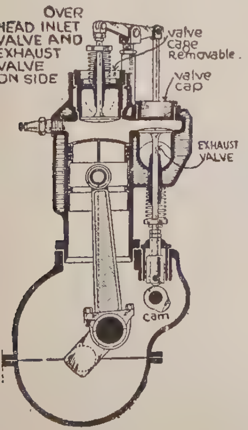

Fig. [illegible]

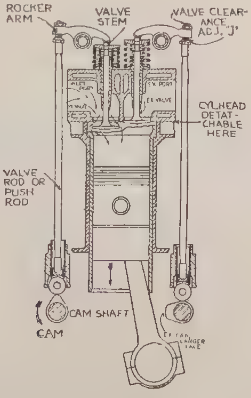

Fig. 92

Valves-in-the-head-and-side are illustrated in Fig. 91. In this instance, the overhead valve is always the inlet, and the valve on the side is the exhaust valve. Both valves in Fig. 91 are operated by one cam shaft on the side. The cylinder is of the "L"-type.

Valves-in-the-head (or both valves placed overhead) with a **detachable cylinder head** are shown in Fig. 92. The head is usually detachable from the valves. Thus valves are ground in the detachable cylinder head.

Note. Although Fig. 92 shows two cam shafts and valve rods on opposite sides of the cylinders, this is seldom found in actual practice. In most instances there is but one cam shaft, and the push rods are all on one side.

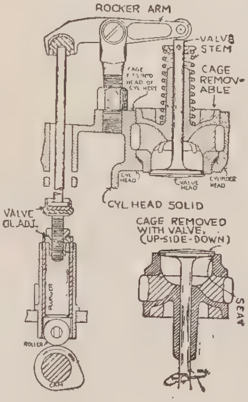

Fig. 93

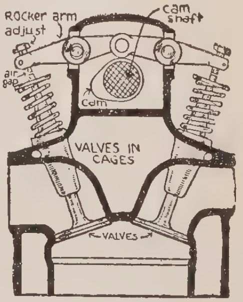

Fig. 94

Fig. 93. Illustration of solid cylinder head with removable cage, with valves ground in the cage.

Fig. 94. Overhead valves operated by an overhead cam shaft.

Valves-in-the-head (or both valves placed overhead in a solid cylinder head) are in cages which are removable and the valves are ground in the cage (Fig. 93). Valves are mechanically operated from the side by the cam shaft.

Valves-in-the-head operated by an overhead cam shaft are shown in Fig. 94. This principle is used on the Liberty Engine and on many other aviation engines.

The method of **driving the overhead cam shaft** is shown in Fig. 95. Note that the shaft (S) which drives the cam shaft is driven from the crankshaft gear. This principle is similar to that employed on the Stutz racing-car engine (Fig. 98).

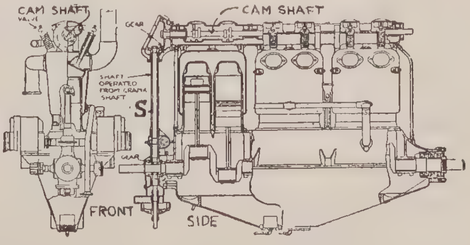

Fig. 95. Wisconsin six-cylinder aviation engine which has a valve action quite similar to that used on the Stutz racing cars. The cam shaft is carried overhead.

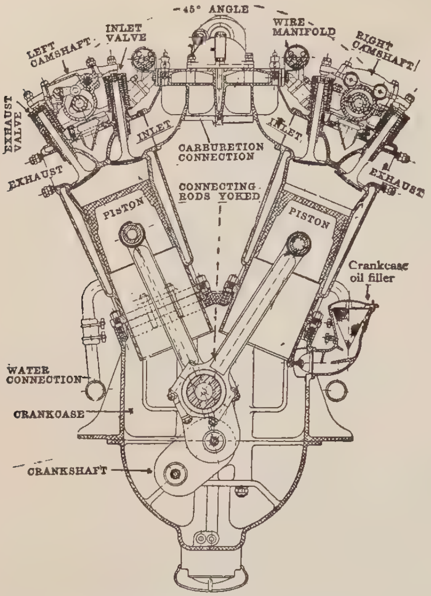

Fig. 96. A twelve-cylinder, or "twin-six" engine with valves-in-the-head operated by overhead cam shafts. This is the Liberty Airplane engine. The cam shaft is driven in a manner similar to that shown in Fig. 95.

The Dual Valve Engine

Dual valves are valves with two inlet and two exhaust valves to each cylinder. The Pierce-Arrow six-cylinder engine (Fig. 97) is an example of a dual-valve engine. The cylinders shown in the illustration are of the "T"-head type, with detachable head, cast in pairs, with a cam shaft on each side.

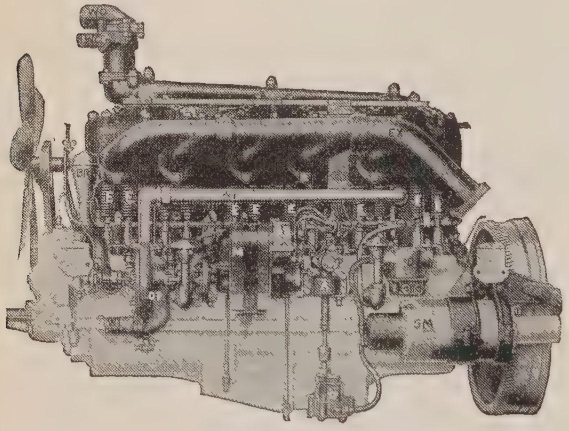

Fig. 97

Exhaust valves (**EE**) are on the left side of the engine and the inlet valves are on the right. This would be termed "valves-on-the-side." On the late model of Pierce-Arrow engines the cylinders are in-block.

Note. The left or right side of an engine or automobile is determined by being seated in the car, looking toward the front.

The Stutz engine (Fig. 98) is another example of dual valves, with both valves-in-the-head of the cylinder operated by an overhead cam shaft.

Advantage of dual valves: It is well known that greater power, especially at higher speeds, is obtained by using large valves. For instance, in standard practice, the rule is to have the valve diameter one-half that of the bore of the cylinder. For a 4½″ bore, a 2¼″ valve is used. In order, however, to get the maximum possible power, a 3″ valve with a ⅜″ lift would give greater power, but this would result in noisy valves, due to the heavy valve spring required to close them promptly, and also on account of the tendency of the exhaust-valve head to warp out of shape when heated.

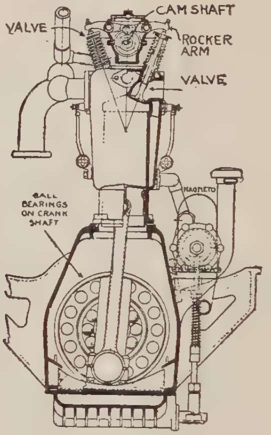

Fig. 98

Therefore, by using two smaller valves of about 2⅛″ diameter with a ⅜″ lift, the same opening area as the single 3″ valve is obtained. This gives the maximum power and a very quiet valve action through the use of light valve springs.

Valve Arrangement

On the "L"-head type of cylinders, all inlet and exhaust valves are on one side, but they do not run consecutively. Owing to the fact that the exhaust manifold must connect with all exhaust valves and the inlet manifold must connect with all inlet valves, the valves are usually arranged as in the illustrations above. The exhaust is on the outside, next to the water jacket on most all engines, because of the greater heat at the exhaust valve. Fig. 99 shows a four-cylinder engine; Fig. 99**A** illustrates a six-cylinder engine. ("X" are exhaust valves).

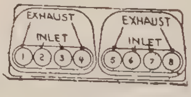

Fig. 99

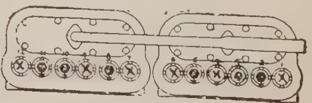

Fig. 99A

Fig. 99. Four-cylinder exhaust and inlet valves.

Fig. 99**A**. Six-cylinder exhaust and inlet valves. "X" are exhaust valves.

Although the valves vary in location and methods of operation, the principle or purpose remains the same; the inlet to admit fresh gas, and the exhaust valve opening at the correct time to expel the burned gas.

Valve Parts

Valve heads are made of cast iron, nickel steel, and tungsten steel. Cast iron is easily machined and works fairly well, but is heavy. Nickel steel does not heat as much as cast iron and does not expand as much as cast iron. Nickel steel heads are electrically welded to steel valve stems. Tungsten steel is hard and stands high temperature without heating. The **"poppet"-type valve** is the type in general use. We shall, therefore, confine our attention to this type. A "poppet"-type valve has **three parts:** a "head," a "stem," which forms the moving part, and a "valve face" which seats into a "valve seat." This valve face is beveled and is perfectly round. When seated, it must fit the valve seat perfectly tight, otherwise during the compression stroke the gas would leak, and on the power stroke, a loss of power would result by the valve leaking at the seat. Therefore it is ground to this seat.

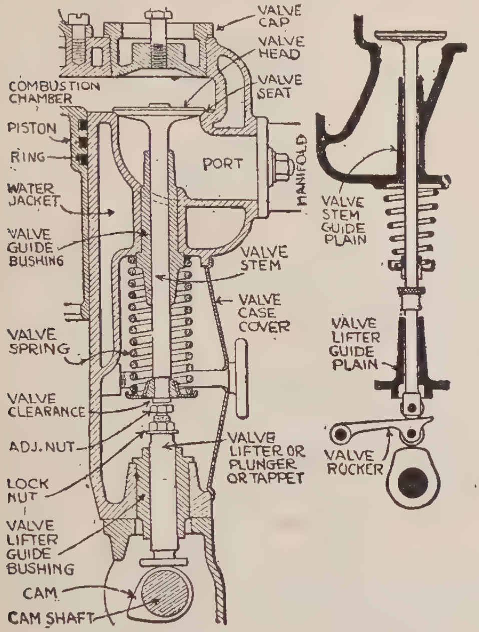

Fig. 100 Fig. 101

Figs. 100 and 101. Two methods of operating the lift of the valve. Note in Fig. 100 that the lift is direct from the cam to the tappet, thence to valve stem, whereas in Fig. 101, a valve rocker arm takes the place of valve tappet. The method shown in Fig. 100 is the one in general use.

The expression **"valve-head diameter"** usually refers to the clear opening of the valve. The "valve-head" is the upper part of the valve and usually measures from one-third to one-half of the cylinder diameter. For instance, on the Continental model "7R" six-cylinder engine, which has a cylinder bore of 3¼", the diameter of the valve at the clear opening, or the small end of the bevel, is 1½", and at the head, or largest diameter, it is 1⅝". Both inlet and exhaust valves on this engine, as also on many others, are the same size.

The **valve lift** of this engine ("7R"), is 5/16". On the Pierce-Arrow, the valve lift is 11/32". "Valve lift" means the height the valve is raised from its seat by the cam. Therefore it is clear that if the valve stem clearance is not correct (the space between the end of the valve stem and the valve lifter), the lift would not be correct, and thus power would be lost, owing to the smaller valve opening. As a result of this, less gas would be drawn into the cylinder.

Valve seats are usually beveled at an angle of 45°. The diameter of the exhaust pipe should at least be equal to the diameter of the valve.

The valve spring holds the valve tight in its seat and must have sufficient tension at all times. If too strong, the valve will close with more noise. If too weak, the valve will not seat properly. The exhaust valve spring usually weakens first on account of being subjected to greater heat.

The valve-spring-retainer-and-lock, originally called the "valve spring washer," is placed at the bottom of the spring and held in place by a two-part lock. Formerly, a "key" was passed through a hole in the valve stem as in Fig. 104, but, as stated, a two-part lock is now placed in a groove in the valve stem under the retainer (washer).

The **valve face** is the beveled part of the valve head. The **valve seat** is the part of the cylinder head in which the valve face is placed. The valve face and seat can be conical or flat. It is usually conical, as in Figs. 100 and 102.

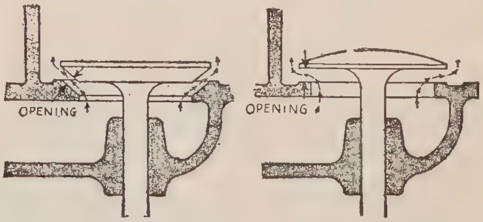

Fig. 102 Fig. 103

Note the conical type of valve in Fig. 102 and the flat type in Fig. 103. It is said that the flat valve gives a greater opening for the same valve lift and has greater possibilities for high-speed work. Seldom used.

The **"tulip"-shaped valve** is another type, formerly used on the Cadillac for inlet valves. It is now seldom used (see Index).

The **valve stem** is the stem part of the valve head. The stem of a mechanically operated valve on the "L"- or "T"-head cylinder of the "side valve" principle usually extends about half-way down to the cam shaft. A valve lifter then lifts the valve stem by action of a nose on the cam as the cam revolves. To set this cam to raise the valve at the proper time, is called "valve timing."

On engines with overhead-valves, there is a rod, called the **"push rod,"** or **"valve rod,"** between the valve tappet and the rocker arm (see Fig. 92, page 53).

Note that a spring is placed between the valve tappet and the valve rod, which tends to keep the tension of the valve rod up and to reduce noise.

Valve-stem-clearance, also called "air-gap," is the distance between the lower part of the valve stem and the valve tappet. On the overhead, or valve-rod type, it is usually between the rocker arm and the end of the valve stem. This distance is regulated by an adjusting nut.

The **valve-lifter,** also called "valve plunger," "valve tappet," and other names, is the part placed between the valve stem and the cam. The top part has an adjustable screw which can be slightly raised or lowered to obtain correct valve clearance.

Exhaust cams usually have a broader nose than the inlet cam, because the exhaust valve remains open longer.

The bottom of the valve lifter is sometimes fitted with a "roller," (**R**), (Fig. 106). The "mushroom" type (Figs. 100, 104 and 105) is the type used most.

A valve rocker—upper—is used on all overhead valves, also called "rocker arm." A valve rocker—lower—is the principle shown in Fig. 101. It is also called a "side tappet lifter." The latter is seldom used.

A valve-stem guide holds the part through which the valve stem passes (Fig. 100). Sometimes it is bushed as shown in Fig. 100. Quite often it is plain, as in Fig. 101.

Fig. 104 Fig. 105 Fig. 106

Figs. 104, 105. Mushroom type of valve lifter.

Fig. 106. Roller type of valve lifter.

Note in Fig. 104 the valve just starting to lift. In Figs. 105 and 106, the valve is just closed.

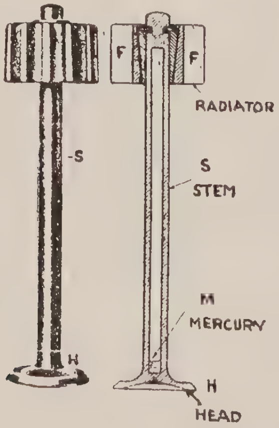
A **valve-lifter guide** (also called "plunger" and "tappet" guide) is shown in Fig. 100, which is fitted with a bushing and can be renewed when worn. It is bolted, sometimes screwed, to the crank case. In Fig. 101, a plain guide is shown.

Enclosed valves are where a cover fits over the valves (Fig. 100). This deadens the noise of the lifter when striking the valve stem and keeps out dust.

Although valves may be placed overhead, or in a combination, as overhead and on the side, the principle of operation is very much the same in either case.

Mercury-Cooled Exhaust Valve

The mercury-cooled exhaust valve is a type of valve at one time used on one of the farm-lighting-plant engines. With high-duty internal combustion engines the exhaust valve is subjected to direct blasts of exhaust gases of about 1,800°F. The only provision heretofore made for radiating the heat from valve head (H) and the stem was through the valve guide. As a result, the stem often became red hot, with the consequent result, warping and loss of compression at the valve seat.



Principle: The effect of the mercury contained within the valve is of course to transmit the heat from the hottest part of the valve up to the portion of the valve stem which is exposed to the atmosphere, and which has a series of aluminum radiating fins (F) connected therewith, to facilitate the cooling of the valve.

The mercury (M) under normal temperature is in liquid state and rests at the bottom of the valve stem. As heat is absorbed by the valve stem and transmitted to the mercury, the mercury is vaporized and immediately rises, until, coming into contact with the cooler part of the valve stem, it will undoubtedly condense and flow back to the bottom of the stem to be again vaporized and to repeat the previous operation.

Purpose of Valve Grinding

The **exhaust valve** is surrounded by a flame when open, and will become "pitted" in time, as shown in Fig. 107.

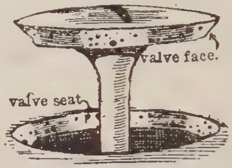


Fig. 107

The exhaust valve requires more grinding than the inlet valve because the hot gases pass out between the valve seat and the valve face when the valve is raised. When the valve is opened, there must be sufficient space to permit the burned gas to pass freely.

The **inlet valve,** admitting gas instead of ejecting a flame, does not pit as badly as the exhaust valve.

In **a perfect seated valve,** the valve face and seat are smooth and even, with dull-gray surface. **A pitted valve** is rough, uneven, and full of tiny holes, and cannot come to a tight seat. A valve in this condition, therefore, must be ground.

The process of grinding a valve is the placing of a grinding paste between the valve face and the seat, and revolving the valve until the roughness is worn down. See Index under "Valve grinding" and "Valve re-seating."

There are several prepared valve-grinding pastes on the market, but a very satisfactory abrasive may be had by mixing flour of emery, of the grade known as No. 120, with a little kerosene or thin lubricating oil, until it has the consistency of paste.

To grind valves in an engine where valves-are-on the-side, the usual plan is to remove the valve caps, if the cylinder head is solid, as in Figs. 108, 109 and 110, and to grind the valves in their seats.

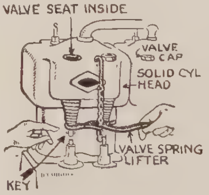

Fig. 108

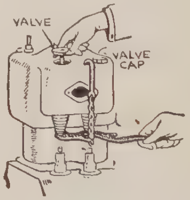

Fig. 109

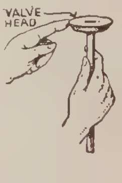

Fig. 110

Fig. 108. **To grind valves in a solid cylinder head,** remove the valve caps; remove the pin (or valve retainer) at bottom of the valve stem. A spring lifter is used to compress the spring.

Fig. 109. Lift valve out of cylinder.

Fig. 110. Smear valve grinding compound around edge of valve. Replace valve in its seat and grind, by turning valve back and forth on its seat until both the valve and seat show a bright ring about 1/32" wide all the way around. Remove all abrasive matter carefully before replacing.

To grind valves in an engine with valves-on-the-side, with a detachable cylinder head, the cylinder head is removed as shown in Fig. 111, and the valves are ground in their seat on the cylinder block as in Figs. 108, 109, 110.

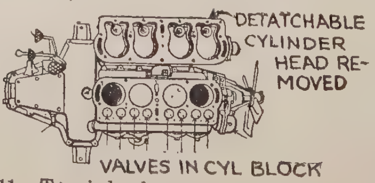

Fig. 111. To grind valves on an engine with valves on the side and detachable cylinder head (Ford engine).

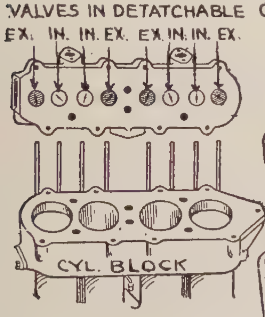
To grind valves in an engine with valves-overhead and with a detachable head, the cylinder head is removed and valves are ground in the head as in Figs. 111 to 115. (The Chevrolet is shown as an example.)

To grind valves in an engine with valves-in-the-head and in cages, remove the valve cage and grind the valve in the seat of the cage. See Index under "Valve grinding, cage type."



VALVES IN DETATCHABLE CYLINDER HEAD

CYL. BLOCK

Fig. 112

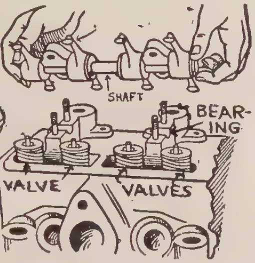

Fig. 113

Fig. 112. Cylinder head removed.

Fig. 113. Remove shaft and rocker arms.

Procedure: Disconnect the upper radiator hose connection. Remove each of the bolts holding the cylinder head to the cylinder casting and lift the head off. The valves, rocker arms, and bearings, being attached to the head, will remain with it as shown in Fig. 112. Next remove the rocker arms and shafts as shown in Fig. 113. Before removing, the bearing caps should be marked with a center punch, so that they will not become mixed when replacing. Next remove the small wire holding the valve-spring cap pin in place (Fig. 114). With a screwdriver and your fingers press down upon the valve spring cap until a spring has been compressed enough to admit pulling out the pin. Remove each valve separately, using care not to mix them in any way, as they must go back into the same valve holes.

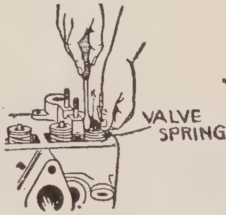

Fig. 114

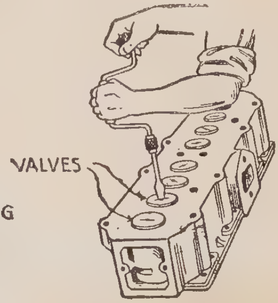

Fig. 115

Fig. 114. Remove valve springs.

Fig. 115. Grinding the valves in the cylinder head.

Grinding: Secure a light coil spring and place it around the valve stem before replacing it for grinding. Smear the compound thinly on the beveled edge of the valve head and on the seat in the cylinder head. Place the valve in the up-turned cylinder head and grind as shown in Fig. 115.

Before replacing the valves it is a good plan to scrape off all carbon deposit from the combustion chamber and piston. Also examine the copper asbestos gasket before replacing the cylinder head. If not perfect, a new gasket should be used.

When replacing the cylinder head bolts, turn each one until the head just touches the cylinder head, then tighten each one evenly, a little at a time. None should be drawn tight until all are set snug.

Refacing Valves and Reseating Valve Seats

If valves become pitted and leak, they need regrinding. If warped, or shoulders form in the seat, then the seat and valve ought to be refaced. See Index under "Reseating valves." This subject is covered in the section devoted to "Repairs." Tungsten valves are hard and when pitted or leaking must be refaced.

INSTRUCTION No. 9

VALVE TIMING: Valve-Stem Clearance; Valve Lift; Setting the Valves; Meaning of Degrees.

VALVE-STEM CLEARANCE

If no space was left between the end of valve stem and tappet, even very slight wear of the valve and seat would prevent the valve from closing properly. Furthermore, there must be some cognizance taken of the expansion due to heat. As the stem expands, it gets longer, so if no clearance were provided the stem would rest against the tappet and would be unable to seat properly.

Valve clearance, also called "air-gap" space, is the space between the end of the valve stem and the lifter ~~or~~ plunger. The width of this air gap ranges from the thickness of tissue paper to 1/16″. The average gap is somewhere about, or slightly less than, postal-card thickness.

Some manufacturers give about 1/1000″ less space to the inlet than to the exhaust, because the exhaust valve stem lengthens more, owing to greater heat. For instance, Hudson gives .004 of an inch to the "air space" on the inlet valve and .006 to the exhaust. It is necessary to adjust the valve-stem clearance when valves become worn and thus lowered, as a result of repeated grinding, or where the valve is in a cage the end of the valve stem or rocker arm or push rod becomes worn, owing to the constant tapping, which causes natural wear in time.

When the distance is too great between the valve stem and the tappet, as a result of wear or improper adjustment, this will produce a clicking noise and can be overcome by proper adjustment. Often a noise which sounds as if coming from the valve stem will be found in a worn valve tappet in its guide, and the noise is thus caused by the cam shifting the valve tappet against its worn guide. In fact, this is a very common trouble. The remedy is to replace the tappet with a new one.

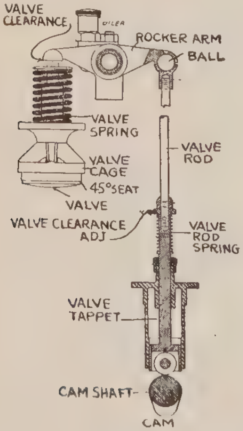

Fig. 1

Fig. 2

Fig. 1. Valve clearance on valves-in-the-head is measured between the end of the rocker-arm and the top end of valve, as above.

Fig. 2. Type of valves on side of "L"-head engine. Clearance is adjusted as shown in illustration. (Hudson six.)

Adjustment of valve clearance where the valves are on the side, as in Fig. 2, can be made by screwing up the adjusting screw if there is too much clearance, or screwing down the adjusting screw if clearance is not great enough. When the correct position is found, the valve-tappet adjusting screw is locked in position with the lock nut.

Adjustment of valve clearance where the valves are in-the-head and rocker-arms over head can be made at the lower part of the valve push rod, if arranged as shown in Fig. 1, which adjusts the clearance between the end of the valve stem and the rocker arm.

On the valve-in-the-head type (Fig. 92, page 53), the adjustment is on the top of the valve push-rod (J). The clearance given to valve stems in this instance is .003″ to .010″ between the valve stem and the rocker-arm, when the valve rod is entirely free from the cam, or when it is not riding the cam. The adjustment is made when the engine is warm.

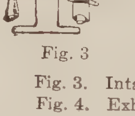

Fig. 3

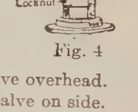

Fig. 4

Fig. 3. Intake valve overhead.
Fig. 4. Exhaust valve on side.

The **Essex overhead inlet valve** is adjusted between the upper push rod and overhead rocker-arm (Fig 3). The exhaust valve is adjusted on the side between the tappet and valve stem (Fig. 4). The inlet is overhead and the exhaust on the side, both mechanically operated from one cam shaft on the side. On the Continental model "7R" engine (side-valve type) the inlet valve is given .004″, and the exhaust valve .005″ clearance. The exhaust valve is given slightly more clearance because it is subjected to a higher degree of heat than the inlet, and, when iron is heated, it expands. The instructions are to adjust when the engine is warm.

Hupmobile instructions call for .004″ clearance for both valves, when the engine is warm.

Pierce-Arrow instructions are to adjust the inlet for .003″ clearance and the exhaust for .005″ clearance, when warm.

Locomobile instructions for Model "48" are to adjust the inlet valves .001″ and the exhaust .004″, when the engine is cold.

Packard "twin six" gives for the inlet and exhaust valves a clearance of .004″ when cold.

Studebaker "Light Six" instructions are to adjust both valves for .004″ clearance with the engine warm.

Studebaker "Big Six" and "Special Six" should have .005″ clearance when the engine is warm, or .008″ when cold.

Some manufacturers give instructions for certain clearances when the engine is warm, and others when the engine is cold. When the engine is warm, appears to be the logical time for adjusting clearance, because the expansion and length of the valve stem are greatest at this time, as the stem expands or lengthens when warm and contracts or shortens when cold.

While it is true that the valve stem expands when heated, it is also true that the cylinders and other metal parts of the engine expand at the same time. In extreme cold weather, the probabilities are that the cylinder contracts and expands to a greater extent than does the valve. This is a problem that has never been definitely settled. Thus the subject of valve clearance is one where expansion and contraction of the metals are factors governing the clearance. Accordingly, one should follow the manufacturers' instructions as to the exact clearance to be given on an engine, as they have no doubt learned the correct clearance from experience.

The usual clearance is from .003″ to .005″, and most of the adjustments are made when the engine is warm. Clearance varies according to size of the engine and also according to the temperature; an engine running unusually hot would require more clearance, as expansion would be greater. By referring to the Index, a table will be found giving the diameter of valves and the valve clearance of different makes of engines.

In the absence of explicit instructions, give the engine .006″ clearance when cold, and after it has warmed up adjust it to about .003″. In this way one will be safe. It is also advisable to **check the valves** to see if they open and close at the proper time. This can be done by observing the marks on the fly wheel and noting if the valves close accordingly.

Valve-Clearance Adjustment

Adjustment should always be made after the valves of an engine have been ground, as the grinding may slightly lower the valve. When checking the adjustment of valve-stem clearance, turn the fly wheel of the engine over until the other tappet and valve in the same cylinder are up as far as they will go, or the valve is wide open. The first valve will then be closed. The clearance should then be measured between the end of the valve stem and the head of the tappet screw.

If it is found that the clearance is not right, loosen the lock nut on the tappet screw and turn the screw up or down, as may be required, to obtain the correct clearance.

It is best to use a "thickness gauge," but if a gauge is not obtainable a piece of newspaper will serve as a gauge. A sheet of ordinary newspaper is between .002″ and .003″ thick. After the tappet screw is adjusted so that the clearance is correct, tighten the lock nut. "Back lash" or lost motion in the cam-shaft driving gears should be taken up in the direction of rotation (crank-shaft drive gear) when clearance is adjusted.

A noisy valve tappet, resulting from wear, and where no adjustment is provided, can be, in some instances, remedied by placing fibre or steel washers under or over the valve ends.

The opening and closing time of the valve is not when the lifter begins to rise, or comes to rest, but when it makes or leaves contact.

Valve-Clearance Pointers

If the engine has good compression when cold and lacks compression and power when hot, this may indicate a lack of sufficient clearance between the valve tappet and valve stem. When cold, the valve seats properly, but when hot, metal expands. Therefore lengthening of the valve stem by expansion causes the valve to seat improperly, with a loss of compression and power. Experienced auto mechanics are aware of the fact that **when an engine has good compression the force of the combustion during the power stroke is greater** than if the engine has poor compression. Thus, since the force is greater with high compression, if there are any parts even slightly loose, such as bearings, too much piston clearance, loose piston pin, etc., a hammer-knock sound will occur and be the more noticeable the higher the compression. Frequently an automobile owner will drive his car in and tell the repairman to "take out the knocks." The repairman immediately proceeds to give the valves less clearance, which quiets the valves and at the same time relieves the knocks in the engine to a certain extent. This results from the fact that when the valves are given less clearance than they should have, the valve opens early and closes late, which reduces the compression, thus reducing the combustion and expansion force on the piston. As a consequence the noise is reduced, but power is sacrificed. **This is bad practice. The proper procedure would be** to properly adjust the valve clearance in the manner designed for the particular engine, and then to take up on the parts inside of the engine that are loose. And if there is a piston slap, be careful to replace the piston with a larger one.

Valve Lift

The inlet cam has a sharp nose. The exhaust cam has a broader nose, because it must hold the valve open longer. The **height of the nose, less the air gap, regulates the lift.** The average lift of either the exhaust or inlet valve is approximately 11/32″ to ⅜″. It is thus evident that if the air gap between the valve stem and the tappet is too large, the valve will not open at all.

If the air gap is increased, the valve will lift very slightly and stay open but a few degrees. If the air gap is **decreased,** the valve will open sooner, rise higher, and close later. This process can be repeated until there is no air gap left.

Therefore, suppose an engine was designed to have 1/16″ air gap and there was no air gap at all; the valves would open possibly 50° too soon, rise 1/16″ higher than intended, and close 50° too late.

In case of **wear of the end of the valve stem or tappet,** it is apparent that as the wear increases, the space or air gap increases, and valves will have less lift, open late and close early, and become more noisy, all of which will affect the power of engine. The valve lift on the **Continental** Model "7R," six-cylinder engine, with 3¼″ bore, by 4½″ stroke, with 1½″ valves, is 5/16″. The **Pierce-Arrow** six-cylinder engine, with a bore of 4″ x 5½″ stroke and using 1⅝″ valves, has a lift of 11/32″. The **Locomobile** six-cylinder engine, model "38," has 5/16″ lift; model "48," a larger engine, has ⅜″ lift.

VALVE TIMING

Before the reader can thoroughly master the subject of valve timing he must first learn the **four-cycle principle** as explained on pages 31 and 32, as it is with this principle we shall deal. In addition, the **meaning of degrees** as explained below, and the **relation of the valve-cam speed to the engine crank-shaft** speed and the importance of **valve clearance** adjustment must be thoroughly understood.

Meaning of Degrees

Suppose we take a fly wheel and divide its circumference into 360 equal parts (Fig. 1); each part would be a degree—expressed with a small "°" as 360°. In fact, any perfect circle can be divided into degrees. The crank shaft revolves in a circle; therefore we will designate the travel of the crank shaft in degrees. Any circle, or, say, travel of the crank pin, would represent 360° when it made a complete circle or revolution. One-half of the circle would be 180°, which would represent a stroke of the piston, or a half-revolution of the crank. One-quarter of the circle would be 90°; one-third of the circle would be 120°.

Note. The fly-wheel movement in the illustrations below is to the left, or counter-clockwise. We are supposed to be looking at the rear, or fly-wheel end of the engine for this purpose.

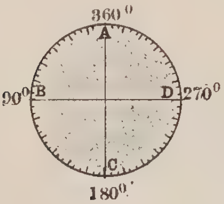

Fig. 1

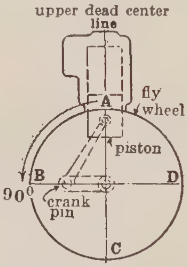

Fig. 2

In Fig. 2, the piston has traveled down from upper dead center, one-quarter of the circle, or one-half of a stroke; the crank pin and fly wheel have turned 90°.

Note. The piston in actual practice will have moved slightly more, depending upon the length of the connecting rod, as will be explained farther on.

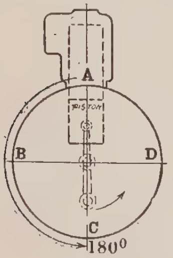

Fig. 3

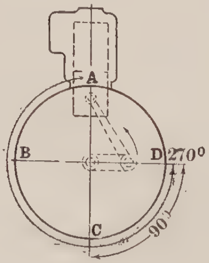

Fig. 4

In Fig. 3, the piston has traveled from top dead center to the bottom of the stroke; the fly wheel and crank pin have traveled 180°.

In Fig. 4, the piston has traveled up from bottom one-half of a stroke, the crank pin and fly wheel have traveled one-quarter of a circle from bottom, or 90° from **C** to **D**. In all, the crank pin and fly wheel have traveled from **A** to **D**, three-quarters of a revolution, or 270°.

In Fig. 5, the piston has made two strokes, one down and one up; therefore the crank pin and fly wheel have made a complete revolution, from **A** back to **A**, or 360° in all.

The idea is to learn that the crank pin travels in a circle and the fly wheel travels in a circle, and a revolution is a complete circle, and a complete circle is 360°. **The piston travels in strokes,** each stroke representing a half-revolution of the crank. If we spaced off 360 marks, equal distances apart, on any circle, then each mark would be called a degree. In Fig. 1, we have spaced off the marks as 5 degrees each.

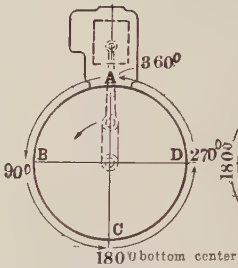

Fig. 5

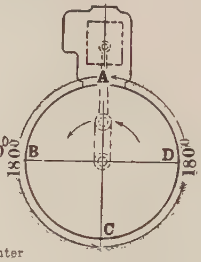

Fig. 6

Meaning of Minutes and Seconds

Now we can divide each degree into, say, sixty equal distances, and call each part or mark a "minute." We could go still farther, and divide each minute into sixty equal distances, and call each part or mark, a "second."

A minute is usually expressed with a single mark after the figure, as, 25′. A second is expressed with two marks, as, 25″.

Note. An inch is also designated with two marks, thus (″), and a foot with one mark, thus (′).

Example: Express ten degrees, six minutes, and five seconds. It would be as follows: 10° 6′ 5″.

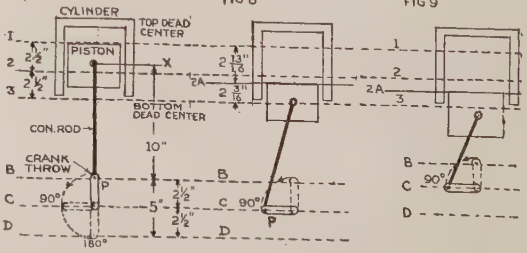
To find the circumference of a fly wheel: Multiply the diameter in inches by 3.1416. If the circumference is then divided by 360, the distance or portion of the fly wheel circumference equivalent to one degree may be ascertained.

Uniformity of Piston Movement Governed by Length of Connecting Rod Relative to Crank Throw

From the foregoing explanations of the piston movement relative to that of the crank throw, it would appear to the reader that when the crank pin moved 90° or one-fourth of a revolution from top dead center, the piston would have moved down exactly one-half of its stroke. This is not correct.

For example, the crank throw is always one-half of the stroke of the piston, or the piston stroke is twice the crank throw; that is, where the cylinders are centrally located, or in line with the crank shaft.

FIG. 7 FIG 8 FIG 9



Figs. 7, 8, and 9. Relative position of piston to crank on a centrally located cylinder.

As an illustration of this, see Fig. 7, in which is shown a connecting rod 10″ long from the center of the wrist pin in the piston (**X**) to the center (**B**). The crank throw is 2½″ from (**B**) to (**C**), therefore the stroke of the piston would be 5″ when the crank pin (**P**) moves from position (**B**) to (**D**).

The foregoing applies to a full stroke, or one half-revolution (180°) movement of the crank pin (**P**).

In the illustration (Fig. 8) the crank pin (**P**) has moved from top dead center (**B**), down 90° to (**C**), which would appear to indicate that the piston would have moved down from top dead center (1) to (2), or one-half of its stroke, which however, is not the case, as will be seen by referring to Fig. 8.

Note that the piston has actually moved down 2½″ plus about 5/16″, or 2 13/16″ instead of 2½″, which is about 5/16″ **more** than one-half of its stroke. Therefore when the crank pin moves the next 90° (**C**) to (**D**), the piston will have to move only one-half of its stroke less 5/16″ (2½″−5/16″=2 3/16″), which will be **less** than half of a stroke.

The shorter the connecting rod relative to the crank throw, the greater the difference in movement there will be between the upper portion of the stroke and the lower portion of the stroke, as represented by the first 90° movement of the crank pin and the second 90° movement of the crank pin.

An exaggerated illustration is shown in Fig. 9, in which the connecting rod has been shortened, but not the crank throw. Note the difference in piston stroke from (1) to (2**A**) in Fig. 9, as compared with (1) to (2**A**) in Fig. 8, while it will be noticed the crank pin has moved exactly the same in each case, that is, 90°.

Effect of Offset Cylinders

In the foregoing, we have taken as an example an engine with a centrally located cylinder (in line with the center of the crank shaft). Many manufacturers build their engines with offset cylinders; that is, the cylinders are placed to the left (when looking from the fly wheel) of the center of the crank shaft. The most peculiar feature of an offset cylinder is that the piston stroke or travel is no longer equal to twice the crank throw, as in the case of a centrally located cylinder. With an offset cylinder, the stroke is slightly longer than twice the crank throw.

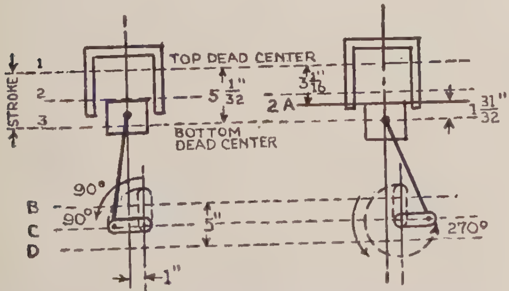


Fig. 10

Fig. 11

Figs. 10 and 11. Relative position of piston to crank on an offset cylinder.

In Fig. 10, we have the same crank throw and length of connecting rod as in Fig. 8, but it will be noticed that by offsetting the cylinder 1″, we have increased the stroke from 5″ to about 5 1/32″.

Another feature to be noticed is that when the crank has revolved 90°, the piston has descended just about one-half of the stroke. Contrast this result with that found in Fig. 8. **The offsetting decreased the effect of angularity during the downward stroke.**

In Fig. 11, when the crank has revolved 270°, it will be noticed that the piston rises only 1 31/32″ (approximately) from bottom dead center. This distance is still farther removed from one-half the stroke than was the case in Fig. 8, consequently **the offsetting increased the effect of angularity during the upward stroke.**

Remarks on Inlet-Valve Opening

It has been explained that the valves are raised by means of cams operated by a cam gear or sprocket placed on the front of the engine, in connection with a gear or sprocket driven from the crank shaft.

If one of the cams raises an inlet-valve just as the piston is starting down on the suction stroke, a charge of gas will be drawn into the cylinder as long as the piston is on the suction stroke and the valve is open. The valve should therefore open in time to give the piston a chance to draw in a cylinder full of gas.

If the valves were to open late in the stroke, a full cylinder of gas would not be drawn in and the power of the engine would be less than what it should be. If the inlet valve opens too early, it will cause back-firing; if too late, a sluggish engine and overheating will result. The inlet-valve timing gear is used for timing the inlet valve to open at the right time, this being done by meshing the gears or setting the sprockets at the right place.

The practice is to allow the piston to descend about an eighth of an inch in the cylinder on the suction stroke before the inlet valve opens, so as to reduce the pressure and create, if anything, a vacuum which causes a greater suction.

Inlet-Valve Closing

It is almost universal practice to leave the inlet valve open until the piston has not merely reached the bottom of the stroke, but has actually traveled slightly up again on the compression stroke. It would seem that under these circumstances part of the gas would be forced out of the cylinder, but this is not the case as the high speed at which the piston is traveling causes the suction to continue for a short time on the compression stroke. This will, of course, vary with the speed of the engine, so that a certain valve setting will not be correct for all speeds, since, if the inlet valve is closed at the correct time for slow speed, it will close too early for higher speeds and less gas will be drawn in than would be the case with correct setting.

However, there is an average speed for all engines, and the valves are set to it accordingly. This average speed on most engines is approximately 1,000 revolutions per minute.

Exhaust-Valve Opening

The exhaust valve must open considerably before the piston reaches the end of the expansion stroke, and although this may waste some of the force of the explosion, it is compensated for by the freedom afforded the piston in completing the exhaust stroke.

It would be wrong to keep the exhaust valve closed up to the very moment when the piston is about to move upward, for, on commencing the exhaust stroke, the piston would be confronted for an instant with the force that had just driven it down, and until the valve was wide open, it would be considerably impeded on its journey.

The exhaust valve is usually opened when the piston has moved through about seven-eighths of the power stroke; that is, before bottom of dead center. Exhaust valves opening too early, however, cause pounding and clatter.

Exhaust-Valve Closing

The exhaust valve must not close before the end of the exhaust stroke. Since the gas which remains in the cylinder head is slightly under pressure at the end of the stroke, the valve is often allowed to remain open until the piston has moved slightly down on the suction stroke, so as to give full opportunity for as much exhaust gas to escape as possible.

In order to understand just how important it really is to expel all of the burned or exhaust gas, it must be explained that one of its chief constituents is carbon dioxide—the most powerful anti-combustion agent known to science. Its presence, therefore, even in small quantities, retards considerably the speed of the combustion development.

It will now be obvious from the foregoing that, if the exhaust gases are to be entirely expelled from the cylinders, the valve must be made to close a little later than "top center," or—as it is technically described—must have a certain degree of "lag"; for it is evident that if we close it at the exact top of the stroke, the contents of the combustion head (which we wish to get rid of) will be imprisoned and will contaminate the incoming charge.

The amount of this "lag" will depend on several things—the shape of the combustion head, the weight of the valve, the strength of the springs, and design of the exhaust system.

Valve Effect of "Lag" or Bounce

Valve spring, strength, and weight have to be reckoned with on account of their influence on **inertia lag** as distinct from that which is **intentional,** for it is well known that as the speed of the engine increases the valve tends to "jump" the closing face of its cam and closes later and later as the speed increases. This is what we describe as "inertia lag." There is a point, however, past top center to which the exhaust extraction lasts, and pending this extracting effect the valve should remain open. But if carried beyond this point, a reverse of the exhaust gases may occur, for it must not be forgotten that the piston has now started down on its suction stroke. It becomes a question, therefore, of closing the valve when the scavenging is as complete as possible.

The best design of cylinder head for an **"overlap"** is the round or "I" head with overhead valves. The ordinary "L" head is not so good, and in certain kinds of heads in which the inlet and exhaust valves are small and close together in a small pocket an overlap is quite useless.

On the other hand, it has been found in racing practice, where the exhaust pipe is very long, straight, and open, and the combustion head suitable for scavenging, that a very considerable overlap can be allowed with advantage.

What Governs Valve Timing

The **size of cylinder,** especially in the stroke and in the type of ignition, shape of manifold, and the speed of engine, governs the valve timing.

Early **setting of valves** on an engine will cause irregular running at lower speeds, unless a very heavy fly wheel is used. It will also increase the gasoline consumption in short-stroke engines.

For high-speed work, the inlet may be opened and closed late. For slow-speed work, closing the exhaust and inlet on center gives the best control, and no blowing back.

The **time of opening and closing of valves** with reference to the engine speed of course has an important bearing on its performance. If the valves open too early it will cause **back-firing,** while if they open too late a sluggish engine and overheating will result.

High-speed (short-stroke) engines have a longer time of valve opening than medium or slow-speed engines. The slower-speed engines have the exhaust opening and the inlet closing nearer to bottom center, while some high-speed engines open the exhaust 65° before bottom center and close the intake 70° after bottom center.

Valve timing of different engines will vary according to the intended average speed and the length of stroke. Long strokes are for slower-speed engines than short strokes. Obviously high-speed engines are not efficient at slow speeds, because the inlet closes too late and the exhaust opens too soon, thus losing part of the charge and part of the power stroke. And slow-speed timing on a high-speed engine does not permit of receiving a full charge nor of getting rid of the back pressure during the exhaust stroke.

The value of the **design of the cam** may be, and nearly always is, lost through improper valve clearance or air-gap adjustment.

A point which suggests itself on the timing of the inlet opening, and which also holds true for other operations on the timing circle, is in the securing of a quiet cam. Quietness in the cams is generally secured at the sacrifice of power. A steep cam is as a rule more noisy and more powerful than one giving a slower opening.

To secure the full opening of the inlet valve at a point which will not be too late to permit a full charge to be taken into the cylinder, and yet at the same time to have a cam which will not be noisy, means that the inlet opening will have to be started fairly early. This is one of the points which often induces a maker to sacrifice the vacuum to some extent for the sake of quietness.

Meaning of Valve Lap

The word "lap" is often used in connection with valve-timing, as also in connection with the firing-order of cylinders.

In speaking of the **firing order** of cylinders we speak of one cylinder "lapping" another. For instance, on a certain eight-cylinder engine there are eight periods of 44 degrees travel of the crank when two cylinders are on power, or "lapping" at the same time.

The use of the word "lap" in connection with valve timing means the period of time that both valves are open at the same time, or + (plus lap).

Zero lap: If the exhaust valve closed just as the inlet valve started to open, we should term this, "zero lap" (no lap at all). "Zero lap" means that the exhaust closes at the same time the inlet valve opens. With zero lap there is no vacuum in the cylinder at time of the inlet valve opening.

Minus lap: If the exhaust valve closes before the inlet valve opens, we should term this "minus lap," designated with a (−) mark. The (−) "minus lap," which is the general condition in use on most engines, the exhaust closes an appreciable period before the inlet opens. This permits the piston to descend slightly on the suction stroke before the inlet valve opens, thus creating a vacuum in the combustion space. Therefore, the rush of gases into the cylinder is greater owing to this partial vacuum.

By referring to Fig. 6, page 32, the exhaust valve will be seen to be closed before the inlet starts to open; this would be termed (−) "minus lap."

Plus lap: If the inlet valve opens before the exhaust valve closes, it is termed "plus lap," designated with a (+) mark. The (+) "lap" means that both exhaust and inlet valve are open together for a period of the lap. In other words, the inlet opens before the exhaust closes. The theory is that the inertia or rush of exhaust gases passing out through the exhaust port is sufficiently great to create a partial vacuum, and causes a stronger inrush of fresh gas.

Owing to the fact that the exhaust and inlet gases should not conflict in their direction, the (+) plus lap is generally used on "T"-head engines.

Valve "Lag" and Valve "Lead"

If a **valve opens late or remains open** after it is supposed to close, it is said to "lag." For instance, the exhaust valve is usually allowed to "lag" about 10 degrees after leaving the top of its exhaust stroke before it closes.

The term **"valve lead"** usually applies to the valve opening before the piston reaches top or bottom center. This distance is called "lead"; and when it closes after center, this distance is termed "lag."

For instance, the setting of the spark is sometimes given a "lead," or the exhaust valve is usually given a "lead" of 46 degrees, meaning that it opens before bottom. The faster engines are designed to run, the greater the amount of "lead" or "advance" given the opening of the exhaust, and also the spark, when running.

Periods of Time Valves are Usually Open

Before taking up this subject in detail, we shall again review the relation of the speed of crank shaft to the cam shaft and get the names of the parts clearly in mind.

A stroke is the movement of the piston from the top to the bottom, or from the bottom to the top. This motion is called "reciprocating motion of the piston." When the piston goes either from top to bottom or from bottom to top, the crank shaft turns one-half of a revolution. (This does not hold true where the cylinders are offset.)

Therefore, four strokes of the piston would represent two revolutions of the crank shaft.

The **cam shaft** turns one-half as fast as the crank shaft, because the cam gear is twice the size of the crank-shaft gear which drives it.

The nose of the **inlet cam** is usually shorter on its length of face than the **exhaust cam**, because the exhaust cam holds the valve open a much longer period of time than the inlet cam holds the inlet valve open. The cams which operate the valves are steel forgings, turned and ground to correct shape. They are then case-hardened to decrease the wear, and are usually made as an integral part of the cam shaft.

The **shape of the cam** determines the actual lift of the valve and the time during which it shall stay open. The symbols, A, B, and C, over Figs. 104 to 106 (page 56) show several generally used shapes.

Cams which are pointed give a slow opening and slow closing, the greatest opening being at the middle of the valve-lift period.

Cams which are more nearly square open the valve rapidly, keep it nearly wide open until ready to close, and then allow it to close quickly.

It is customary to design the positioning of the cam shaft and valve tappets, so that the tappets are not directly over the center of the shaft, but are offset slightly on the lift side. This gives a more direct lift instead of a side thrust, as would be the case if they were centered.

In actual practice, **the inlet valve seldom opens on top,** usually after the top of stroke, varying from 5 to 15 degrees flywheel measurement as explained in Fig. 12, (page 64), which opening is 8 degrees after the top of the stroke.

The **inlet seldom closes when the piston reaches bottom,** but from 5 to 38 degrees after bottom. (Fig. 13, page 64.)

The **exhaust valve seldom opens on bottom,** but usually 40 to 50 degrees before bottom (Fig. 14, page 64).

The **exhaust valve seldom closes on top of stroke,** but usually 5 to 10 degrees after top. (In Fig. 15, page 64, the illustration shows the exhaust valve closing on top, in order that the reader may more clearly understand the illustration.)

The cam turns at the same speed as the cam shaft. The nose on the cam raises the valve. Therefore the inlet valve will be raised once during the four strokes, and the exhaust valve will be raised once during the four strokes.

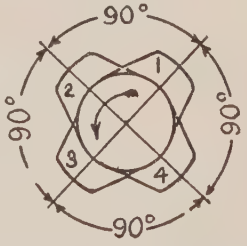

Fig. 11A. This illustration is supposed to represent the movement of the cams during a period of four strokes of the piston, as explained below and on page 33.

By referring to Fig. **11A**, the inlet cam on the first stroke will be found to be in the position of (1), and will turn from 1 to 2, or 90 degrees during the first stroke.

The exhaust cam will then be in position (2), and will turn from 2 to 3, or 90 degrees, during the first stroke.

During each stroke the cam moves 90 degrees, whereas during the same period the crank moves 180 degrees.

Inasmuch as a stroke of the piston is from top to bottom, or 180 degrees travel of the crank, it will be necessary to distinguish the difference between the time of opening and closing of the valves and the period of travel of the crank shaft during the four actions of suction, compression, explosion, and exhaust periods, as explained in the discussion that follows.

Note. When speaking of "top," it refers to **top dead center** (or upper dead center), or when piston is at the top of its stroke, and "bottom," refers to **bottom dead center** (or lower dead center), or when piston is at the bottom of its stroke.

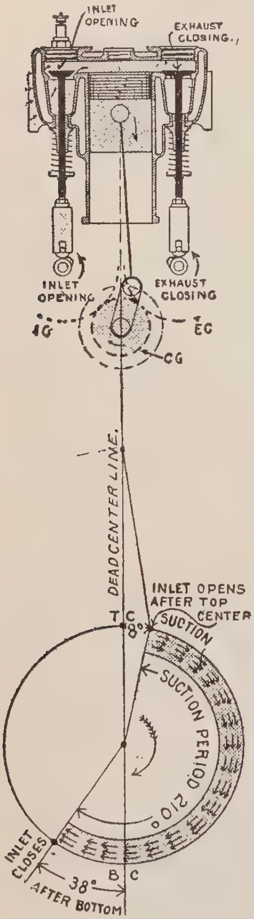

Fig. 12

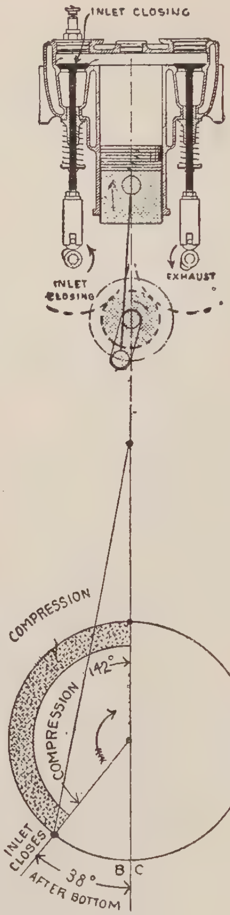

Fig. 13

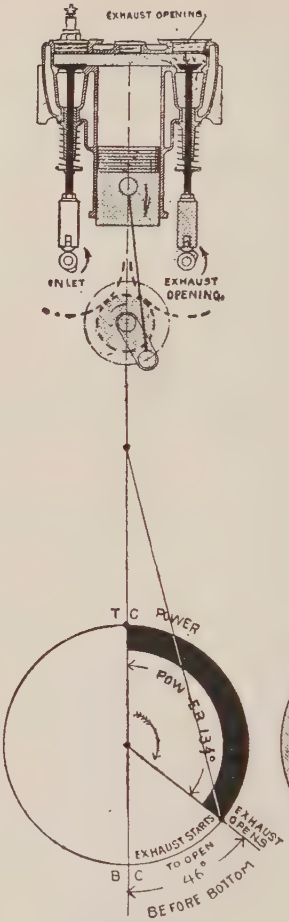

Fig. 14

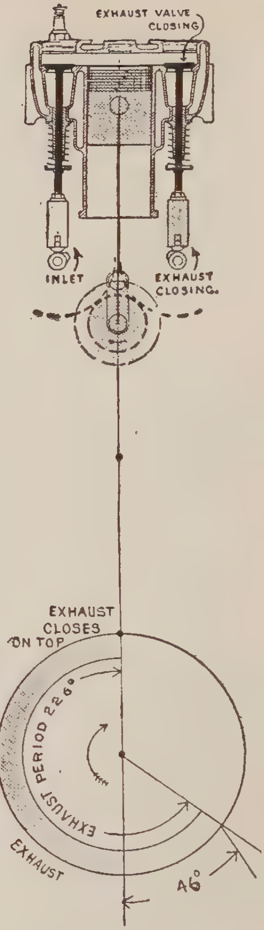

Fig. 15

Explanation of the Period of Suction, Compression Power, and Exhaust

Example: Inlet opens 8° after top, closes 38° after bottom. Exhaust opens 46° before bottom, and closes on top.

Fig. 12 shows the inlet valve starting to open 8° after top center ("TC") (viewing the engine from front); note that the inlet will remain open during the suction period until the crank is 38° after bottom center ("BC"). The period of travel of the crank during the suction period is 210°. The inlet valve is open during this period.

Fig. 13 shows the inlet valve closed. The piston will now travel up on compression to top center ("TC"). The period of travel of the crank during the compression period is 142°.

In Fig. 14, the spark occurs at top (in actual practice, just before the top), therefore, the next stroke down is a power stroke. Note that the period of travel of the crank pin during the power stroke is only 134°, as the exhaust valve starts to open at 46° before bottom. Note, too, that the exhaust cam is just starting to open the exhaust valve.

In Fig. 15, the exhaust opens 46° before the piston reaches bottom. The exhaust valve remains open during a period of 226°, the crank traveling from 46° before bottom, to bottom, thence to top ("TC"). In this instance the exhaust valve closes on top or dead center. In actual practice it usually closes a little after top dead center (about 5° to 10°).

Note. Fig. 15 shows shading of the exhaust period. This shading should extend to the right of the 46° mark.

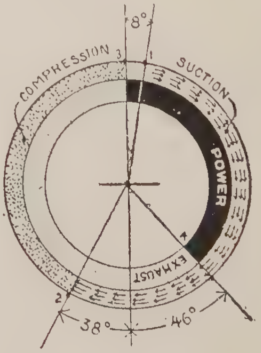

Fig. 16. Illustrates all that is shown in Figs. 12 to 15, combined in one illustration.

Observe the position of the cams during the various periods. The cam turns at one-half the speed of the crank shaft. Therefore, if the crank shaft revolves twice to complete the four strokes, the cams will make one revolution.

Valve-Timing Position

The **position of the crank shaft** determines the position of the piston.

The **position of the piston** determines the point where the valve is set to open or close.

Therefore the cam shaft must be so placed that the cam will raise the valve when the piston is at a certain position.

This is accomplished by **meshing the cam gear with the crank-shaft gear** when the piston is in correct position.

Marks are usually placed by the manufacturer on the cam gears which will indicate just where to mesh gears. The flywheel is also used for timing, if there are marks on it, which is usually the case.

It is also important to secure the proper valve clearance when timing the valve.

Setting Valves on a Single-Cylinder Engine

Suppose the valves are to be set on a single cylinder "T"-head engine, with exhaust to close on dead center, and inlet to open one-eighth inch after top on the suction stroke.

Setting the exhaust valve: First, place the piston (by turning the crank-shaft) to top dead center; then mesh the exhaust cam gear with the crank-shaft gear, so that the exhaust valve is just seating.

Setting the inlet valve: Move piston down one-eighth of an inch from top; mesh inlet cam gear with crank-shaft gear, so that the inlet valve is just starting to rise.

It will be noted that the inlet opens and the suction stroke begins right after the exhaust closes. Therefore the **closing of the exhaust and opening of the intake** is the point to work from.

A matter of importance to remember, is **the spark.** When setting valves, be sure the contact on timer or magneto is set to occur when the piston is on top of compression stroke, a full revolution from where the inlet valve starts to open. (This will be treated under "Ignition timing.")

Setting the Valves on a Multiple-Cylinder Engine

Setting the valves on a multiple-cylinder engine is identically the same operation as timing a single-cylinder engine.

If there is a multiple of cylinders, say four, then there must be at least one inlet and one exhaust valve for each cylinder. Therefore, there must be four cams for the four inlet valves and four cams for the four exhaust valves. The usual plan is to place the piston of No. 1 cylinder at the top of its stroke, and to work from that point.

If the engine cylinders are "T"-head, then there are **two cam shafts:** one for the inlet valves and one for the exhaust valves, placed on opposite sides of the cylinders.

If the cylinders are "L" or "round" head, with cam shaft on the side, then there is usually but **one cam shaft.**

Timing the Valves on a "T"-Head Multiple-Cylinder Engine

On a "T"-head engine, all exhaust cams are on the exhaust cam shaft and all inlet cams are on the inlet cam shaft. Therefore when setting valves on a "T"-head cylinder engine (Fig. 17), there are two cam gears to set, the inlet and the exhaust. If the cylinder is a four or six, or any multiple of these, setting, or meshing the cam shaft gear with the crank-shaft drive gear so that one cylinder is correctly timed, is all that is necessary, as the other cams are fastened permanently on the cam shaft, and must open and close all other valves at the correct time.

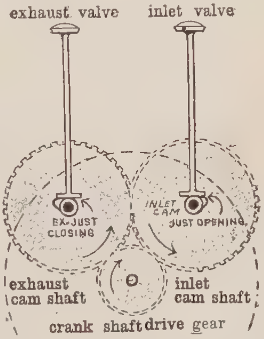

Fig. 17. View from front of engine.

For example, suppose the inlet valve opened on top dead center and the exhaust closed on top dead center. The piston of No. 1 cylinder (front of engine) would be placed at the top dead center of its stroke and the cam gears would then be meshed at this position.

The **setting of the inlet cam gear** would be such that the nose of the inlet cam was just starting to raise the inlet valve in the direction of rotation (see Fig. 17).

The **setting of the exhaust cam gear** would be such that the nose of the exhaust cam was just permitting the tappet to leave the stem of the exhaust valve (Fig. 17).

Timing the Valves on an "L"-Head Multiple-Cylinder Engine

To set the cam for valve opening on an "L"-head cylinder, it is only necessary to set the one cam gear, which is the exhaust cam, at the closing point (see Fig. 18). If the engine has a multiple of cylinders all other cams will then operate as they should, as all exhaust and all inlet cams are on the one cam shaft and are set permanently when the cam shaft is made.

MARK ON FLY WHEEL "EC" TO BE IN LINE WITH MARK ON CYLINDER
EX.CAM JUST LEAVING EX.VALVE.
cam shaft gear
crank shaft gear
FLY WHEEL.

Fig. 18. View from front of engine.

The usual plan is to place No. 1 piston in the position where the exhaust valve is to be closed, and mesh the cam-shaft gear with the crank-shaft drive gear at this point. Although it is only necessary to set the exhaust cam so that the exhaust valve will close, on an "L"-type engine, there are marks on the fly wheel which are used for checking the timing. This is explained farther on.

Timing Valves on an "I" or Round-Head Type of Engine

The **overhead valves** are usually operated by push rods, all from one side of the engine and from one cam shaft. Therefore the timing would be the same as for an "L" head.

With an **overhead cam shaft,** the valves are usually operated by one cam shaft. Therefore the principle is the same.

Remarks

It is well to note that even though there are four, six, eight, or twelve cylinders, each of the pistons must pass through the four strokes during two revolutions of the crank shaft, even though two of the cylinders are firing at once during part of the time (which they are in a six, eight, and twelve cylinder engine).

Just how these four strokes are made by each piston during two revolutions of the crank, is explained under "Firing order," farther on.

In a **four-cylinder engine,** remember that, owing to the shape of the crank shaft, pistons 1 and 4 are always up or in line when 2 and 3 are down, or vice-versa. In a **six-cylinder engine,** pistons 1 and 6, 3 and 4, and 2 and 5 are in line.

Before timing the valves on No. 1 cylinder, adjust the valve clearance on this cylinder.

After completing the valve timing on No. 1 cylinder, adjust the valve clearance on the remaining cylinders.

Timing Marks on Flywheel

Usually marks also appear on the circumference surface of the fly wheel, which indicate the position in which the crank shaft is to be placed for correct setting of valves and meshing of cam gear and crank-shaft gear.

The mark on the flywheel is placed in line with a center mark (or a "trammel," also called an "indicator," or a "pointer") on the cylinder, or elsewhere.

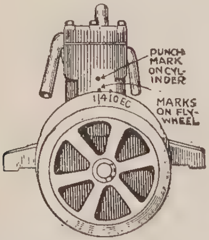

Fig. 19

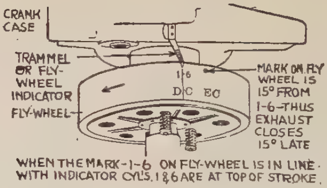
Note. On engines with unit power plants, instead of the center line being on the cylinder, a small hole at the top of the fly-wheel case is provided, in order that the line and figures on the fly wheel can be seen through the hole.

Valve-Timing "Indicator" or "Trammel"

A trammel or indicator is a stationary starting point on which to base all work. It is sometimes attached to the base of a cylinder or other point, instead of a center line on the cylinder. It is usually directly over, or in front of, the fly wheel, as in Fig. 20 (flywheel indicator).

Example of timing the valves on an "L"-head six-cylinder engine by marks on the flywheel: The exhaust valve closes at 15° past top. It is not necessary to know this, however, as the marks are all that is necessary to follow.



CRANK CASE
TRAMMEL OR FLY-WHEEL INDICATOR
FLY-WHEEL
1|6
D|C EO
MARK ON FLY WHEEL IS 15° FROM 1-6—THUS EXHAUST CLOSES 15° LATE
WHEN THE MARK-1-6 ON FLY-WHEEL IS IN LINE WITH INDICATOR CYL'S. 1 & 6 ARE AT TOP OF STROKE.

Fig. 20. Showing the purpose of an "indicator" or "trammel" as applied to a 6-cylinder engine.

Procedure: When the long mark 1-6 on the fly wheel is in line with "indicator" on the crank case, pistons Nos. 1 and 6 are at their highest points or upper dead center. After turning the fly wheel to this mark, then turn the fly wheel to the left (when behind it) until the small dot mark is under the indicator. This is the point (15°) at which to set the exhaust valve, just closing, and at which point the cam gear should mesh with the crank-shaft gear. Therefore it is plain that setting the exhaust valve just closing, on a 6-cylinder engine with valves on the side, is all that is necessary.

Variation of Valve-Timing Marks (on Fly Wheel)

Sometimes the **marks may vary.** For instance, instead of "1-4 UP" or "1-4 DC," it may appear as, "T C 1-4" (top center 1-4) or "U C 1-4" (meaning upper dead center), or some similar mark meaning the same thing.

Some manufacturers vary their marking on the rim of the fly wheel as follows: Inlet opens "IN-O" or "I. O." Inlet closes "IN-C" or "I. C."

Exhaust opens "EX-O" or "E.O." or "X.O." Exhaust closes "EX-C" or "E.C." or "X.C."

If the figures 1-4 or 2-3 appear after or before any of these marks, as "1-4-IO.," this means the number of the cylinders, as "1 and 4, inlet opens."

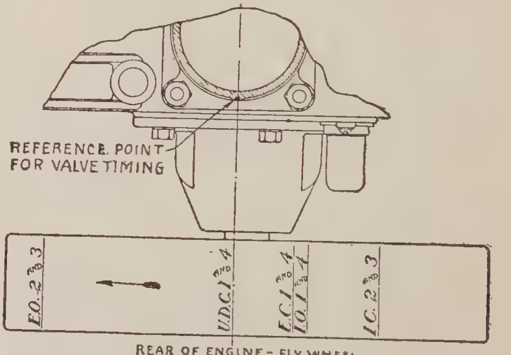


Fig. 20A. Valve-timing marks on the fly wheel of a Reo four-cylinder engine.

For an example of valve-timing marks on a four-cylinder engine fly wheel, see Fig. 20A. Here the engine fly wheel has upon its face the following marks:

I. O., meaning, inlet valve opens.
I. C., meaning, inlet valve closes.
E. O., meaning, exhaust valve opens.
E. C., meaning exhaust valve closes.
U.D.C., 1 and 4, upper dead center; cylinder 1 and 4.
U.D.C., 2 and 3, upper dead center; cylinder 2 and 3.

These points, marked upon the face of the wheel, show where the exhaust and inlet valves of each cylinder should open and close. A reference point (the small boss marked with a cross upon cylinder No. 4, next to dash), is used in this instance, instead of an indicator.

The engine cylinders are numbered 1, 2, 3, and 4, No. 1 being next to the radiator, and No. 4 next to the dash. By referring to Fig. 38, page 45 of crank shafts, previously given, it will be seen that cranks 2 and 3, and 1 and 4 are exactly 180 degrees apart. Therefore the same marking on the flywheel that serves for No. 2 also serves for No. 3, and the marking for No. 1 serves for No. 4, these points being exactly one-half revolution, or 180 degrees, apart, as before mentioned.

Checking the Valve Timing

Although it is only necessary to set the exhaust cam so that the exhaust valve will just close, on an "L"-type of cylinder engine there are marks on the fly wheel which are used for checking the timing.

As an example, a four-cylinder "L"-type engine is used (Fig. 21), with timing scale as an example of checking the timing, as follows:

Dead center of cylinders 1 and 4 are marked on fly wheel "1-4."

Dead center of cylinders 2 and 3 are marked on fly wheel "2-3."

Inlet valve opens 5° past top center, marked on fly wheel "1-4 IN. O."

Inlet valve closes 40° past bottom center, marked on fly wheel "1-4 IN. C."

Exhaust valve opens 40° before bottom center, marked on fly wheel "1-4 EX. O."

Exhaust valve closes 7° past top center, marked on fly wheel "1-4 EX. C."

The same marks appear for cylinders 2 and 3.

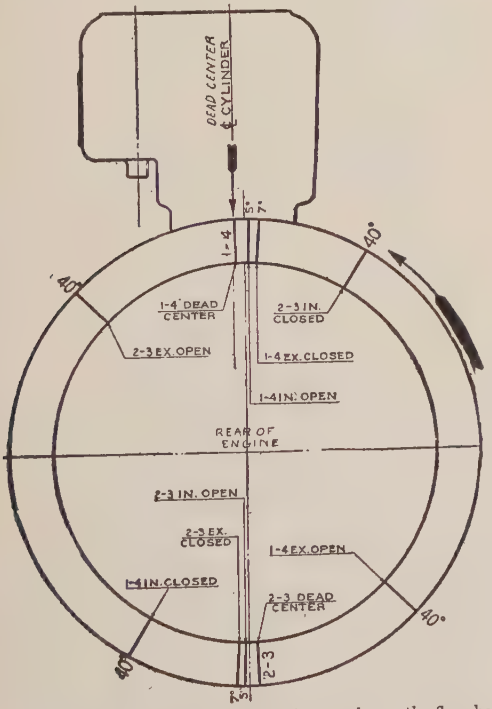

Fig. 21. An example of valve-timing marks on the fly wheel of a four-cylinder engine. See text for checking valve timing from these marks. View from rear of engine. Note that the fly wheel turns to the left.

The purpose of checking the valves is to see that they are opening and closing as marked on the fly wheel.

To determine whether or not the valves are properly timed, first open the relief cocks on top of the cylinders, then have someone crank the engine over slowly until the line marked "1-4" is opposite the center line of the cylinders. At this point the exhaust valve in either No. 1 or No. 4 cylinder should just commence to close. It will be the case in one or the other.

If you find that the exhaust valve in No. 4 cylinder is beginning to close and you wish to check up the valve timing in No. 1 cylinder, turn the fly wheel around to the left (standing in rear of engine) one complete revolution, until line "1-4" is again brought opposite the center line of the cylinder; then continue slowly turning the flywheel about three-quarters of an inch farther to the left until the line marked "7° (1-4 EX. C.)" coincides with the center line of the cylinders. This is the point at which the exhaust valve in the No. 1 cylinder should just seat itself or close.

To determine whether or not the valve is seated, see if the tappet or push rod underneath the valve can be turned with the fingers. If the tappet turns freely, the valve is seated; but if the tappet is hard to turn, that will show that the valve is still being held slightly open. If this is the case, loosen the lock nut on the tappet screw, and turn the screw down until the valve has the proper clearance, then turn the lock nut down tight against the tappet.

When the valves are closed there should be a clearance between the end of the valve stem and the tappet screw of from .003 to .005 of an inch. This amount of clearance is necessary to allow the valve to seat tightly.

Note. The opening and closing time of a valve is not when the lifter begins to rise or comes to rest, but when it makes or leaves contact.

To check the timing of the inlet valve in No. 1 cylinder, turn the fly wheel slightly to the right until the line "1-4" is in line with the center of the cylinders, and then turn the fly wheel about one-half an inch to the left until the line marked "5° (1-4 IN. O.)" coincides with the center line of the cylinder. At this point the inlet valve should just begin to open.

Continue turning the fly wheel half a turn to the left, stopping when the line marked "40° (1-4 IN. C.)" comes in line with the center of the cylinders. At this point the inlet valve should just close.

To see if the exhaust valve in No. 1 cylinder opens at the proper time, revolve the fly wheel still farther to the left, and stop when the line "40° (1-4 EX. O.)" comes up in line with the center of the cylinders. This is the point where the exhaust valve in No. 1 cylinder should just begin to open. This operation completes the checking of cylinder No. 1, with the exception of the **exhaust closing,** which can be checked by the 7° mark "(1-4 EX. C.)" being in line with the dead center line of the cylinder.

To check the timing of cylinder No. 2, turn the fly wheel until the line marked "2-3" is in line with the center line of the cylinders. If the exhaust valve in the No. 2 cylinder is closed, turn the fly wheel through one complete revolution, until the line "2-3" is up again; the exhaust valve in No. 2 cylinder should then be just starting to close. Proceed now the same as in timing the No. 1 cylinder. The valves in cylinders No. 3 and No. 4 are timed in the same manner.

Cylinders Nos. 1 and 4 are timed from the center line "1-4"; 5° to the left for inlet opening, and 7° for exhaust closing, and cylinders No. 2 and 3 from the line "2-3"; 5° to the left for inlet opening and 7° for exhaust closing.

It is advisable, when checking the opening and closing points of the valves with the marks on the flywheel, to make a note of the variation of each of the valves from the marks in the fly wheel.

Then, after all the valves have been checked, you can compare the variations for the different valves and in this way determine whether the variations are due to the large time gear on the end of the cam shaft not being properly set with relation to the timing gear on the end of the crank shaft, or to wear in any particular cam or valve tappet. A variation, not to exceed one-half of an inch either way from the lines on the fly wheel, is permissible, and will not make any material difference in the timing of the valves. If the variations exceed this and are uniform for the different valves, the correction should be made by resetting the cam-shaft gear.

Note. If one person feels the tappet head of the valve which is being checked, while another slowly pulls the fly wheel round in its proper direction of motion, the precise moment at which the valve commences to lift can readily be determined by the binding of the tappet head against the stem of the valve.

HOW TO CONVERT DEGREES ON THE RIM OF THE FLY WHEEL TO INCHES[1]

The following table is provided for converting degrees into fractions of an inch. For example, if a certain engine is to be timed when the inlet opens, say 10° after top of stroke, and there are no marks on the fly wheel to indicate this position, by referring to this table the distance in inches to measure on the fly wheel from upper dead center mark can be found.

It will be necessary however, to know the diameter of the fly wheel. Suppose the fly wheel is 17 inches; refer to first column and find 17, then go out to column under 10° and you have 1.48 (one and forty-eight one-hundredths of an inch). This would represent the distance to measure for the inlet opening mark on the fly wheel. Forty-eight one-hundredths (.48) is not so easy to measure on the rule. Therefore refer in the conversion table below, to .48 and note it is equal to 31/64 of an inch. Therefore we would have 1 34/64″.

Another example: What would 2½° represent in inches on a 17-inch fly wheel? Procedure: find 17, go out to column under 2°, and we find .30. Put this down. Refer to the conversion table and note .30 = 19/64. Now refer back to the column headed 1°, and we find .15, which is equal (below), to 5/32″ or 10/64.″ One-half of 10/64″ = 5/64″. Therefore 2°, or 19/64″ + 5/64″ = 24/64″ = ⅜″.

HOW TO MARK A FLY WHEEL IN DEGREES AND INCHES

Most fly wheels of engines are marked in some manner. If, however, you know in degrees what timing to give an engine, and if the flywheel is not marked, then with the assistance of the table on page 68, the markings can be punched on the cylinder with a center punch.

The first procedure would be to make a punch mark, or place an "indicator" at the base of the rear cylinder (**A**), Fig. 23. Be sure it is exactly in the center of the cylinder (see Fig. **20A**, page 66); however, when the piston is on top dead center when the indicator is being located, it could be placed to one side, as on the Reo.

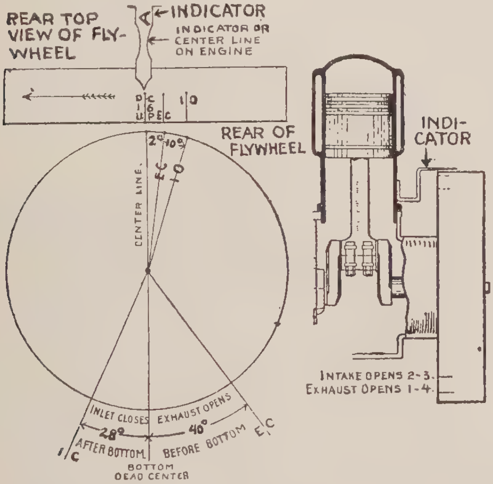

Fig. 22. (Left.) Looking down on top of the flywheel when standing in rear of it.

Fig. 22. (Right.) Side view.

Next, place the piston of No. 1 cylinder at the top dead center of its stroke.

Next, punch a mark or line on the flywheel directly in line with the indicator. Mark this line "DC-1-6," meaning that the pistons of cylinders 1 and 6 are at the top, or dead center. (We shall assume that it is a six-cylinder engine. If a four-cylinder, mark "DC-1-4".)

Suppose the **valve timing** is as follows: Exhaust valve closes 2° past top and opens 40° before bottom, and inlet valve opens 10° after top and closes 28° after bottom, as measured on the fly wheel, which is the usual method of following degree marks (Fig. 22).

The next procedure is to measure the diameter of the fly wheel. Suppose it measures 14″. Refer to the table (page 68) and find 14 in the first column under "Diam. Wheel." Note that 2° measured on the circumference of the fly wheel would be .24 (twenty-four one-hundredths of an inch). Refer to the conversion table in the same table, lower down on the page, and note that .24 is equal to 15/64 of an inch. Now, make another mark 15/64 of an inch to the right of the mark "DC-1-6," and mark it "EC" (exhaust closes).

Note. Looked at from the front of an engine, the fly wheel revolves clockwise, or to the right. Looked at from the rear of engine, which is the position from which we are looking at the engine in Fig. 22, the flywheel revolves counter-clockwise, or to the left.

When the flywheel is moved to the left so that the mark "EC" comes in line with the indicator, the "EC" represents a 2° movement of the flywheel, and the piston would be slightly down on its stroke from the piston dead-center position and the exhaust valve would just close.

If the engine was an "L"-head cylinder type, this marking would suffice, as the cam-shaft gear is usually meshed with the crank-shaft gear at the position where the exhaust closes.

If the engine was a "T"-head cylinder type, the inlet cam shaft would have to be timed as well as the exhaust. In our example (Fig. 22) the inlet valve opens 10° past top. Refer to the table and note 10° on a 14″ flywheel is 1.22 (one inch and twenty-two one-hundredths of an inch). Refer to the conversion table and note that .22 is equal to 7/32 of an inch. Now make another mark on the fly wheel 1 7/32 of an inch to the right of the mark "DC-1-6," and mark it "IO" (inlet opens).

When the flywheel is moved to the left so that the mark "IO" comes in line with the indicator, the "IO" represents a 10° movement of the fly wheel, and the piston would be slightly down on its stroke from piston dead-center position and the inlet valve would just begin to open.

The inlet cam-shaft gear is meshed with the crank-shaft drive gear at this position.

Marking of the position of other pistons on the fly wheel can be made in the same manner. This is not necessary for timing, but it is necessary for checking the timing.

Another Method of Marking a Flywheel in Degrees

Although the table on page 68 shows how to find in inches or a fraction thereof just where to mark a flywheel in degrees, another method is given below. Suppose there are no timing marks on the flywheel and you desire to mark it so that the exhaust valve closes 10° after top dead-center (see Fig. 23).

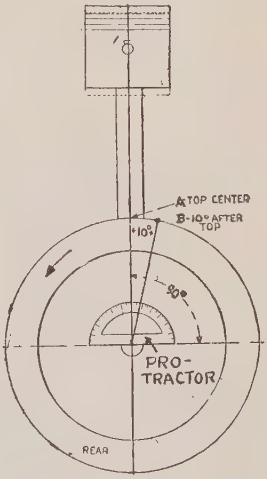

Fig. 23

Set the engine so that the piston in No. 1 cylinder, namely the cylinder nearest the radiator, is at the top of its stroke. With the use of the protractor or with a square, make a mark at **A** on the rim of the flywheel, on the inner edge, which mark will be directly above the center of the crank shaft when the piston is at top of its stroke.

Then, with the protractor placed against the flywheel so that the 90° mark points directly toward mark **A**, go 10° to the right on the protractor (standing in rear of engine), and then make a mark at **B** on the flywheel. This mark will be 10° to the right of mark **A**. Now turn the fly wheel until mark **B** is at top center.

With the engine in this position mesh the timing gears so that the exhaust valve of No. 1 cylinder is just closing.

It is understood that when standing behind the fly wheel it would turn to the left, as shown by the arrow point. Therefore, the piston must first reach top center (**A**) with the exhaust valve still open, and travel 10° farther to (**B**) before it closes.

This method is inaccurate. The method described under Fig. 22 is preferable.

To Locate Position of Piston

In the previous matter we have considered placing the piston on top dead center of the compression stroke. How to tell when the piston is on top of the compression stroke is explained below.

Usually a mark is placed on the fly wheel to indicate when the piston is at top of its stroke. For instance, in a four-cylinder engine, a mark will probably be on the fly wheel, such as "DC 1-4," meaning "dead center up 1 and 4," or pistons 1 and 4 are at top of stroke. In a six-cylinder the mark would probably appear as "DC 1-6 up," meaning pistons 1 and 6 are on top. Or the mark may be "1-4 up," or "1-6 up," meaning the same. These marks on fly wheel are placed in line with the center mark on the cylinder, or in line with an indicator. After finding the top, by moving the fly wheel to the right, the piston is placed before top; if moved to the left, it is placed after top.

On a four-cylinder engine, when No. 1 piston is on top, No. 4 is on top also. On a six-cylinder engine, when No. 1 is on top, No. 6 piston is also on top.

It is necessary, however, to find just what stroke pistons 1 and 4 or 1 and 6 are up on. Therefore watch the valves.

When No. 1 piston is at top on compression stroke, both valves would be closed; the exhaust cam of No. 4 would just be at the point of closing the exhaust valve; the inlet cam of No. 4 would be at the point of just starting to open No. 4 inlet valve, because when No. 1 starts down on power, No. 4 (or No. 6, if a six-cylinder engine) would have just completed its exhaust stroke and would start down on the suction stroke.

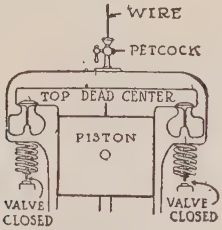

Fig. 24

If the engine happens to be a "T"-head engine with a compression cock in the center and there are no marks on the fly wheel, it is easy to find when the piston is on top by placing a wire or bicycle spoke through the pet cock and turning the engine over; when the wire rises to its highest point the piston is on top of dead center (Fig. 24). The next point is to find if it is on top of compression stroke, which position will be indicated by the position of the cams, as explained above.

If a cylinder is of the "L"-head type, and the fly wheel is not marked, it may not be possible to get a wire into the cylinder. In this case open the compression cock and place your finger over it; have someone crank the engine slowly until you feel compression; let this escape gradually. When the gas has ceased escaping, the piston is at or near top dead center. The compression stroke is found by watching to see when both valves are closed.

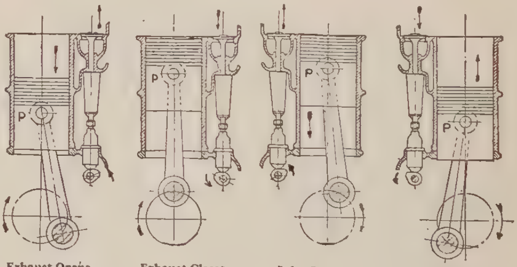
Another plan is to remove the lower crank case and turn the crank until the connecting rod is in a perfectly vertical line; at the same time watch the valves, as mentioned above.

Example of Valve Timing with Position of Piston

The illustrations below represent the **valve timing of the Locomobile "38" and "48" six-cylinder "T"-head engine.** The figures below are expressed in inches of piston travel from dead centers. Degrees are also mentioned.

To speak of timing an engine in inches of piston travel means that we set the valves to open or close when the piston is in a certain position with respect to the cylinder. For example: to set the exhaust valve to close ⅛" past top dead center, bring the piston to top dead center of the exhaust stroke; turn the engine in the normal direction of rotation until the piston has descended ⅛" on its stroke; set the valve to close at this point. These measurements may be made by means of a wire inserted through the pet cock, as shown in Fig. 24.

Speaking of timing an engine where the timing is expressed in degrees refers to the degrees motion of the crank shaft or flywheel. For example: to set the exhaust valve to close 10°27′ past top dead center, bring the piston to top dead center of the exhaust stroke; turn the engine in the normal direction of rotation a distance of 10° 27′, as measured on the flywheel, and set the valve to close at this point.



Exhaust Opens **Exhaust Closes** **Inlet Opens** **Inlet Closes**

Fig. 25. Relative position of piston to the opening and closing of valves (Locomobile).

"38"—exhaust opens .780" before bottom center, or 52°33′; closes ⅛", or 10°27′, past top center. Total exhaust opening is 248°59′.

"38"—inlet opens at top center; closes .67" or 48°3′ past bottom center. Total inlet opening is 228°3′.

"48"—exhaust opens 3/4" before bottom center; closes top center.

"48"—inlet opens 3/32" past top center; closes ¾" past bottom center.

Note. Locomobile "48" two-spark engine varies from the "48," in that the exhaust closes on top and the inlet opens 3/32" past top. The "38" was discontinued in 1918.

Hudson Valve Timing in Inches

The timing of the **Hudson "Super-Six" six-cylinder "L"-head engine, measured according to piston travel:**

Fig. 26—inlet opens 1/64" after top dead center.

Fig. 27—inlet closes 17/32" after bottom dead center.

Fig. 28—exhaust opens 57/64" before bottom dead center.

Fig. 29—exhaust closes 1/32" after top dead center.

The wire used for these measurements should be exactly 5 1/16" long.

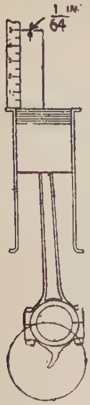


Fig. 26

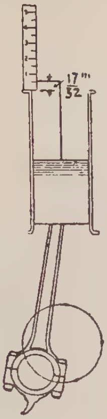

Fig. 27

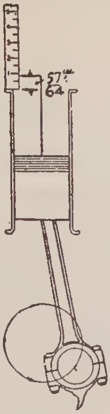

Fig. 28

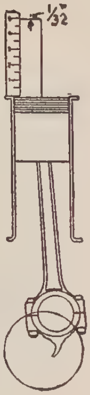

Fig. 29

The timing of the **Hudson in degrees relative to the movement of the flywheel:**

Intake opens 7° after top dead center; closes approximately 42° after lower dead center;

Exhaust opens about 55° before dead center; closes 8° after top dead center.

Dodge Valve Timing

Valve timing of the Dodge four-cylinder "L"-head engine: First see that the valve lifter or tappets are properly adjusted, which is .003 clearance for inlet and .004 for exhaust. Then turn the crank shaft clockwise until the top of piston No. 1 is 1/16" above the top of the cylinder on exhaust stroke, after passing top d.c. Turn the cam shaft counter-clockwise until No. 1 exhaust valve is just fully closed. Gears are then meshed. The **inlet opens** 10° after top and **closes** 35° after bottom; **exhaust opens** 45° before bottom and **closes** 8° after top. **Fly wheel** is 16¼" diameter for cars using a cone clutch and 15½" diameter for cars using the disk clutch. A degree on the larger wheel spans a distance of 0.1418", and on the smaller wheel, 0.1353".

To assemble timing gears on the Dodge: Turn the crank shaft clockwise until the top of No. 4 piston is ⅝" (or 5°) below top of the cylinder, on the compression stroke. Then rotate the cam shaft counter-clockwise until No. 3 exhaust valve is ready to open. The crank-shaft and cam-shaft gear should then be meshed so that the single punch mark in the latter is between the two on the former.

Timing the Valves of the 1921 Buick Six-Cylinder Engine

The exact point in the cycle at which the valves are opened and closed is determined by the shape of the cams which operate them and by the angular relation between the cam shaft and the crank shaft. If it should ever become necessary to remove one of these shafts or the gears which drive them, they must be replaced in proper relation to one another or the valves will be "out of time." To obtain this relation, the punch-marked tooth on the crank-shaft gear (Fig. 30) should be set to match with the punch-marked space on the cam-shaft gear.

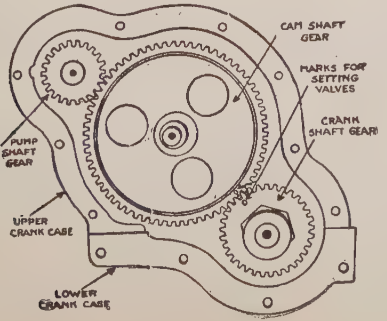

Fig. 30

Adjusting Buick-Six Push Rods

With the timing gears properly meshed, **the final setting of the valves can be made** by adjusting the push rods (valve rods), to proper length by means of the adjusting ball ends and lock nuts.

In making this adjustment, turn the engine by hand, in a clockwise direction, until the line marked "1 and 6" on the flywheel, comes into line with the line on the rim of the inspection hole. This is the firing position for cylinders Nos. 1 and 6, numbering from the radiator back, and one or the other of these cylinders will be found to have both valves closed, so that both rocker arms will have a slight amount of play.

The push rods for these rocker arms should then be adjusted from the back of the cams and while the engine is warm (see instruction plate on side of engine), so as to give .010" clearance between the end of the valve stems and the rocker arms. This is approximately the thickness of a sheet of heavy paper or very light card.

Push rods for the other cylinders may be adjusted in the same manner. Best results will be obtained if these adjustments are made while the engine is idle.

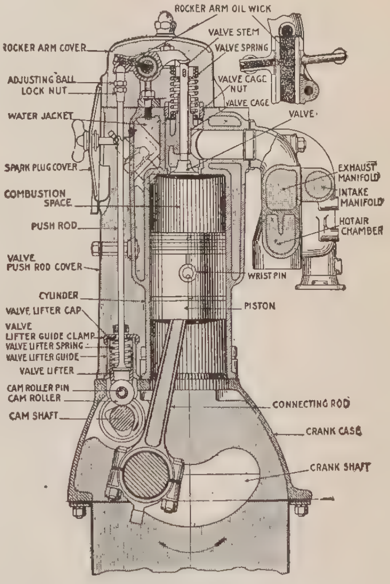

Fig. 31. The Buick six-cylinder engine has both inlet and exhaust valves placed in-the-head of the cylinder and is a typical modern type of engine with valves-in-the-head. The valves are in cages which can be removed for grinding.

One half-teaspoonful of kerosene inserted around the valve stem at least once a week while the engine is running will keep the valve free from carbon and prevent it from sticking in the valve cage.

In setting the marks on the flywheel be careful to turn the motor only in a clockwise direction, otherwise the backlash in the timing gears will affect the result. Caution: If adjustment is made while the engine is cold, the expansion of the push rods when the engine gets warm will cause the valves to be held open.

Grinding Buick-Six Valves

To keep the engine up to its maximum efficiency, the valves must be gas tight when closed. When **leakage occurs** the valves should be ground as follows: Compress the valve spring and lift the push rod out of the socket in the valve lifter. Loosen the valve cage nuts with the special drift furnished in the tool kit and remove by unscrewing. A light tap with a hammer on the end of the valve stem will loosen the cage so that it may be withdrawn. Be careful not to injure the small bronze packing ring on top. Remove the valve spring and after cleaning with gasoline or kerosene, smear the valve and its seat with fine emery flour and oil or with one of the grinding pastes now on the market. **Grind** by turning the valve back and forth on its seat until both valve and seat show a bright ring 1/32″ wide all the way around.

Be careful to clean out all traces of abrasive material before replacing valve. After grinding valves, it will usually be found necessary to readjust the push rods to compensate for the wear. For Buick ignition timing see the Index.

THE TIMING GEARS; FRONT END DRIVE SYSTEM BY GEARS

The cam shaft can be driven by **gears** or a **silent chain.** This subject relates to a gear driven front end system.

Since the position of the cam shaft is always the same with reference to the pistons (because the cam shaft is always in mesh with the crank-shaft gear), and since the cams are all integral parts of the shaft, the valve timing cannot change. If the gears are ever removed, they may be put back in the proper position by seeing that the marks on the edges of the teeth "dovetail" together.

If you find that the marked teeth do not come together, do not jump at the conclusion that the gears are improperly set, but first verify the setting by checking the timing of the valves with the marks on the flywheel.

If the timing of the valves of an engine is not correct, it is then necessary to re-mesh or re-set the timing gears. It will be necessary to place the piston of No. 1 cylinder at top of its stroke. Then remove the gear cover and turn the crank until the "EX. C" (exhaust closing mark of cylinder No. 1) is in line with the center mark on the cylinder (in rear).

Note. On engines with unit power plants instead of the center line being on the cylinder, a small hole at the top of the flywheel case is provided so that the line and figures on the flywheel can be seen through the hole. See Index for Continental engine, showing location.

Now remove the cam gear from its shaft and turn the cam shaft in its direction of rotation (it is the opposite of the direction of rotation of the crank shaft), until the exhaust valve on cylinder No. 1 is just closing; keep the cam shaft in this position; replace the large cam gear on the end of the cam shaft, properly meshing it with the gear on the crank shaft.

There are usually punch marks stamped on the gear teeth, as shown in Fig. 32. On some engines, figures are stamped on the gear teeth, as in Fig. 33, and, in some instances, a letter "O" or "C." These marks are stamped between the two teeth of one gear and in the center of a tooth in the other gear, both of which should be carefully noted when meshing the gears. At this point the valves are supposed to be correctly timed.

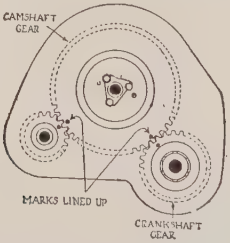

Fig. 32. Note the crank-shaft gear mark which meshes with the cam-shaft gear mark. On the left side a mark on the cam shaft is meshed with a mark on the gear which drives a magneto and which must be timed the same as the cam shaft. The magneto, however, is usually timed or set by loosening its coupling from the shaft with which it connects. See Index under "Setting the magneto."

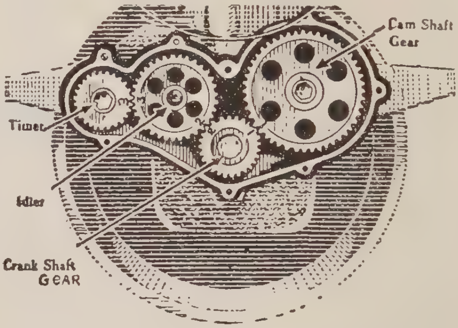

Fig. 33. Note the meshing of the crank-shaft gear mark (1) between the two teeth on the cam-shaft gear mark (1). Also observe that in this instance (Overland model 85), there is an idler gear interposed between the crank-shaft gear and the gear which drives the ignition timer. This idler gear runs free and is used to obtain a correct ratio and to drive the timer shaft. It must be meshed as shown when the ignition timer is in proper position, as will be explained under "Ignition timing."

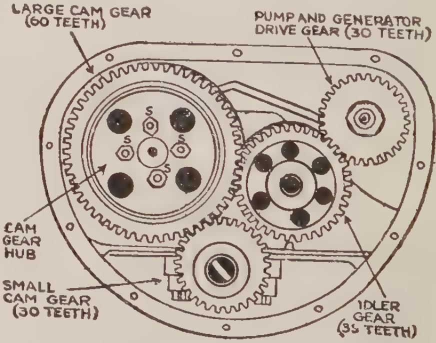
Example of Setting the Cam Gear on the Reo Models "T 6" and "U 6"

The illustration (Fig. 34) **shows the timing gears** (with cover removed) and the relation which they bear to one another.



LARGE CAM GEAR (60 TEETH)
PUMP AND GENERATOR DRIVE GEAR (30 TEETH)
S
S
S
S
CAM GEAR HUB
SMALL CAM GEAR (30 TEETH)
IDLER GEAR (35 TEETH)

Fig. 34. Gears on the front of the Reo model "T6" and "U6" engine.

The small cam gear (usually termed "crank-shaft gear") is keyed to the crank shaft and revolves with it. This gear has 30 teeth.

The large cam gear is fastened rigidly to the cam shaft by four studs (S) and lock nuts. This gear has 60 teeth and, therefore, revolves just half as fast as the crank-shaft gear and in the opposite direction.

The pump and generator-drive gear has 30 teeth, and is driven through the idler gear at the crank-shaft speed, but in the opposite direction to that of the small cam gear. One of the studs is marked with a center punch so as to insure correct replacement, should the gear for any reason be removed.

The teeth of the large cam gear and the one on the crank shaft are also given center punch marks for meshing reference. These markings should dovetail.

The teeth of the idler gear and the one driving the water pump and generator are not marked, and can be meshed at any point.

If the timing gears are assembled as described above, the timing must be correct.

In case a new gear is assembled on the engine, the following may be of some assistance in obtaining the correct timing or setting:

Cam gear setting: The fly wheel on this engine is of such diameter as to require its turning through an angle of approximately seven degrees to produce a one-inch movement of its face with respect to some fixed point.

Now, since the error in cam setting must not exceed one half-inch, this movement is equivalent to 3½° movement of the flywheel or crank shaft.

If, for any reason, the valve closing is not within this limit, the setting may be corrected in the following manner:

The large or 60-tooth cam gear (and with it, of course, the cam shaft) would move 6°, or 360 divided by 60, if shifted one tooth; this is the equivalent of 12° on the fly wheel or crank shaft, since, it will be remembered, the gear on the crank shaft has but 30 teeth.

If one inch on the flywheel is equivalent to 7°, 12° would represent approximately a 1¾″ movement of the flywheel.

If the cam openings were off two inches on the fly wheel, it would be a simple matter to change the meshing of the cam gear one tooth in the direction required, and to have an error of ¼″, which would be within the ½″ limit.

If, however, the error of the cam shaft was but 1″, it would be impossible to get nearer than ¾″ by shifting this gear one tooth, which is ¼″ in excess of the limit desired. Means must, therefore, be provided for shifting the gear a fraction of a tooth, or, in other words, a fraction of 6°.

For example, if the gear had 54 teeth instead of 60 teeth, this could be accomplished by removing the gear from the shaft and shifting the former one quarter-turn; 54/4 equals 13½, which would, in effect, be the same as shifting one half-tooth. In order to obtain a shift of one half-tooth (3°) with a gear of 60 teeth, two of the four studs which hold the cam gear to the cam shaft are placed 3° off of the 90° center lines and three of the holes in the cam-gear flange are slotted, the fourth being a tight fit over the stud.

Therefore, if the gear is taken off and shifted 87° or 93°, the effect is the same as changing the meshing of the gear one half-tooth. We shall have changed the relative position of the gear teeth to the cam shaft just 3°, this being equivalent to 6° on the flywheel, or approximately ⅞″. This arrangement gives this engine a means whereby the greatest variation in cam-shaft setting may never exceed ½″.

Valve Timing of Reo

The fly wheel of the engine has upon its face the marks: "U.D.C.1 & 6," meaning upper dead center, cylinders 1 and 6; "INTAKE OPEN 1 & 6," meaning that the intake valve in No. 1 or No. 6 cylinder commences to open; "SPARK," meaning that a spark should take place in No. 1 or No. 6 cylinder with the spark fully retarded.

These markings on the face of the fly wheel register with the top of the right-hand motor support. The spark occurs 1½″ late at full retard. The intake valve opens at the upper dead-center point. Since the cranks for cylinders Nos. 1 and 6 are on the same side of the center, it will be understood that the marks which serve for cylinder No. 1 also apply to No. 6.

To check valve setting: First screw out the spark plug from each cylinder, thereby relieving compression and permitting the engine to be turned over easily. Selecting No. 1 cylinder (it being the most convenient), crank the engine slowly with the hand crank until the inlet valve for this particular cylinder just commences to open. This can be determined by placing a piece of fine tissue paper between the inlet valve stem and its lever. When there is just sufficient pressure of the lever on the valve stem to prevent withdrawal of the paper, the inlet valve is commencing to open. At this moment the marking "INLET OPENS 1 & 6" on the face of the flywheel should not be more than ½″ either way from the top of the right-hand engine support. Before checking the valve setting, it is important that all backlash of the valve tappets be removed.

If one cylinder checks, it will not be necessary to check the valves in the other cylinders, as the cam shaft is accurately ground and the cams are in correct relation to one another.

Relation of Valve Clearance and Valve Timing, and Meshing of the Timing Gears

After your engine has been overhauled a few times the cam-shaft gear will have developed a dozen or more meshing marks. Each workman will have added a few marks that may or may not be right and changed a few that were right, until finally it is hopeless to match any of them.

This need not seriously inconvenience you, for if you understand valve timing, you can forget the gear marks and work entirely from the fly-wheel marks.

A "trammel" is a stationary starting point from which to base all your work (see Fig. 20, page 66). The trammel generally is directly over or in front of the flywheel, but may be located elsewhere if some careless workman has removed your flywheel and replaced it in a different position (flange connection, or a new flywheel with the key in the wrong place). The trammel should be shifted until it registers properly when the cylinder indicated is at top center.

Check up the top center mark by making sure that the piston in the cylinder indicated is exactly at top center and that the trammel registers exactly in line.

Now that you are certain of the trammel, move the flywheel in the direction in which it should travel (generally counter-clockwise, if flywheel is between you and the cylinders) until the marks I. O. (intake opening) No. 1 and No. 4 register with the trammel. Leave the flywheel alone now, and turn the cam shaft until the nose of the inlet cam on No. 1 cylinder is down. Adjust the air-gap (valve-stem clearance) for post-card distance. Turn the cam shaft in the direction of its travel until the air-gap is gone and any further movement would start to lift the valves. Put on the cam-shaft gear, being careful not to move either the cam shaft or the crank shaft. Have the gear key in place, but do not permanently fasten the gear yet.

Turn the fly wheel in its proper direction and **check up the intake closing.** If both opening and closing of this valve are right, it means that the cam shaft and air gap are correct, and the gear can be permanently fastened.

If the valve opens on time but closes at the wrong time, it means that both the cam shaft and air gap are wrong. **If the valve closes too soon,** the air gap is too large and does not hold the valve open long enough. **If the valve closes late,** the air gap is too small and holds the valve open too long.

Make a mark with a lead pencil or with chalk on the fly wheel, midway between the actual closing and the proper closing. Turn the flywheel to this new mark and adjust the tappet to correspond. The tappet must be just barely in contact with the valve stem. The air gap is now O. K., but the cam shaft is still out of time.

Turn the fly wheel back to the opening mark and remove the gear. Turn the cam shaft until the air gap is gone, replace the gear and check up the closing. The cam shaft and air gap are now correct and the remaining tappets are adjusted after registering each mark with the trammel. Do not use a sheet of paper or post card to measure with. Turn the fly wheel and adjust each tappet by the flywheel marks.

If the valve opens a certain number of degrees early and closes the same number of degrees late, the cam shaft is right but the air gap is wrong.

If a valve opens a certain number of degrees early and closes the same number of degrees early, the air gap is right but the cam shaft is wrong.

Make a habit of checking up this air gap occasionally with the flywheel marks.

After the valves have been ground or new valves put in—check up. Don't let your engine overheat or lose power through the fault of the air gap.

It will be observed that valve clearance, referred to above as "air-gap," is a very important adjustment.

SILENT CHAIN FRONT END DRIVE SYSTEM

Where silent chains and sprockets are used instead of gears, the procedure is similar. Note, however, that the cam shaft revolves in the same direction as the crank shaft.

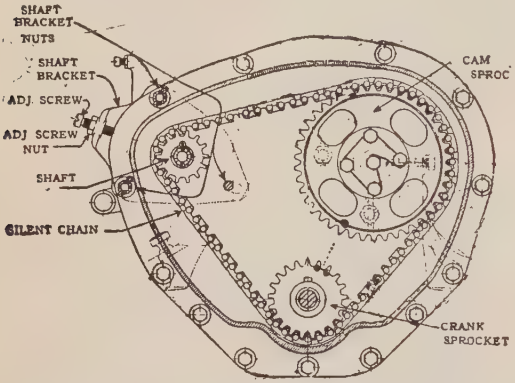


Fig. 35. Cam-shaft gear on the Studebaker "EJ" driven by a silent chain. Note that the chain has an exterior adjustment.

To set the cam shaft if silent chain has been removed: Fig. 35 shows one silent chain driving the cam shaft and generator in a Studebaker model "EJ" six-cylinder engine. If the engine was a four-cylinder engine, cylinders 1 and 4 would be up together, whereas with a six-cylinder engine, cylinders 1 and 6 are up at the same time.

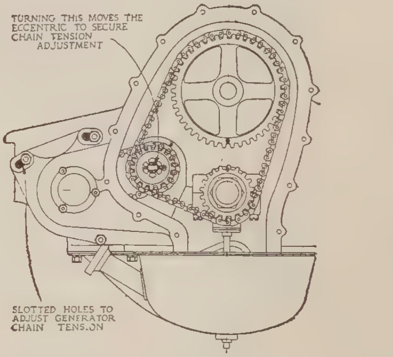
Procedure: Crank the engine until cylinders 1 and 6 are on upper dead center of compression stroke by getting marks "UP-D-C 1-6" on the fly wheel opposite pointer, on the rear of the starter housing. With the crank shaft in this position turn the cam-shaft sprocket until the punch mark on the cam gear will be directly between the two punch marks on the teeth of the crank-shaft gear (Fig. 35). Replace the chain, being careful to see that the cam shaft or crank shaft are not moved.

It is not necessary to set the accessory shaft sprocket which drives the pump, generator, and ignition unit (the sprocket on the left side marked "shaft"). The ignition unit can be set by moving it on its own shaft. See Index under "Ignition timing."

Silent chains will stretch, especially when new, or after a few thousand miles or so of running, and will likely cause a **noise** by striking the bottom of the chain housing.

Adjustment can be made by moving the generator. There are three bolts holding the generator. They are to be loosened and the chain-adjusting screw given a turn or so, moving generator out, thus tightening chain. This movement usually allows about 1/16" movement of the generator sprocket. Be sure and tighten all bolts and nuts.

Too tight a chain adjustment will cause "singing" as well as undue wear on one side of the bearing.



TURNING THIS MOVES THE ECCENTRIC TO SECURE CHAIN TENSION ADJUSTMENT
SLOTTED HOLES TO ADJUST GENERATOR CHAIN TENSION

Fig. 36. An example of two silent chains with two adjustments for slack. (King.)

To set the cam shaft on an engine using two silent chains (Fig. 36) the procedure is similar, except that the chain driving the generator is not considered.

Note in Fig. 36 that the crank-shaft gear (lower) drives the large cam-shaft gear and also a double sprocket from which another chain drives the generator.

To adjust the cam-shaft chain an eccentric shaft is provided.

To adjust the generator chain, the generator is moved as shown in Fig. 36. If a chain is adjusted too tight, it will hum or sing at high speeds. If the chain should stretch to such an extent that no more adjustment is available, then either install a hunting or off-set link section, or a new chain, if badly worn. See Index under "Silent chains."

In re-timing, or any other operation requiring the removal of the chain, be sure that the chain is replaced so that it runs in the direction indicated by the arrows on the sides of the links.

Note. In order to reach the silent chain and cam sprockets, it is usually necessary to remove the radiator, starting crank stud, fan, fan pulley, and gear-housing cover. When replacing, be sure the gasket of the housing is in good condition.

Should it be necessary to remove the cam-shaft sprocket from the shaft, see that it is replaced in the exact position in which it was when it came off. On most gears and sprockets there are holes provided for a **"gear puller"** which is used to draw gears off.

Hupmobile Valve Timing

When timing this engine, reference to the marks on the gears should not be made, because they have no bearing on the engine timing. The appearance of the chain with the front cover removed is shown in Fig. 37.

There are two timing methods. The first is as follows: turn the engine over until the marks "Intake Opening" on the fly wheel line up correctly with the line on the housing; turn the cam-shaft gear until the intake cam is just beginning to lift the intake valve of No. 1 cylinder; place the chain in proper position and allow just a little slack.

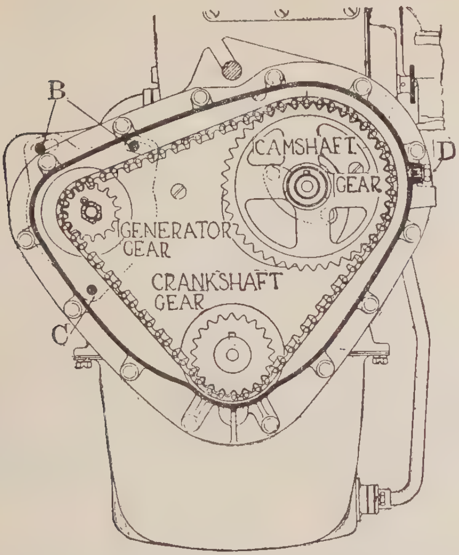


Fig. 37. Hupmobile front end drive system. Adjustment of slack in chain is taken up by loosening bolts (**B**) and (**C**) and sliding the generator to one side, at the top (**B**).

The second method is as follows: remove the cylinder head so that it will be possible for you to measure the distance of the piston travel. Turn the piston of No. 1 cylinder 5/16″ past top dead center on the intake stroke, which is, of course, when the piston is traveling downward. Turn the cam shaft so that the intake valve is just ready to open; then place the chain in its proper position.

In order to place the chain on the gears it may be necessary to loosen the rear engine bolt. Place a jack under the bottom of the oil pan near the front and raise the engine slightly.

Remarks on Front-End Drive Methods

Cars using silent chain front-end drive are the Ambassador, Ace, Ogren, Revere, Haynes, Jordan, Moon, Saxon, Brewster, Cadillac, Chalmers, Chandler, Cleveland, Hupmobile, King, LaFayette, Lincoln, Meteor, Mercer, National, Packard, R & V Knight, Stearns-Knight, Studebaker (one model), Templar, Willys-Knight, Winton.

Virtually all the other cars use the helical-gear front-end drive. Where the gear-type front-end drive is used, alternate gears are of different metals, such as iron and steel, and also of compressed cotton. The majority of gears are steel against cast iron, as this has been found to reduce "resonance."

Where both gears are of cast iron, or both of steel, the gears are prone to "sing."

Duralumin, which can be forged, is used for gears in the Continental and Marmon engines.

A Fabroil gear, which is a specially compressed, spirally wound cotton type of gear, made by the General Electric Co., is used on Buick, Paige, Wills-Saint Claire, and DuPont cars.

Where silent chains are used, it must be possible to reduce the length of the chain by degrees one full link, after which a link can be removed from the chain and the adjustment let out again. This gives unlimited adjustment. On those cars not provided with chain adjustments, it is, however, always best to renew a chain entirely if it is worn. The adjustment must also be accessible, so that it can be easily made when required.

There are several types of chains used and different methods of securing adjustment, as follows:

1. Movable idler.
2. Movable sprocket (Figs. 35, 36, 37).
3. Eccentric adjustment (Fig. 36).
4. Double adjustment.
5. Automatic idlers (Fig. 38).

The movable idler is used for adjustment or to take up chain whip.

The movable sprocket for adjustment is used on one of the shafts where it can be moved in or out without destroying any alignments or adjustments.

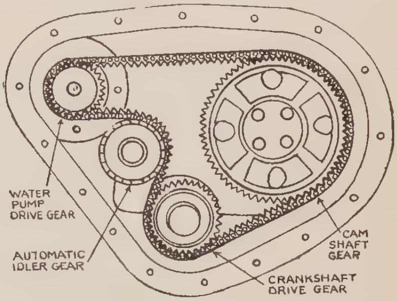

Fig. 38. A front-end drive system used on the model "75" Haynes. An automatic take-up for slack in the chain is provided. The cam gear operates the cam shaft, which operates the inclined valves.

The subject of silent chains is also dealt with elsewhere; see Index under "Silent chains."

Average Valve Timing

There is very little difference between the average timing of the four and the six-cylinder engine.

On the six, the average inlet opening is 10.7° past top center and the closing point 37.6° past bottom center.

On the four, the average for the inlet opening is 11.1° after top center, and the closing point is 36.8° after bottom center. The small difference would hardly be noticeable.

The exhaust on the average six **opens** 46° before bottom center and on the **four** at 46.3°. **The closing point of sixes** averages 7° after top, and on the four, 7.7°.

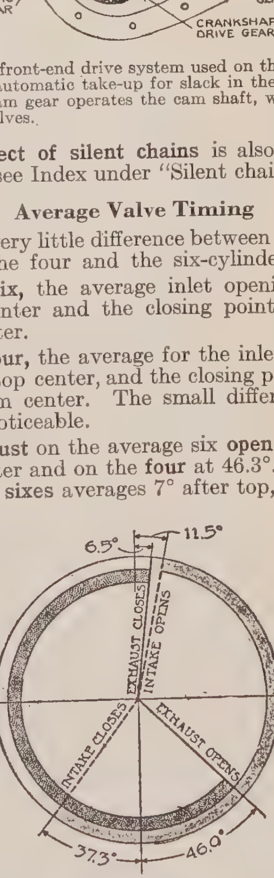

Fig. 39

On an average engine, therefore, the inlet would open 11.5° after top and close 37.3° after bottom. The exhaust would open 46° before bottom and close 6.5° after top.

The illustration (Fig. 39) is a **typical diagram of valve timing** with the timing designated in degrees. When reading such diagrams, imagine the circle being the rear of a fly wheel, which revolves to the left. The light shading represents the period of travel when the inlet valve is open, or 205.8°. The dark shading represents the period of travel when the exhaust valve is open, or 232.5°.

See also Index under "Valve timing" for the valve timing of engines on leading makes of cars; and under "Valve clearance" and "Diameter of valves."

INSTRUCTION No. 10

FIRING ORDERS: One, Two, Three, and Four-Cylinder Engines

Firing Order of One and Two-Cylinder Engines

There are four strokes to two revolutions of the crank shaft to complete a cycle operation, as explained on page 32.

A stroke of the piston means a travel from top to bottom, or from bottom to top, or 180° movement, or one-half of a revolution of the crank shaft. (This is not strictly true when offset cylinders are used.)

There are four strokes of 180° on all four-cycle engines; therefore there would be two revolutions of 360° each, or 720° travel of the crank.

There is but one power stroke (firing impulse) during the four strokes, or two revolutions of the crank shaft. Note, also, that the power stroke is a very short one, owing to the fact that the exhaust valve starts to open a considerable time before the piston reaches the bottom of its stroke. If the exhaust valve should open 46° before bottom, then the travel on the power stroke would be but 134° instead of 180°.

Therefore, if there is but one power stroke to two revolutions of the crank shaft (720° travel of crank shaft), we should have only 134° out of the two revolutions, or 720° on which there is power.

Fig. 1

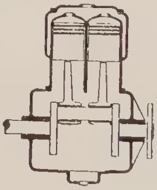

Fig. 2

Fig. 1. One-cylinder engine with a 360° crank shaft. Firing impulse every two revolutions; see diagram below.

Fig. 2. Two-cylinder vertical engine with a 360° crank shaft. Firing impulse every revolution.

CYLINDER NO.	1
1ST REVOLUTION	S
	C
2ND REVOLUTION	P
	E

1	2	CYLINDER NO
P	S	1ST REVOLUTION
E	C	
S	P	2ND REVOLUTION
C	E	

Fig. 1 shows a single-cylinder engine. There is **one explosion during every two revolutions of the crank shaft,** or, in other words, there is one stroke of the piston when power is being developed, and three when there is no power, the piston then being moved by the momentum of the fly wheel.

As the piston must be carried through the three dead strokes, it is necessary to use a heavy fly wheel, so that when it is started, it will continue to revolve for a sufficient time to move the piston until the next power stroke.

There is vibration from a one-cylinder engine on this account, for the weight of the piston sliding first one way and then the other has nothing to balance it.

It can be balanced to some extent by attaching a weight called a "counter-balance," to the crank shaft opposite to the crank pin, in the same manner that the wheels of a locomotive are balanced, but even then there is vibration owing to the power stroke at uneven intervals.

Note. In the two small diagrams under the illustrations, **P** means power stroke; **S,** suction; **C,** compression; **E,** exhaust. The "firing impulse," is the time at which combustion takes place at the beginning of the power stroke.

Fig. 2 shows a two-cylinder vertical engine with a 360° crank shaft. If the piston of No. 1 cylinder is on power (**P**), No. 2 would be on suction (**S**)—see diagram. Therefore we should get an even firing impulse, or **one during each revolution.** But as both pistons are moving together, there would be considerable vibration, as both are on top or bottom at the same time. Counter-weights are also used on the crank shaft of this type of engine in order to counter-balance. (Seldom used.)

Fig. 3 shows a two-cylinder vertical engine with a 180° crank shaft. There are **two firing orders** of this engine, each of which would cause vibration. Refer to diagrams. In the first, if No. 1 is on power (**P**), No. 2 would be coming up on compression (**C**), and would fire next. Therefore, there would be **two firing or power impulses during one revolution,** and on the second revolution there would be no firing impulse at all. With the other order of firing, if No. 1 was on power (**P**), No. 2 would be coming up on exhaust (**E**). The crank would therefore travel 540°, or 1½ revolutions with but one firing impulse.

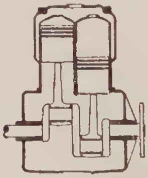

Fig. 3

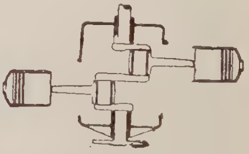

Fig. 4

Fig. 3. Two-cylinder vertical engine with a 180° crank shaft. Two different firing orders—see diagram below.

Fig. 4. Two-cylinder opposed type engine with 180° crank shaft. Firing impulse every revolution. Mechanically balanced.

CYLINDER NO	1	2
1ST REVOLUTION	P	C
	E	P
2ND REVOLUTION	S	E
	C	S

—OR—

CYLINDER NO.	1	2
1ST REVOLUTION	P	E
	E	S
2ND REVOLUTION	S	C
	C	P

CYLINDER NO	1	2
1ST REVOLUTION	P	S
	E	C
2ND REVOLUTION	S	P
	C	E

In the **two-cylinder type of engine with cylinders** opposite and the crank shaft set 180° (Fig. 4), one piston slides inward as the other slides inward, so that one balances the other. This type of engine is called an "opposed" type of engine. Cylinders are set 180° apart, and so also is the crank shaft. When one piston starts down on the power stroke, the other starts down on suction. Therefore, as shown in the diagram under Fig. 4, there would be a firing impulse at each revolution of the crank shaft or every 360°. Thus it is mechanically balanced.

The fly wheel of a two-cylinder engine need not be as heavy as that of an engine with one cylinder because it is required to carry the piston through only one dead stroke before another power stroke occurs. On 6, 8, and 12-cylinder engines, the fly wheel is very small in diameter.

The more cylinders an engine has, the more steadily it may run, for the explosions may be arranged to follow one another so closely that there is no moment when one of the pistons is not on the power stroke. This is termed "lapping" of power strokes.

Firing Order of a Three-Cylinder Engine

The three-cylinder engine fires 1, 3, 2 from the front of the engine, or 1, 2, 3 if from the rear.

The action of the firing of a three-cylinder engine is as follows: Taking three points of the circle, **A** at the top, **B** and **C** on either side below, the piston of No. 1 cylinder is connected with a crank at **A**, of No. 2 cylinder at **B**, and of No. 3 cylinder at **C**.

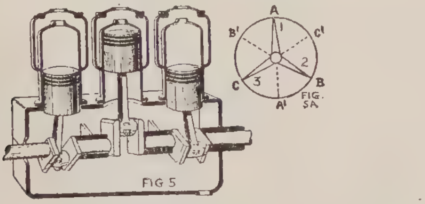

Fig. 5. A three-cylinder engine crank set in three positions of a third of a revolution, or 120° apart.

No. 1 cylinder will be at full compression, **No. 2 cylinder** at two-thirds inlet, and **No. 3 cylinder** one-third, exhaust 240°.

The crank of No. 1 cylinder performs its half revolution, bringing it to position **A′** (Fig. 5A); while it is doing this, No. 2 cylinder is completing its inlet stroke and two-thirds of its compression stroke, and the crank is passed on to position **B′**, leaving only one-third of a stroke to complete compression and to bring the crank to **A,** when the firing of **B** commences.

Meanwhile, **C** is completing its exhaust and inlet strokes, and has passed through two-thirds of its compression stroke, so that when No. 2 cylinder has completed its impulse, No. 3 has but to be carried over the small gap by the fly wheel, which gap represents the minus lap.

Each of the three cylinders fire once every 720° (two revolutions), or 240° apart. No. 1 **(A)** fires and moves 240°, which brings No. 2 **(B)** in firing position. No. 2 **(B)** fires and moves 240°, which brings No. 3 **(C)** in firing position. No. 3 **(C)** fires and moves 240°, which again brings No. 1 **(A)** in firing position.

No. 1 **(A)** has now made two revolutions or 720° which completes the four-cycle evolution.

The working, or power stroke is 134°; 240° less 134° equals 106°, during which time no work is being done, that is, the fly wheel carries the crank 106°.

Firing Order of a Four-Cylinder Engine

Four-cylinder engines are so arranged that there is a power or firing impulse every stroke, or two firing impulses every revolution, one beginning as the previous one ends.

In order to complete **the four-cycle evolution of suction, compression, explosion,** and exhaust for each piston, it is necessary that each piston have four strokes. As 1 and 4 work together and 2 and 3 work together, then during the four strokes (two up and two down), there are two revolutions of the crank shaft which will complete the cycle evolution for each piston, with a firing order of either 1, 2, 4, 3, or 1, 3, 4, 2.

The crank shaft of a four-cylinder four-cycle engine is always set at 180°.

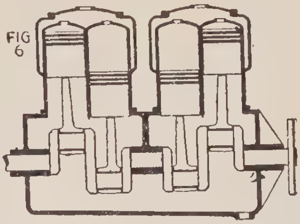

Fig. 6. Four-cylinder engine with crank shaft set at 180°. Power stroke every half revolution, or stroke of piston.

The construction of the crank shaft which is generally used on four-cylinder engines is shown in Fig. 6. This crank shaft would not permit the firing to be 1, 2, 3, 4, because, when No. 2 was ready to go down on the power stroke, No. 3 would have to be coming up on compression, but as No. 3 is always the same position as No. 2, then it could not be coming up, as it would already be up with No. 2. It follows, then, that the firing order must then be as given above: 1, 2, 4, 3, or 1, 3, 4, 2.

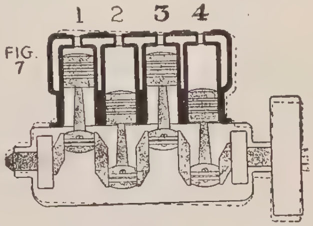

Fig. 7. Type of crank shaft which would permit a four-cylinder engine to fire 1, 2, 3, 4, but which is never used.

A four-cylinder engine which could be made to fire 1, 2, 3, 4, would have a crank shaft made as shown in Fig. 7, but it would vibrate excessively on account of the rocking motion of firing from one end to the other. Therefore the **firing order on all engines is arranged to decrease vibration** as much as possible. The alternate distribution of impulse (firing) tends to steady the engine, as in the sequence 1, 2, 4, 3, or 1, 3, 4, 2.

Cylinders are originally made to fire in proper order by the manufacturer, by setting the cams on the cam shaft and by wiring the distributor to connect with the proper spark plugs. **The order of firing** depends on the ideas of the maker, and may be either, 1, 2, 4, 3, or 1, 3, 4, 2, on a four-cylinder engine.

The eight "V"-type of cylinder engine uses a four-cylinder 180° crank shaft with two connecting rods to one crank pin.

The twin six or twelve "V"-type engine uses a regular six-cylinder crank shaft. This will be treated farther on, together with the firing order.

Relation of One Piston to the Other

On a four-cylinder engine, as already stated, the firing order must be 1, 2, 4, 3, or 1, 3, 4, 2.

The following explanation and charts will make clear just what action is taking place in cylinders when the engine is firing in the order 1, 2, 4, 3, or 1, 3, 4, 2.

If piston No. 1 is going down, say, on power, No. 2 must be coming up on either compression or exhaust. If coming up on compression it would fire next. No. 3 would then be coming up on exhaust and No. 4 going down on suction. In this case, the firing order would be 1, 2, 4, 3. (See chart No. 1, showing firing order 1, 2, 4, 3.)

If No. 1 was going down on power and No. 2 coming up on exhaust, then No. 3 would be coming up on compression and would fire next. In this case, the firing order would be 1, 3, 4, 2. (See chart No. 2, showing firing order 1, 3, 4, 2.)

Remember, the two down strokes are suction and **power.** The two up strokes are **compression** and **exhaust.** Each piston must be doing one of the four, during each of the four strokes or two revolutions.

The change of firing is accomplished by the movement of cams on the cam shaft, the cams on cylinders Nos. 2 and 3, being the only two affected. A study of charts No. 1 and No. 2, which represent a four-cylinder engine firing 1, 2, 4, 3, and 1, 3, 4, 2, will give the reader an idea as to what is taking place in each cylinder during the four strokes.

Relation of the Cam Movement to Crank Shaft

As we have seen, the only two firing orders that a four-cylinder engine can have is 1, 2, 4, 3, or 1, 3, 4, 2. To change from one to the other would necessitate changing the cams operating the valves on cylinders 2 and 3, which of course would necessitate putting in different cam shafts.

Chart No. 2. Firing order 1, 3, 4, 2.

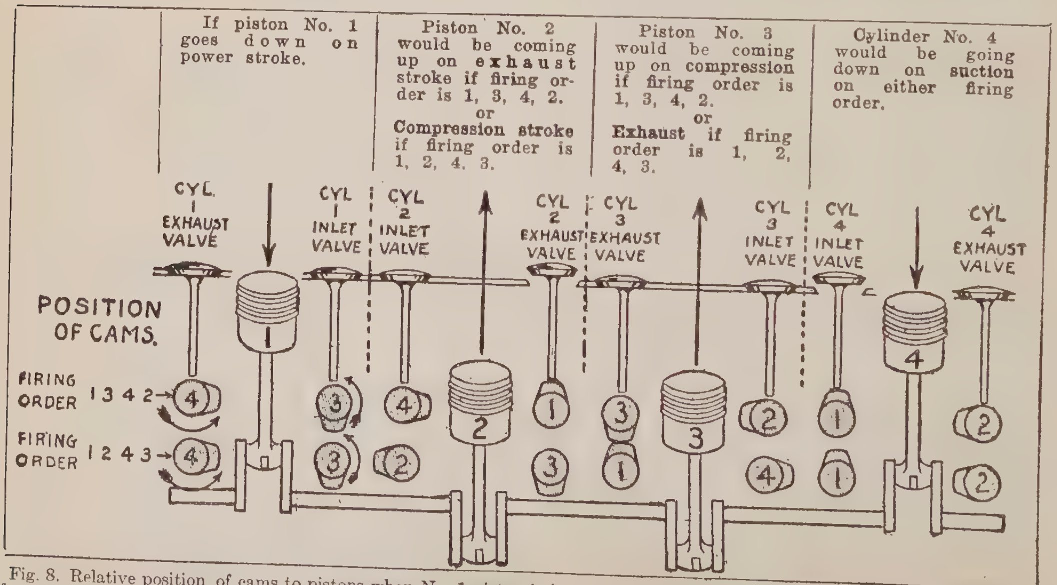
Fig. 8 below gives a good illustration of the position of the cams in relation to the two firing orders.

The lower row of cams shows the position of the cams on the cam shaft when the engine is firing 1, 2, 4, 3 and No. 1 piston is ready to start down on the power or firing stroke.

The upper row of cams shows the position of the cams on the cam shaft, when the engine is firing 1, 3, 4, 2 and No. 1 piston is ready to start down on the power or firing stroke.

Every stroke of the piston, or 180° movement, represents a half-revolution of the crank shaft.

Every half-revolution of the crank shaft represents one-quarter revolution, or 90° movement of the cam shaft and of the cams. A careful study of Fig. 8 is recommended.



If piston No. 1 goes down on power stroke.

Piston No. 2 would be coming up on **exhaust** stroke if firing order is 1, 3, 4, 2. or **Compression stroke** if firing order is 1, 2, 4, 3.

Piston No. 3 would be coming up on **compression** if firing order is 1, 3, 4, 2. or **Exhaust** if firing order is 1, 2, 4, 3.

Cylinder No. 4 would be going down on **suction** on either firing order.

Fig. 8. Relative position of cams to pistons when No. 1 piston is just starting down on power stroke. Approximate position of cams is shown with a firing order 1, 3, 4, 2 (upper row), and 1, 2, 4, 3 (lower row of cams). The figures in the center of the cams correspond with those on the cams in Fig. 10, page 33. At each stroke of the piston, or one half-revolution of the crank shaft, the cams travel 90 degrees or a ¼ revolution.

HOW TO DETERMINE THE FIRING ORDER OF A FOUR-CYLINDER ENGINE

Fig. 9 shows how the cam shaft with its cams is driven by a **silent chain sprocket.** Also note the **mark on the fly wheel** which is in line with the punch mark on the crank case, when pistons 1 and 4 are on upper dead center. Pistons 2 and 3 are on lower dead center. The setting of the valves and of the gears is determined when the pistons are in this position.

Fig. 9

For example: The exhaust valve on No. 1 cylinder closes at 10° past upper dead center. Therefore, as the piston of No. 1 cylinder is now on top dead center, the fly wheel must be revolved in the direction of rotation, 10° from upper dead center. At this point the exhaust valve of No. 1 cylinder should just close. This is sufficient, as all other valves will be timed to open and close at the correct time, since this is an "L"-head cylinder block with all valves on one side and all cams on one cam shaft. Note that the detachable cylinder head has been removed.

If the exhaust does not close at 10° past dead center, then it is either because the clearance of the exhaust valve tappet is set too close and holds the valve open too long, or the cam-shaft gear is not meshed properly.

The firing order of this engine can be determined by observing the position of the pistons and valves: The exhaust and inlet of No. 1 are closed; the piston of No. 1 cylinder is at the top of compression and will go down on power stroke. The piston of No. 2 cylinder is at the bottom of its intake stroke and will come up on compression; the inlet valve is still open and the exhaust closed. The piston of No. 3 cylinder is at the bottom of its stroke and will come up on the exhaust stroke; the exhaust valve is open and the intake valve is closed. The piston of No. 4 cylinder is at the top of its exhaust stroke and will go down on suction; the exhaust valve will close within a 10° movement of the crank shaft (note the exhaust cam just leaving the No. 4 exhaust valve tappet in the direction of its rotation), and the inlet will open immediately as the piston starts down.

To determine the firing order: If No. 2 will come up on compression as No. 1 piston goes down, and if the power stroke follows immediately after the compression stroke, then No. 2 will fire next. Therefore the firing order must be **1, 2, 4, 3.** The only other firing order it could possibly have would be 1, 3, 4, 2—but this would be impossible because No. 3's exhaust valve is open and it will come up on the exhaust, and after the exhaust comes suction. No. 3 has just fired, therefore No. 1 will fire next.

How to determine quickly the firing order of a four-cylinder engine[1]: When the nose of the first and third cam (inlet or exhaust) are on opposite sides of a shaft, the engine fires 1, 2, 4, 3. When the first and third cams are on the same side of the shaft, the firing order is 1, 3, 4, 2.

Note. The cam shaft is operated by a silent chain and sprocket which turns in the same direction as the crank shaft. The crank shaft turns twice while the cam shaft turns once.

The cams in Fig. 8, page 78, are made to open and close exactly on a full stroke of the piston, or 180° movement of the crank, which is unusual in actual practice.

On the engine in Fig. 9, the cams are set as in actual practice. For instance, the valves open and close as follows: Exhaust closes 10° after top. Inlet opens 6° after top. Exhaust opens 50° before the piston is at bottom dead center. Inlet closes 40° after bottom dead center. The bore of cylinders is 3¾″ diameter and the stroke of piston is 4¼″.

The make of the engine shown in Fig. 9 is the Golden Belknap and Swartz Co.'s model "E-M 31," four-cylinder side-valve detachable head engine. Horse power is 22½ at 935 feet of piston speed per minute; produces 36.9 h. p. at 2,800 r. p. m. on actual brake test and 31.9 h. p. at 2,000 r. p. m.

---

[1] This applies to engines where the first valve is an exhaust valve, which is usually the case, as exhaust valves are placed next to the water jacket. On some early models of engines, the first valve was an inlet valve.

INSTRUCTION No. 11

SIX, EIGHT, AND TWELVE-CYLINDER ENGINES: Firing Order; Rotary-Valve and Rotary-Cylinder Engines; Sleeve Valve Engine; Overhead Cam-Shaft Engine

THE SIX-CYLINDER ENGINE

In the six-cylinder engine, **the variance in construction** from the four-cylinder engine is principally in the addition of more cylinders and the shape of the crank shaft.

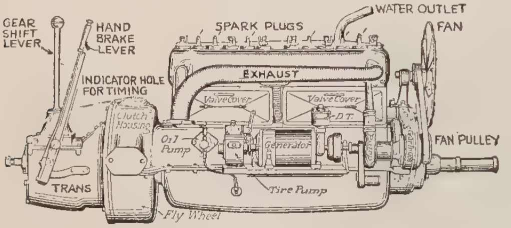

Fig. 1. Six-cylinder unit power plant, valve side. Cylinders of the "L" type. Thus the valves are all on one side.

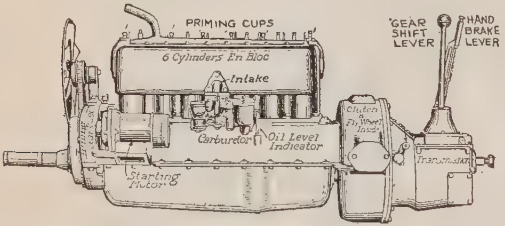

Fig. 2. Left side or carburetion side. The inlet pipe passes between the cylinders to the valve side.

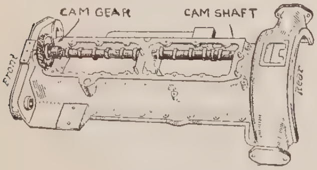

Fig. 3

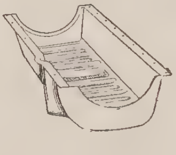

Fig. 4

Fig. 3. Upper part of crank case supporting cam shaft and bearings.

Fig. 4. Lower part of crank case or oil pan.

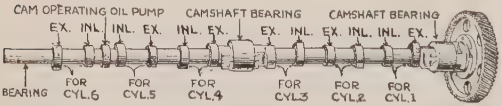

Fig. 5. Six-cylinder cam shaft. All cams on one shaft.

The cylinders may be in "pairs," in "triplets," or "in-block." The six-cylinder engine shown in Figs. 1 to 5 is the **Haynes,** and is a typical example of a "unit power plant." The cylinders are "in-block" with all valves on one side. This is, therefore, an "L"-head type cylinder block. The crank shaft shown in Fig. 8 is a three-bearing crank shaft and the cam shaft (Fig. 5) has three bearings.

The Pierce-Arrow six-cylinder engine (Fig. 97, page 54) is a "T"-head type with cylinders "in-block." The inlet valves are on the right side and the exhaust valves on the left side. There are two exhaust and two inlet valves for each cylinder on the Pierce-Arrow, and this is, therefore, a "dual" valve engine.

The Locomobile six-cylinder engine is also a "T"-head type, but with cylinders in pairs. The inlet valves are on the left side and the exhaust valves on the right side.

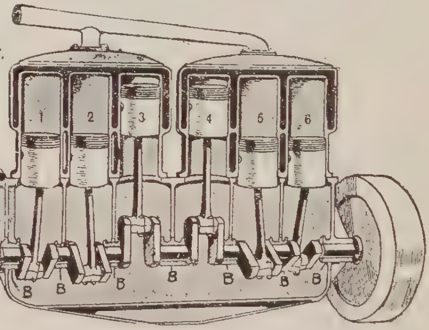
The Haynes, Locomobile, and almost all other six-cylinder engines have but one inlet and one exhaust valve for each cylinder.

Note. The right side of an engine or automobile is the side seen when seated in the car. That is why we designate the cylinders "right" and "left." The reverse is the case, of course, when facing the front of engine.

The six-cylinder engine operates on the four-cycle principle, the same as the four-cylinder; in fact, the general principle is that the crank shaft must turn two revolutions during the cycle or four strokes. The cam shaft turns one revolution.

Each piston completes the four strokes during two revolutions of the crank shaft. The crank shaft is divided into three pairs of "throws." A "throw" on a crank shaft is the part to which the big end of the connecting rod connects and is really the "crank pin." Each pair of these crank shaft "throws" (1 and 6, 3 and 4, and 2 and 5) are placed 120° or one-third the distance of a circle apart.

FIG. 6



There are **two kinds of six-cylinder crank shafts:** left hand and right hand (see Figs. 7 and 8). The cylinders usually fire on a right-hand crank 1, 5, 3, 6, 2, 4, while on a left-hand, the order is usually 1, 4, 2, 6, 3, 5. There are four firing orders which will be explained farther on.

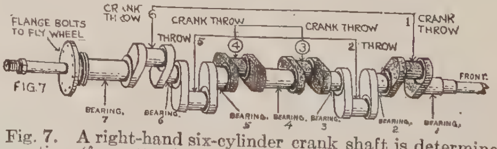


Fig. 7. A right-hand six-cylinder crank shaft is determined by noting (from the front end of the shaft) the position of the center throws, 3 and 4 to 1 and 6. If they are to the right of 1 and 6, as shown in Fig. 7, then it would be a right-hand crank (view from front). Being a right-hand crank, therefore, it will fire 1, 5, 3, 6, 2, 4, or 1, 2, 4, 6, 5, 3.

FIG 8

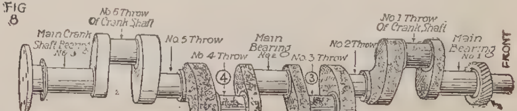

Fig. 8. A left-hand six-cylinder crank shaft. Note that 3 and 4 throws are to the left of 1 and 6, when looking at the crank shaft from the front end. Therefore it would fire 1, 4, 2, 6, 3, 5, or 1, 3, 5, 6, 4, 2.

The number of bearings for the six-cylinder crank shaft may be three, five, or seven. Three or five bearings is the usual number. Fig. 7 shows a seven-bearing six-cylinder crank shaft which is unusual and Fig. 8, a three-bearing crank which is in general use.

Carburetion: A six-cylinder engine usually requires special intake pipes and a double or multiple jet type of carburetor to meet the demand of the multiple of cylinders and the distance which the carburetted gas must travel.

The timing of six-cylinder valves is identical with that of the four. The process is gone through with in just the same manner. It is only necessary to time with the exhaust valve closing on the first cylinder on the "L" type, and with the exhaust valve closing on exhaust side and the inlet opening on inlet side on the "T"-head type.

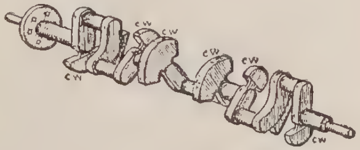

Fig. 8A. One method of balancing a six-cylinder crank shaft.

Counter-balance weights are sometimes applied to a six-cylinder crank shaft to relieve the "whip" or vibration at high speeds. Fig. 8A above shows the counter-balance weights (CW) electrically welded to the crank-shaft arms.

There are six power impulses or explosions during two revolutions of the crank shaft.

Another type of six-cylinder engine is the engine used on the Rumpler, a German make of car. This engine uses three pairs of cylinders placed 60° apart. One pair of cylinders is set vertically over the crank shaft, and there is a pair of cylinders placed at an angle of 60° on each side.

Firing Order of a Six-Cylinder "Right"-Hand Crank

The throws of a six-cylinder crank shaft are divided into three positions, or 120° apart.

1 and 6 are always in line
3 and 4 are always in line
2 and 5 are always in line

They may be placed to the right or the left, as shown in Figs. 9 and 10.

In Fig. 9, the first firing order is 1, 5, 3, 6, 2, 4 (it could also be 1, 2, 4, 6, 5, 3).

Fig. 9, right-hand crank shaft, shows pistons 1 and 6 up. If No. 1 starts down on "firing," No. 5 would be coming up on compression, as it would fire next. No. 3 would be 120° behind No. 5 and would fire next. No. 6 being 120° behind No. 3, it would fire next, then No. 2, then No. 4.

For the second firing order (1, 2, 4, 6, 5, 3) start with No. 1, then 2, 4, 6, 5, and 3 (Fig. 9).

Note. The view is from the front of the engine. Although the pistons are shown out of line, this is necessary in order for the reader to understand the relative positions, one to the other. When in cylinders, they are all in line and the connecting rods are out of line.

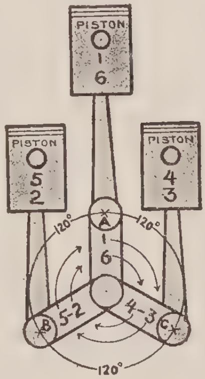

Fig. 9

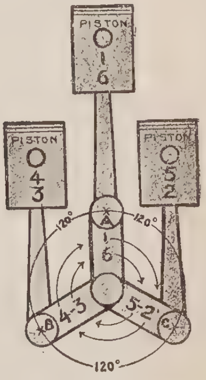

Fig. 10

Firing Order of a Six-Cylinder "Left"-Hand Crank

In Fig. 10 first firing order is 1, 4, 2, 6, 3, 5 (it could be 1, 3, 5, 6, 4, 2). If No. 1 starts down on firing, No. 4 would fire next, then No. 2, then 6, 3, and 5 in their respective order.

For the second firing order (1, 3, 5, 6, 4, 2), start with No. 1, then No. 3, 5, 6, 4 and 2 (Fig. 10).

Relation of One Piston to the Others for Two Firing Orders of a Six-Cylinder Engine

The chart below shows what action is taking place in the cylinders, when the engine is firing 1, 4, 2, 6, 3, 5 (top row and Fig. 10), and when firing 1, 5, 3, 6, 2, 4 (second row of figures and Fig. 9).

THE EIGHT-CYLINDER "V"-TYPE ENGINE

The advantage of a multiple-cylinder engine is principally in the flexibility of control, by which is meant quick acceleration or quick pick up of the engine from slow to fast speed, the absence of gear shifting, and a more perfect control. The more cylinders firing or "lapping," the more flexible the control, or in other words, the power impulses are more frequent. In fact, the more cylinders, the more the lapping of one firing impulse with another, or the more cylinders are on power stroke at the same time. Thus we obtain a more even torque, or steady stream of power impulses.

The simplest arrangement of the eight cylinders would be all in line, just as the six or the four are arranged. But this would be impracticable, owing to the extreme length and also to the abnormally long crank shaft and the extra bearings which would be necessary, while the crank case for such an engine would be very heavy. To get around these difficulties the cylinders are arranged in two sets of four opposite to each other, at an angle of 90° in the form of a "V."

Note. The Lincoln and Wills St. Claire engines are at an angle of 60°.

Crank shaft: Arranged in this way ("V"-type), the eight-cylinder engine is no longer than a four-cylinder one of equal bore. As compared with a six, it has about 30 per cent less length, resulting in a shorter crank case—a weight-reduction factor. In addition, its crank shaft is of the same form as that of a four, the throws being all in one plane; whereas those of a six crank shaft are in three planes, which is a more difficult manufacturing job. Furthermore, the shorter shaft is less given to periodic vibration. The cam shaft is also shorter and less prone to whipping.

Let us next consider the **cylinder and connecting-rod arrangement of the eight "V"-type cylinder engine.** Where the cylinders are "opposite," this means the lower end of the connecting rod is "yoked." The cylinders are in line with the opposite cylinders when looking from the side of the engine.

Where the cylinders are "staggered," this means that the lower ends of the connecting rods are not together but are "side by side" on the same crank-shaft bearing. This naturally necessitates the cylinders on one side being placed a little to the side, or not exactly in line with the opposite cylinder when looking from the side of the engine. This arrangement is termed "staggered."

The cam shafts on the eight "V"-engine may be one or two. The majority use one cam shaft. The Cadillac uses a cam shaft with eight cams operating the sixteen valves, whereas some of the other eight "V"-type engines use one cam shaft with sixteen cams (one for each valve).

Example of an Eight-Cylinder "V"-Type Engine

As an example of an eight-cylinder engine and its construction, the Cadillac make is shown in the following illustrations.

Although a later model Cadillac is somewhat different in minor construction details, the illustrations of the model given will furnish a good general idea as to how a modern eight-cylinder engine is constructed.

On the later model Cadillac, the engine is of the same bore and stroke as formerly: 3⅛″ bore by 5⅛″ stroke; piston displacement 314 cubic inches. Cylinder heads are now detachable. It is no longer necessary to remove the radiator to take out the water strainer between the radiator and water pump. Other changes also have been made.

The front end of the Cadillac eight-cylinder engine is shown in Fig. 11. There are two groups of cylinders, each of a block casting of four cylinders, mounted at 90° to each other on an aluminum crank case. **The cylinders** are 3⅛″ bore and 5⅛″ stroke. **The piston** displacement is 314 cubic inches; the horse-power rating is 31.25. In dynamometer tests the engine shows 70 h. p. at 2400 r. p. m.

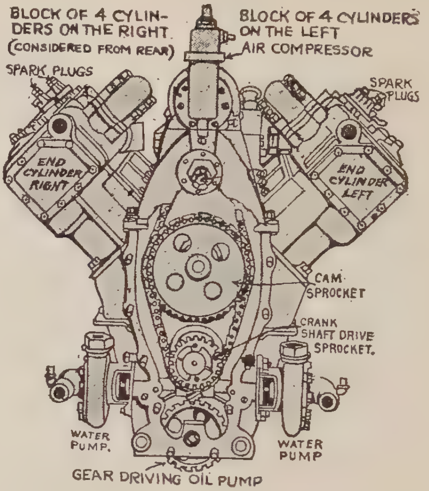

Fig. 11. Front view of an eight-cylinder "V"-type engine.

The crank shaft is identical in design with that used in a four-cylinder engine, and the cam shaft carries the same number of cams as in a four-cylinder design. This engine weighs approximately 60 pounds less than the former four-cylinder Cadillac engine of equal horsepower. There is but one carburetor used.

Each of the two cylinder castings contains four L-shaped cylinders with detachable heads.

The exhaust valves are of the conventional poppet shape. The inlet valve on the early models (as shown in Fig. 11), was of the "tulip" shape. This is not now used. Over each cylinder is a removable cap which gives access to the water jacket and to the combustion chamber. Between the second and third cylinder in each block the breather pipe is brought up through the cylinder casting (now on the valve cover plates). In rear of the fan is the power tire pump for tire inflation (now bolted to right-hand side of the transmission case).

Fig. 12

Fig. 12A

Fig. 12. Valve-operating mechanism of the eight cylinder "V"-type engine (Fig. 11).

A cross-section view of the engine with the cylinder mounted in two groups of four cylinders each at an angle of 45° from vertical center, or 90° from cylinder centers is shown in Fig. 12.

The single cam shaft is located directly above the crank shaft, and the means whereby one cam operates the two intake valves for the opposite cylinders is shown.

The valve operating mechanism is shown in Figs. 12 and 12A. Note how one cam operates two opposite valves. The cam bears against the rollers (**R**) at the ends of the small arms which are pivoted to the plate above, and which are interposed between the ends of the push rods and the cams, so that the lift will be straight upward instead of having a side thrust.

Adjustment of valve clearance is obtained in the usual way by lengthening the tappet (**T**). The upper part of the tappet screws into the lower and the two are locked by a nut. The position of the cylinders makes the valves easily accessible.

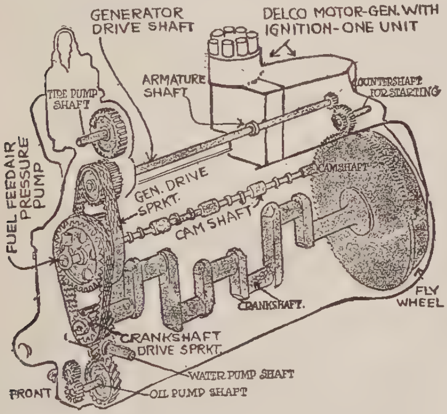

Fig. 13. Note the silent chain of the engine front-end drive from crank shaft to cam shaft and generator shaft. In the later models of the Cadillac the distributor is not mounted on the generator housing, as shown, but is mounted behind the fan housing.

Note the single cam shaft shown in Fig. 13. There are eight cams which operate the sixteen valves (eight inlet and eight exhaust valves). Each cam operates two valves through the rollers shown on opposite sides (Fig. 12A). The shaft is carried on five bearings.

On another make of "V"-type engine, there are two cam shafts. This permits the direct opening of valves without the rocker arms between cams and tappets, and also permits any desired timing.

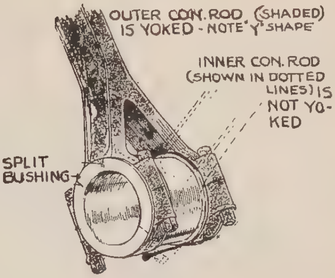
The front-end drive system is shown in Fig. 13. Note the two silent chains, one driving the cam shaft; the other is driven from the cam shaft which drives the Delco electric system. There are **two water pumps** on the cross-shaft below the crank shaft, and this shaft in turn drives the gear-type oil pump. The tire pump was formerly driven by a spur gear, as shown, but is now driven from the side of the transmission and is driven by a sliding gear.

Crank shaft: A three-bearing crank shaft is used, with the throws at 180°, as in a four-cylinder design.

Connecting rods are "yoked." Two connecting rods attach to each crank pin, this being made possible by having one connecting rod with a split or forked lower end, and the other with a single end to fit between the forks; this is called the "yoked" design.

Note how the two connecting rods are attached to one bearing in Fig. 14. The outer connecting rod fastens to the outer ends of the split bushing with a two-bolt cap for each arm of the yoke. The bushing is fixed to this rod by pins.

The other, or inner connecting rod goes between the two arms of the yoke, as shown by the dotted outline.



OUTER CON. ROD (SHADED) IS YOKED - NOTE 'Y' SHAPE
INNER CON. ROD (SHOWN IN DOTTED LINES) IS NOT YOKED
SPLIT BUSHING

Fig. 14

This inner rod is free to move on the bushing. Therefore, the bearing for the yoke-end rod is the inner surface of the bushing against the shaft, while that of the inner rod is the outer surface of the bushing.

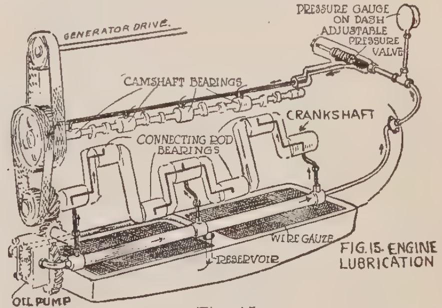


Fig. 15

Lubrication: The oil pump draws the oil up from the reservoir and forces it through the pipe running along the inside of the crank case (Fig. 15). Leads run from this pipe to the crank-shaft main bearing and thence through drilled holes in the shaft and webs to the rod bearings. It also is forced from the reservoir pipe up to the pressure valve, which maintains a uniform pressure above certain speeds, and then overflows from this valve to a pipe extending parallel with and above the cam shaft. Leads from this latter pipe carry the oil by gravity to the cam-shaft bearings and chains. Pistons, cylinders, etc., are lubricated by the overflow thrown from the rods.

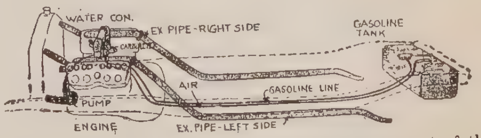

Fig. 16. Diagram showing the general arrangement of the fuel, water, and exhaust systems of the Cadillac chassis. There are two exhausts and two mufflers, one for each set of cylinders; while the gasoline is fed by pressure to the carburetor, which is between the two cylinder blocks. The air-pressure pump for forcing the fuel is at the front of the engine. There are two water pumps and two sets of water connections to the radiator. Carburetion and thermostat cooling are explained in the section on "Carburetion and Cooling."

Firing Order on an Eight-Cylinder "V"-Type Engine

The firing order of an eight-cylinder "V"-type engine is shown in Fig. 17.

On a "V"-type engine (Fig. 17) the right and left block of cylinders is the right and left sides observed when seated in the car. Therefore cylinder 1L would mean No. 1 cylinder of the left block, beginning with the front of the engine; No. 4 cylinder would be the rear cylinder.

The figures 1 to 8 at the side of each block represent the order in which the cylinders fire and do not refer

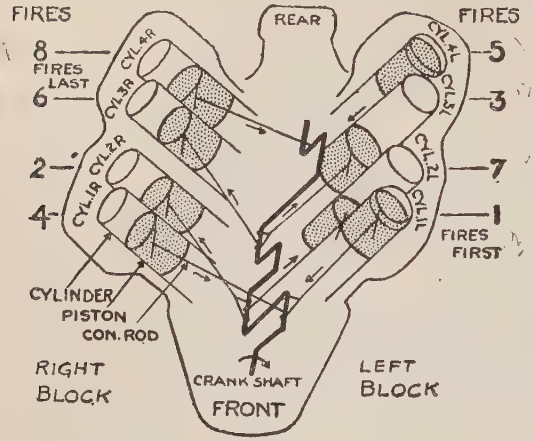

Fig. 17

to cylinder numbers. Therefore note that No. 1L fires first, then 2R, 3L, 1R, 4L, 3R, 2L, 4R.

Relative position of pistons: By observing piston No. 1 (Fig. 17), which is now ready to start down on its power stroke, or just commencing its working stroke, just what is taking place in all other cylinders can be seen by referring to the following:

1L:	Just starting down on power stroke.
2R:	Going up on compression; it will fire next.
3L:	Just starting up on compression; it will fire after No. 2 cylinder 2 R.
1R:	Going down on suction.
4L:	Just starting down on suction.
3R:	Going up on exhaust.
2L:	Just starting up on exhaust.
4R:	Going down on power.

It will be observed that No. 1 L and 4R will both be on power stroke; No. 2R and 3L on compression; No. 1R and 4L on suction; No. 3R and 2L on exhaust, for a certain period of time, which is termed "lapping" of strokes.

THE TWELVE-CYLINDER "V"-TYPE OR "TWIN SIX" ENGINE

The twelve-cylinder engine is referred to in this instruction as either a "twelve-cylinder" or a "twin six." Manufacturers use both terms. Literally, a twelve-cylinder engine would mean a type of engine having twelve cylinders placed in line on a crank shaft having twelve throws.

The "twin six" or twelve-cylinder "V" engine term, to be exact, consists of two sets of six cylinders placed at an angle of 60° over a regular six-cylinder crank shaft with six "throws" of the crank.

Note. The Liberty engine cylinders are at an angle of 45°.

Therefore, if the reader thoroughly understands the six-cylinder engine, it will not be a difficult matter to understand the twelve-cylinder "V"-type.

Before proceeding with the explanation of the "twin six," refer to the illustrations (Figs. 18, 19, and 20), and note the different angles in which cylinders are placed. Note, too, the evolution of raising the cylinders from 180° to 60°.

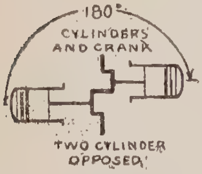

Fig. 18

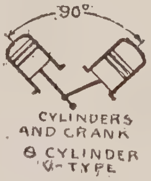

Fig. 19

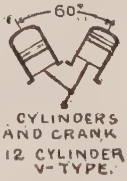

Fig. 20

Fig. 18 represents the two-cylinder opposed type of engine with cylinders 180° apart. Firing impulse every 360° of crank-shaft movement.

Fig. 19 represents the eight-cylinder engine with cylinders placed 90° apart. Firing impulse every 90° of crank movement.

Fig. 20 represents the twelve-cylinder engine with cylinders placed 60° apart. Firing impulse every 60° of crank movement.

Construction: As previously stated, by placing six more cylinders on a six-cylinder crank case and placing them "V"-type, at an angle of 60°, the same crank shaft and practically the same crank case can be utilized without materially increasing the size or weight of the engine, the addition being merely another set of cylinders and connecting rods.

The "twin six" engine offers more evenly divided impulses than the eight. Two cylinders are working together at all times, and part of the time three are working together.

On the eight-cylinder "V"-type, cylinders are set at an angle of 90°, or one-half the distance of firing of the four cylinders. In other words a four-cylinder fires every 180°, and by setting cylinders at 90° we get an impulse every 90°.

A six-cylinder engine fires every 120°. Therefore on a twelve-cylinder "V"-engine, we would place cylinders at an angle of one-half of 120°, which would be 60° instead of 90°, and thus get a firing impulse at every 60° movement of the crank shaft.

Firing order: The crank shaft of a "twin six" is a regular six-cylinder crank shaft. The crank may be a right-hand crank or a left-hand, as explained. The firing order of a "twin six" would then be the same as a "six," that is, if we consider each block of cylinders on a twin six as a separate six-cylinder engine.

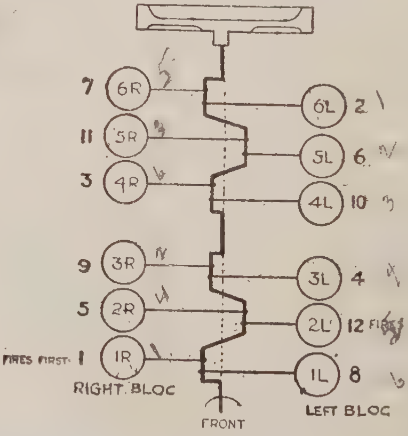

Fig. 21. If we consider each side as a separate six-cylinder engine, the firing order would be 1, 4, 2, 6, 3, 5 on each side. Note the crank shaft; the throws 1 and 6, 2 and 5, 3 and 4 are in line. This would be a left-hand crank shaft.

Taking each side separately as if a separate six-cylinder engine with the firing order 1, 4, 2, 6, 3, 5, note that the right block (Fig. 21), starting from front, would fire, 1R, 4R, 2R, 6R, 3R, 5R. Now start at the rear of the left block, 6L, 3L, 5L, 1L, 4L, 2L. If the cylinders were numbered from the rear, on the left block, as 1L, 2L, 3L, etc., the firing order would be 1L, 4L, 2L, L, 3L, 5L, the same as the right block, but from ear to front.

Combining the two six-cylinder engines, the firing rder of the "twin-six" engine would be as shown in ig. 21.

The figures outside of the circles indicate the order in which he cylinders fire on the Packard twin six. 1R fires first, then L, then 4R, 3L, 2R, 5L, 6R, 1L, 3R, 4L, 5R, 2L.

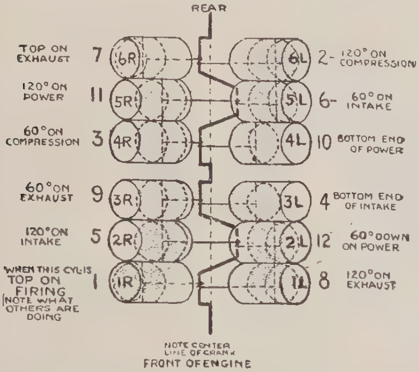

Fig. 22

The relative position of the pistons and what is taking lace in each cylinder when cylinder 1R is just starting ts power stroke is shown in Fig. 22.

The crank pins are 120° apart, whereas the firing mpulses are 60° apart.

The order in which the cylinders fire is designated y the numbers outside of the cylinders, in heavy type.

Note the position of the pistons when No. 1R is just eady to go down on power.

Laps of power strokes: Remembering that the xhaust valves open 46° before bottom dead center, hich is the same as saying that they open 134° fter top dead center, let us see how the cylinders ork together.

In Fig. 23, cylinder 1R has just fired, therefore it s delivering power. Cylinder 6L has completed 20° of its compression stroke. Cylinder 4R has ompleted only 60° of its compression stroke.

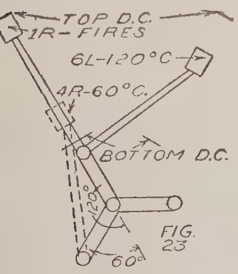

Fig. 23

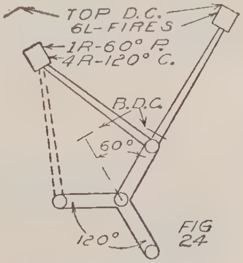

Fig. 24

Let us now examine the engine after the crank haft has revolved 60° to the position shown in Fig. 4. Cylinder 1R has completed 60° of its power troke and is still delivering power. Cylinder 6L as fully completed its compression stroke and now res; thus both cylinders 1R and 6L are delivering ower. Cylinder 4R has now completed 120° of its ompression stroke.

Let us now examine the engine after the crank haft has revolved another 60° to the position shown Fig. 25. Cylinder 1R has completed 120° of its ower stroke and is still delivering power. Cylinder 6L has completed 60° of its power stroke and is still delivering power. Cylinder 4R has now completed its compression stroke; it fires and therefore it is also delivering power. Therefore, at this point **all three cylinders are delivering power.**

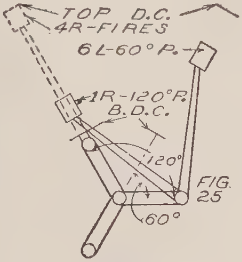

Fig. 25

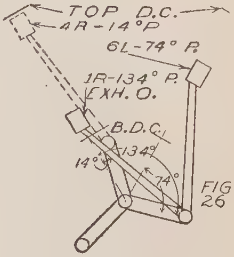

Fig. 26

Let us now examine the engine after the crank shaft has revolved another 14° to the position shown in Fig. 26. Cylinder 1R has now completed 134° of its power stroke and, at this time, the exhaust valve opens so that it has just stopped delivering power. Cylinder 6L has completed 74° of its power stroke and is still delivering power. Cylinder 4R has completed 14° of its power stroke and is still delivering power. Thus we see that during 14° of crank-shaft rotation (the time involved while going from the position shown in Fig. 25 to the position in Fig. 26), we had all three cylinders delivering power, but at the instant shown in Fig. 26, only two cylinders are delivering power.

These two cylinders will carry the load alone until the crank shaft has revolved another 46°, after which, cylinder 3L will start to fire, while cylinders 6L and 4R are still delivering power. Thus it is seen that the revolution of the crank shaft is made up of alternate intervals of 14° during which three cylinders are delivering power, and of intervals of 46° during which two cylinders are delivering power.

The cylinders on the Packard are staggered (see Fig. 21). Note that the left cylinders set ahead of the right. This is in order that the connecting rods may be placed "side by side" on the crank pin instead of being "yoked."

The cam shaft: One cam shaft with a separate cam for each valve is used.

4 Valve spring.
5 Valve-spring collar.
6 Valve-spring collar key.
7 Valve roller-holder screw.
8 Valve roller-holder screw check nut.
9 Valve roller-holder screw plate.
10 Piston pin.
11 Connecting rod.
12 Valve roller-holder guide yoke.
13 Valve roller-holder guide.
14 Valve roller-holder and roller assembly.
15 Crank case upper to lower stud nut.
16 Crank-case overflow valve stud nut.
17 Crank-case overflow valve spring.
18 Crank-shaft oil thrower.
19 Fan driving pulley key.
20 Cam-shaft spiral gear, front.
21 Cam-shaft sprocket.
22 Distributor driving shaft nut.
23 Distributor driving shaft gear.
24 Distributor driving shaft.
25 Cam-shaft driving chain.
26 Cam-shaft driving chain oil tube assembly.
27 Gasoline power-pressure pump eccentric lock.
28 Gasoline power-pressure pump eccentric.
29 Motor-generator sprocket eccentric.
30 Motor-generator sprocket coupling, female.
31 Cam-shaft driving chain oil tube flange nut.
32 Distributor driving shaft bushing, upper.
33 Cylinder water-jacket plate.
34 Cylinder water-jacket plate screw.

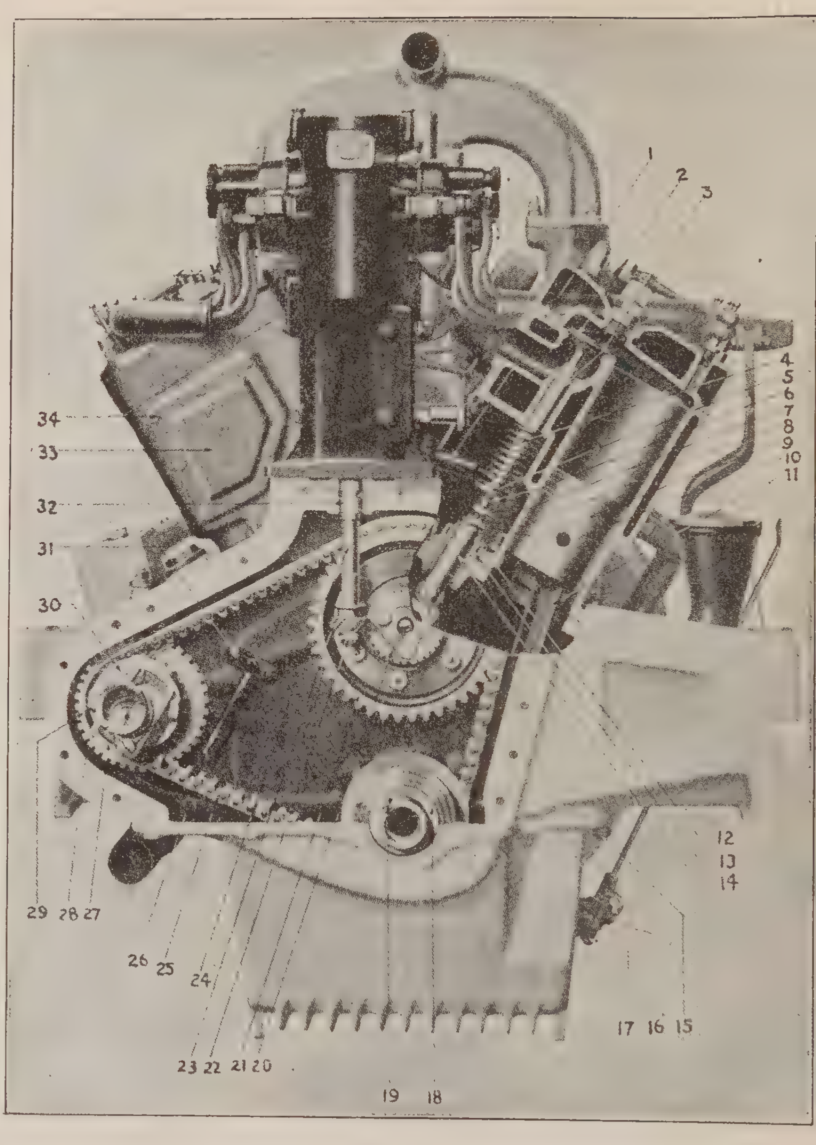

Fig. 28

Fig. 28. Front sectional view of Packard twin-six engine model "3-25" and "3-35." Four-cycle type with two blocks of "L"-head cylinders bolted to the crank case at an inclined angle of 60°. The cylinder bore is 3" and the stroke 5". The left block is set 1¼" ahead of the right block to permit the lower end connecting rod bearings from opposite cylinders being placed side by side on the same crank pin. This arrangement also permits the use of a single cam shaft with a separate cam for each valve operating directly on the valve push-rod roller.

Compression in all cylinders should be equal and up to the standard. Weakness or loss of compression is most probably due to imperfectly seated valves, which may be caused by insufficient clearance between the valve stems and lift rods, carbon deposits on the valve seats, or sticky valve stems and guides. Compression should be tested for uniformity in all cylinders at regular intervals.

To test the compression in a cylinder, remove the spark plug and replace it with a standard compression gauge. Then with the ignition switch off and pet cocks in all cylinders closed, crank the motor, using the electric starter. At cranking speed with the engine cold, the gauge should register 75 pounds plus or minus 3 pounds with the throttle wide open.

A change in the setting of the cam shaft is possible only by removal or disarrangement of the front end chain. Adjustments to the chain do not affect the valve timing.

In resetting the cam shaft, the arrows on both the crank-shaft and cam-shaft gears should point directly upward and should be in line with the arrow on the front end cover face of the engine. In this position, the inscription on the fly wheel, "exhaust closes 1 and 6-R," will be on the top dead center line of the engine, which is the center between the two cylinder blocks, and No. 1 right piston will be in the firing position.

The main and connecting rod bearings are of the babbitt-faced bronze type. The bearings are set with a .0015" to .002" clearance and are consequently flooded with a film of oil between the shaft and the bearing surface, making adjustment for wear necessary only at long intervals.

To grind the valves disconnect the carburetor inlet manifold and spark plug connections and remove the cylinder heads.

Valve clearance: Inlet and exhaust valves should have .004" clearance between valve stem and roller-holder set screw when the engine is cold. Be sure that the valve is fully seated when measuring clearance.

The vibration damper on the front end of the crank shaft should be adjusted to slip under a pull of approximately 140 lbs.

COMPARISON OF THE LAPS OF FIRING OR POWER STROKES OF A 4, 6, 8, AND 12-CYLINDER ENGINE

The eight and twelve-cylinder engines are "V"-type. The diagrams shown below as an example are based on the exhaust valve opening 46° before bottom. The point of the exhaust valve opening varies. However, the comparison would be the same.

Four-Cylinder Lap of Power Strokes

On a four-cylinder engine a power impulse occurs every 180°, or half-revolution, or four impulses during two revolutions of the crank shaft. There are four periods of 46° travel, or 184° in all, during the four strokes, in which there is no power impulse.

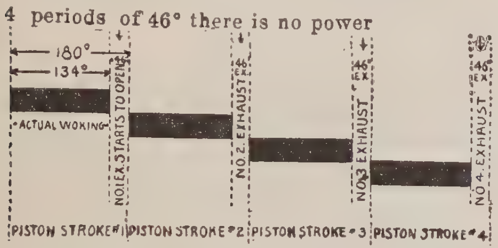

Fig. 1. 4-cylinder power-stroke periods.

Note in Fig. 1 that if piston No. 1 is firing, it does not travel its full stroke with a crank movement of 180° on power, because the exhaust valve starts to open, say 46°, before it reaches the bottom of its stroke, therefore it really travels but 134° on its power stroke. Consequently, before the next piston fires there is a gap of 46°.

Therefore, in a four-cylinder engine there are four periods of 134° when one cylinder is firing or working under a power impulse, and four periods of 46° when no cylinder is firing or working. The fly wheel must then take the pistons over center during the "no" working strokes.

Six-Cylinder Lap of Power Strokes

On the six-cylinder engine there is a power impulse every 120°, or one-third revolution of the crank shaft, or six power impulses during the two revolutions.

Each piston is working on all of its stroke of 180°, except 46°, leaving 134° actually working.

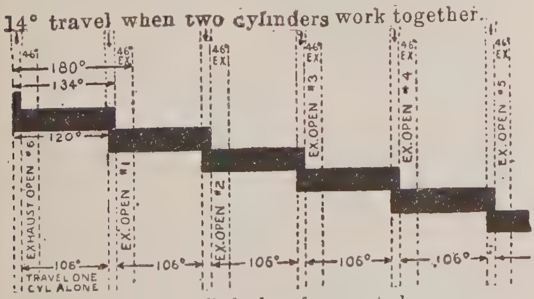

Fig. 2. 6-cylinder lap of power strokes.

The second cylinder to fire starts to work 120° after the first starts to work (Fig. 2), and works 14° before the exhaust opens or the impulse ends on the first cylinder. Consequently there is no idle space between the firing of the cylinders, but quite the reverse, for there is a "lapping" of power strokes.

Thus, there are, during the two revolutions of the crank shaft, six periods of 106° travel when one cylinder is working alone, and six periods of 14° travel when two cylinders are working together.

Therefore, 7/60ths of the time two cylinders are working together and 53/60ths of the time one cylinder is working alone.

The Eight "V"-Cylinder Lap of Power Strokes

The eight-cylinder "V"-type engine with cylinders 90° apart would act very much the same as a four-cylinder engine, if we consider each block separately.

There are eight power impulses or explosions during each cycle of two revolutions of the crank shaft. In other words, the four strokes of two revolutions are just the same as in a four, but there are eight power impulses or explosions during these two revolutions. There is a power impulse every quarter turn (90° movement) of the crank shaft, and thus there is no intermission between them, but rather an "overlapping" so complete that the turning effort is practically constant.

When one cylinder (Fig. 3) is firing, it would travel 134° on the power stroke, at which time the exhaust valve opens (46° before bottom, as an example).

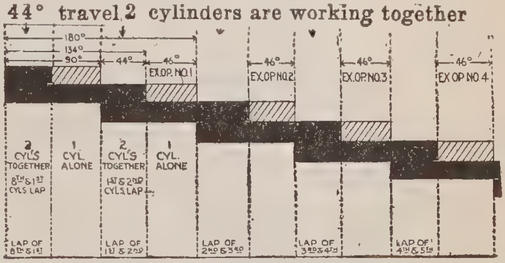

Fig. 3. 8-cylinder lap of power strokes.

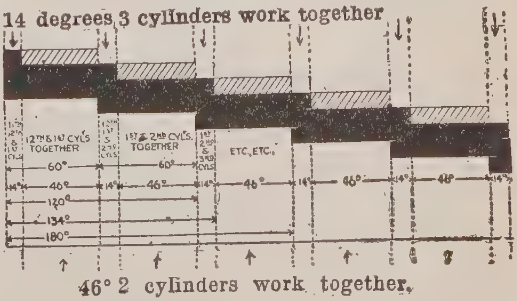
The second cylinder starts to fire 90° after the first, and moves for 134° before its exhaust valve starts to open.

Therefore there are, during the four strokes, or two revolutions of the crank shaft, eight periods of 44° travel when two pistons are working together, and eight periods of 46° travel when one piston is working alone. Therefore 22–45ths of the time two cylinders are working together and 23–45ths of the time one cylinder is working alone.

Twelve-Cylinder Lap of Power Strokes

With the twelve-cylinder "V"-type engine with cylinders 60° apart, there are twelve power impulses during two revolutions of the crank shaft. There is a power impulse every 60° movement of the crank shaft.

When one cylinder is firing, it travels the same as those previously described, namely, 134° before the exhaust valve opens; it then continues for 46° more, till it reaches the end of its exhaust stroke.



14 degrees 3 cylinders work together
11TH 12TH & 1ST CYLS
12TH & 1ST CYL'S TOGETHER
12TH 1ST & 2ND CYLS
1ST & 2ND CYL'S. TOGETHER
1ST 2ND & 3RD CYLS
ETC., ETC.
60°
14°
46°
120°
134°
180°
46° 2 cylinders work together.

Fig. 4. 12-cylinder lap of power strokes (only part is shown).

When the first cylinder fires (Fig. 4), and the piston has traveled only 60°, the second cylinder fires and joins No. 1; they then work together for a period of another 60°, when the third cylinder fires and joins No. 1 and 2. Now No. 1 has still 14° to travel before its exhaust valve opens; consequently the three work together until that occurs.

At the 134° point No. 1 cuts out and Nos. 2 and 3 work together for a period of 46° when No. 4 fires and joins them, and so it continues throughout the cycle.

Thus with every 60° movement of the crank shaft there is a period of 14°, during which three cylinders work together; or, in one complete revolution of the crank, or 360° movement, there will be six periods of 14° when three cylinders work together, and six periods of 46° alternating with these, when two cylinders work together. Therefore there are, during two revolutions of the crank shaft, twelve periods of 14° travel when three cylinders are working together and twelve periods of 46° travel when two cylinders are working together.

THE SLEEVE-VALVE ENGINE (STEARNS-KNIGHT AS AN EXAMPLE)

The sleeve-valve engine differs from any other four-cycle engine only in its method of admitting and exhausting the gas.

The sleeve valves: Instead of raising and lowering the poppet valves, to admit and expel the gas, there are two sleeves with ports or slots in them. At certain times, these ports on the same side of the cylinder come in line, as shown in Figs. 1 and 1A and Figs. A to F. These sleeves take the place of valves.

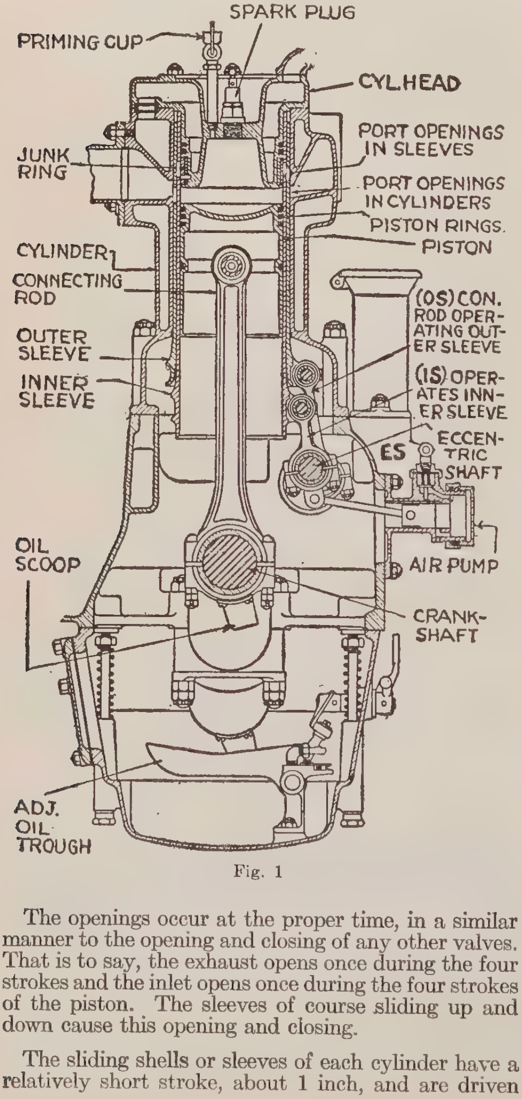


Fig. 1

The openings occur at the proper time, in a similar manner to the opening and closing of any other valves. That is to say, the exhaust opens once during the four strokes and the inlet opens once during the four strokes of the piston. The sleeves of course sliding up and down cause this opening and closing.

The sliding shells or sleeves of each cylinder have a relatively short stroke, about 1 inch, and are driven by two short connecting rods or side-arms working off a lay crank shaft, or eccentric shaft, the cranks having a very small throw.

Eccentric shaft: The sleeves are caused to slide up and down by an eccentric shaft (**ES**), which takes the place of a cam shaft, and which has eccentrics raising and lowering small connecting rods (**OS** and **IS**, Figs. 1 and A to F). This eccentric shaft is driven by a chain from a sprocket on the crank shaft of the engine. It is driven at the same speed as any other cam shaft, i.e., one-half the speed of the engine crank.

The eccentric pin operating the inner sleeve is given a certain lead or advance over that operating the outer sleeve. This lead, together with the rotation of the eccentric shaft at half the crank-shaft speed, produces the valve action illustrated in Figs. A to F, which shows the relative position of the piston, sleeves, and cylinder ports at various points in the rotation of the crank shaft.

Valve timing: The timing shown in Figs. A to F is not different from that ordinarily used in poppet-valve engines, but the valve area is greater than that of an ordinary poppet valve. The equivalent of increased valve area is gained also by the directness of the valve opening and the absence of restrictions in the gas passages.

Compression or junk ring: The sliding sleeves end right up in the deep cone-shaped combustion head, which is a detachable unit. This head is of a special design, inasmuch as it is provided with a set of piston rings, three narrow and one double, the latter being specially wide and termed the compression or junk ring. These rings prevent any escape of pressure in an upward direction.

Piston rings: The usual set of three rings on the working piston maintain pressure tightness in the lower direction.

The main principle of this engine (made under Knight's patent) is the substitution of sliding valves for the usual poppet or tappet valves. The sliding valves consist of two concentric shells of cast iron accurately turned, working in between the driving piston and the cylinder walls. These shells have two series of large area ports or slots cut in the upper ends, which register together at the required instant in the respective strokes of the piston. One pair of slots forms the **inlets** and the other pair the **exhausts.**

Setting ignition: Set cylinder No. 1 piston on top of compression. Retard contact-breaker box on Bosch magneto. Set points on interrupter just breaking. There is a mark on the flywheel which, when lined up with the mark on the cylinder, will show when 1 and 6 or 1 and 4 are up. Firing order on the six is 1, 5, 3, 6, 2, 4 and 1, 3, 4, 2 on the four.

Fig. 1A. Side view showing a partly sectional view and front-end drive system of the Stearns-Knight sleeve-valve engine.

Explanation of Valve Opening and Closing, and Firing Order (Stearns-Knight Six-Cylinder Engine as an Example)

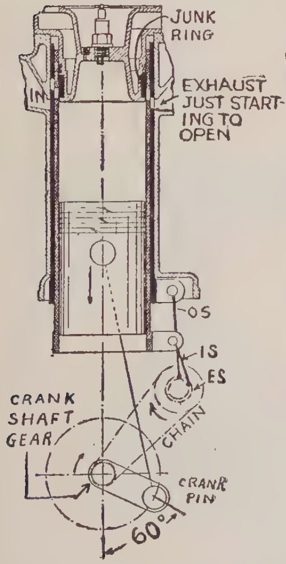

Fig. A

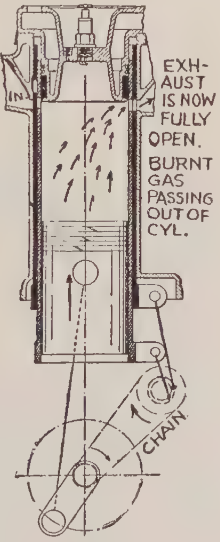

Fig. B

The eccentric shaft sprocket (ES, Fig. A) is twice the size of crank-shaft sprocket. It therefore revolves at one-half the speed of the crank shaft, the same as any cam shaft. (OS) means outer sleeve and (IS) inner sleeve eccentric rod.

The motion of the eccentric rods (OS) and (IS) is controlled by an eccentric on a shaft driven by sprockets.

Firing order, 1, 5, 3, 6, 2, 4. View is from front of engine.

The "ports" are the openings in the sleeves and cylinders.

In Fig. A, the **exhaust starts to open** at 60° before bottom. Toward the end of the power stroke, as in any four-cycle engine, the exhaust port is uncovered by a downward motion of both sleeves, the inner moving at a higher speed than the outer. Instead of a valve opening, the opening occurs in the sleeve.

In Fig. B, the **exhaust is fully open.** At the starting of the exhaust opening the outer sleeve port is approximately in register with the cylinder exhaust port, the full opening being obtained chiefly through the more rapid motion of the inner sleeve, its port "catching up" with the port in the outer sleeve.

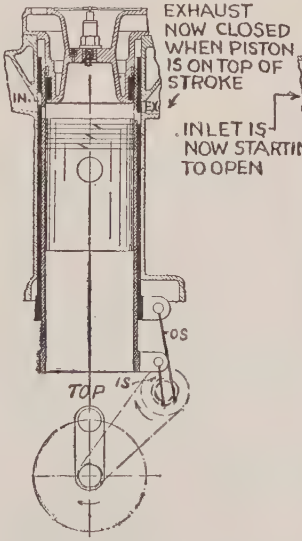

Fig. C

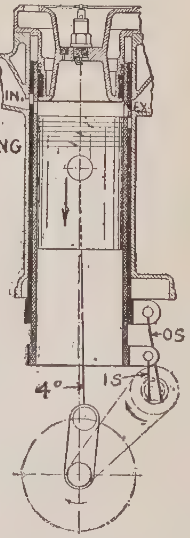

Fig. D

In Fig. C, the **exhaust closes** on top. The inner sleeve first reaches the bottom of its travel (note position of eccentric rod IS), and the outer sleeve, following it, closes the exhaust opening by over-running the cylinder port.

In Fig. D, the **inlet opens** 4° after top. At the closing of the exhaust, the sleeves are moving in opposite directions, the inner one up and the outer one down (see eccentrics **OS** and **IS**). The inlet ports in the sleeve then overlap, the opening being in line with the cylinder wall. The inlet ports in the sleeves are moving in opposite directions.

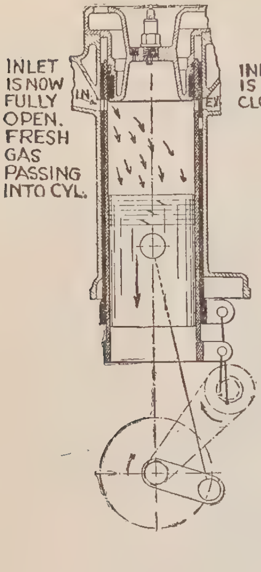

Fig. E

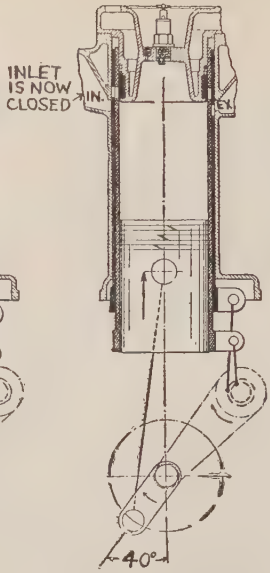

Fig. F

In Fig. E, the **inlet is full open.** The continued but slow downward movement of the outer sleeve, together with the increasingly rapid upward motion of the inner, causes the two sleeve ports to coincide with each other.

In Fig. F, the **inlet closes** 40° after bottom center. From the point of full inlet opening, both sleeves travel upward, the inner at a higher rate than the outer. This action is continued until cut-off is secured and the port closed by the lower edge of the inner sleeve port over-running the lower edge of the "junk" ring carried by the head casting of the cylinder.

As the inlet closes, the next stroke up would be the compression stroke, and when on top, the explosion would occur and the piston would go to the position shown in (A).

Valve timing of the Stearns-Knight early model four-cylinder engine is shown in Fig. G. Valve timing of the Stearns-Knight six cylinder (early model); the same except inlet opens 4 degrees instead of 8 degrees, and exhaust closes on top dead center instead of 4 degrees after.

This valve-timing diagram can more clearly be understood after reading under the subject of valve-timing, as on page 69, which gives an explanation of how a flywheel is usually marked. See "note" at bottom of page 63 for meaning of "top dead center," "bottom dead center," etc.

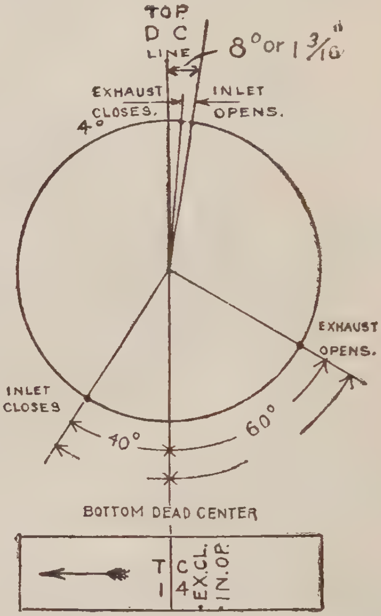

Fig. G. Knight 4-cylinder valve timing. The flywheel below is as if viewed from the rear. The diameter is 17".

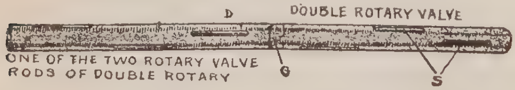
THE ROTARY-VALVE ENGINE

This type of engine is the same as any other four-cycle principle of gasoline engine, except instead of the "poppet type" of valves the "rotary type" is used to admit gas to the cylinder and to permit burnt gases to pass out. The Speedwell was one make of car which used the double-rotary valve.



The rotary valve is nothing more than a long cylindrical piece of metal with holes in the shape of slots cut as at (S) and (D) above. Instead of valves popping up and down, this rod is placed alongside of the cylinder and is operated by a chain or gear from the crank shaft. As it turns, the openings in the rods (rotary valve) perform the same function as the poppet valves.

There are two types of rotary-valve engines, the double valve and the single valve.

The double rotary valve can be compared with the poppet-type valve engine using the "T"-head type of cylinder, which has the intake valves on one side and the exhaust on the other. On the double rotary valve we have an "intake rotary valve" on one side and the "exhaust rotary valve" on the other side (Figs. 1, 2, 3, and 4). On a four-cylinder engine, each valve would have four slots.

The single rotary valve can be compared with the poppet-valve type of engine using valves-in-the-head, operated by one overhead cam shaft. Instead of poppet valves and cam shaft, however, there is one long rotary valve, with openings as shown in Figs. 5, 6, 7, and 8. Note the position of these openings during the periods of intake, compression, firing, and exhaust.

THE ROTARY-CYLINDER ENGINE

Fig. 9 shows the Gnome aviation seven-cylinder engine which is treated fully in other sections of this book.

In the ordinary motor-car engine the cylinders are bolted to a crank case and the crank shaft is made to turn around by the force of the explosions in the cylinders.

In the rotary-cylinder engine the crank shaft is held stationary and the cylinders are mounted on a cylindrical crank case which can revolve. Connecting rods are fastened to crank-shaft pins (Fig. 10).

The revolving cylinder or "rotary-cylinder" type is a French invention. This style of engine was used extensively during the war in small, high-speed, single-seated machines; another is the La Rhone.

Principle of operation: When an explosion occurs in one of the cylinders the energy can do nothing else but force the piston down. This action turns the rodholder on the crank shaft, which causes the rods, pistons, and hence the cylinder to revolve as a unit. The crank shaft (Fig. 11) remains stationary, and, due to this fact, the pistons will assume different positions in the cylinders owing to the location of the rods on the crank pin. For instance, in the movement of the cylinder **A** from **X** to **Y**, the piston in the cylinder will travel downward, as shown in the illustration, until it reaches bottom of its stroke. This type of engine is not adapted for automobile work.

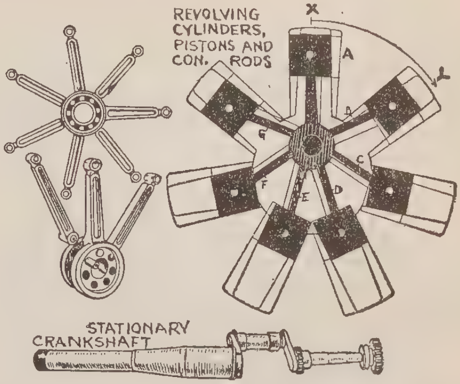

Fig. 10 (upper, left); Fig. 9 (upper, right); Fig. 11 (below).

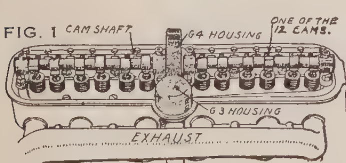
Fuel system. Gasoline is fed to the crank case through the hollow crank shaft to a spray nozzle in the crank case. The gasoline in the tank is under 5 lbs. pressure per sq. in. by air pump. When the cylinders are within 20° of the end of the inlet half-revolution, a series of small inlet ports around the circumference of the cylinder wall is uncovered by the top edge of the piston whereby the combustion chamber is placed in communication with the crank chamber. The crank chamber is at atmospheric pressure, and the combustion chamber is below atmospheric; the result is, a suction is created which draws gas from the crank chamber to the combustion chamber. The air for mixture is provided by admission through the exhaust valve during the first part of the inlet stroke. Originally an inlet valve was located in the center of the piston head—this is not now used.

THE WEIDLEY ENGINE WITH OVERHEAD CAM SHAFT AND VALVES

Valves: In this type of engine the cam shaft is placed overhead as in Fig. 1, with the cams integral. There are two overhead valves for each cylinder (see Figs. 3 and 4); therefore there are twelve cams, one for each valve. Engine in this example is a six-cylinder.

FIG. 1



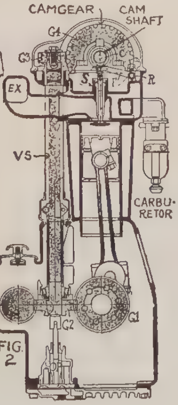


FIG. 2

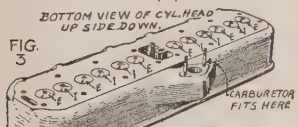
FIG. 3



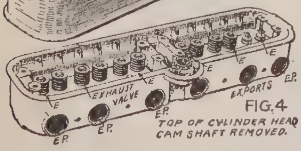


FIG. 4 TOP OF CYLINDER HEAD CAM SHAFT REMOVED.

The cam shaft is operated by a gear (G1) on the crank shaft, which operates a gear (G2, Fig. 2), which is called the lower timing gear; this gear is placed at the lower end of a vertical shaft (**VS**) with an upper timing gear (G3), which operates the cam-shaft gear (G4). By referring to Fig. 2, it will be seen how the cam (C) operates the tappet arm (**F**), which in turn opens the valve against the tension of the spring (**S**). While the construction varies, the principle, it will be noticed, is just the same as in any other engine. The cam shaft turns one revolution to two of the crank shaft.

The cam shaft mounted on the cylinder head has four bearings and these are 1 3/16″ in diameter. The end bearings are 1¼″ by 1¾″ long, and the middle ones, which are on either side of the driving gear, are 1¾″ by 1⅝″ long. A hole ⅜″ in diameter is drilled through the cam shaft for its entire length, and carries oil to the cams and bearings.

The cylinder head is detachable from the cylinder, and the cylinders are all in one block; therefore to grind the valves or to get to the valves, the cover is removed, and then the cylinder head. Fig. 4 shows the cylinder head removed and Fig. 3 shows the cylinder head turned up side down, exposing to view the valves seated in the cylinder-head casting.

To grind valves: First, remove head. If a single valve is to be ground the valve spring may be compressed and the pin holding the spring removed, when the valve can be dropped out and the seat ground, or the cam shaft may be removed, which is easily done. The springs and pins are removed and the cylinder head is turned over on a bench, as in Fig. 3, and the valves are ground as in any other engine. See Index for method of valve grinding.

To set the valves: The inlet opens 10° past top and the flywheel is marked "IO." The exhaust closes at 10° after top. Therefore, set the cam shaft with piston No. 1, 10° past top center; the cam is just leaving the exhaust valve (see **C**, which would be a little farther in the direction of rotation, as it now has the valve open). The gears are then meshed at this point. The timing of both inlet and exhaust is done by one cam shaft, the same as on an "L"-type cylinder.

FRANKLIN AIR-COOLED ENGINE

Engine: Six cylinder, 3¼ x 4 inches. Piston displacement 199 cubic inches. H. P. in accordance with the S. A. E. is 25.3, at maximum 31. About 1,700 r. p. m. is maximum speed. The gear ratio of the car on high gear is 3.9 to 1, the wheel being 32 inches, which means 1,950 revolutions of the engine per mile. Weight of car under 2,300 lbs. Maximum speed of car 50 m. p. h. or over.

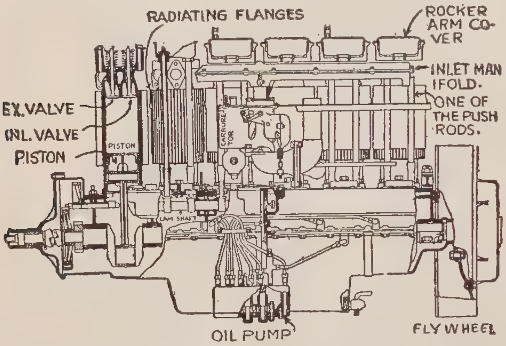

Fig. 5. Side view of Franklin air-cooled engine.

Overhead valve mechanism with one cam shaft on the side is used. Atwater-Kent ignition. Carburetor of Franklin design.

Pistons: As the normal working temperature in the Franklin engine is distinctly high, the makers were not very ready to believe in the aluminum piston, but they have now adopted it as a stock practice and consider that the better mean effective pressure of the new engine is largely due to the improved piston cooling obtained. At first there was a little trouble from wear on the skirt; it was difficult to get a close enough fit to insure absence of slap without abrasion. The trouble was overcome completely by turning a shallow, square groove of screw-thread form from the bottom of the skirt to just beneath the lower ring. This holds oil securely and allows a smaller clearance than is possible with a plain piston. Piston clearance is .005″. Three piston rings 3/16″ wide with .015 to .020″ clearance between ends are fitted to each piston.

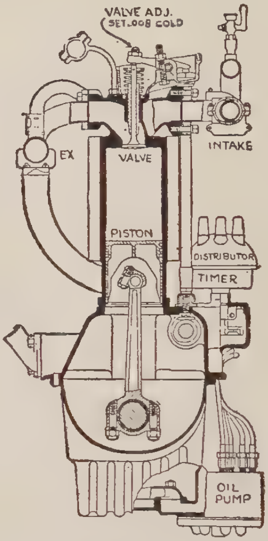

Fig. 6. End sectional view of Franklin engine.

There is an interesting **lubrication system** employed, individual oil supply being sent to every point. The oil pump, which is a conventional gear pattern, is mounted on a large plate, and the delivery from the pump is distributed to a number of oil leads by means of passages in the plate. Actually the plate is die-cast aluminum with distributing grooves, and these grooves are made into closed passages by putting a piece of thin sheet copper over the face. This gives direct-pressure feed to all bearings on the crank shaft and to various other points.

Valve Clearance

Valve clearance is .010″ when cold and adjustment is made between the end of the rocker arm and the adjusting screw. See Index for "Franklin cooling system and wiring diagram."

INSTRUCTION No. 12

THE CONTINENTAL ENGINE

Continental Model "7R" Red Seal Engine

Model "7R" is a popular six-cylinder engine as used on several makes of passenger automobiles.

Specifications: Cylinder, 3¼″ bore, 4½″ stroke; displacement, 224.00 cu. in.; horsepower, S. A. E. rating 25.35; B. H. P., 1,000 r.p.m., 26; 2,600 r.p.m., 55; weight 575 lbs.; cooling, centrifugal pump; lubrication "force-feed" with drilled crank shaft and gear-type oil pump; carburetor, vertical outlet type, 1¼″; provisions for standard makes of starter, generator and ignition systems; clutch, multiple disk or 10″ plate; construction, unit power plant; suspension, three point.

Valve Timing

Valve timing, 7R: Inlet opens 12° after top; **closes** 20° after bottom; **exhaust opens** 40° before bottom; **closes** 8° after top.

The timing marks on the flywheel can be seen through the inspection hole in the housing, directly over the flywheel. A steel pointer is used to line up the flywheel marks when checking the valve timing.

Valve timing, "7W" (an older model engine): **Intake opens** on upper dead center and **closes** 33° past lower dead center. **Exhaust opens** 67° before lower dead center and **closes** on upper dead center. This setting gives an inlet period of 213° and an exhaust period of 247°.

See Index "Questions and answers on Continental engines."

Lubrication of Continental "Model 7R" Red Seal Engine

Gear type of oil pump attached as a separate unit outside of the engine, near the front end of the crank case. Driven by spiral gears. Maintains a pressure of 5 to 30 lbs., depending upon car speed, temperature of oil, and general operating conditions.

Oil pressure is adjusted in the same manner as explained of the Continental "L4" engine in the Commercial car instructions, except that the amount of pressure should range from 10 to 15 lbs. at a car speed of 15 m.p.h. Oil is forced from the pump to the main oil line and distributed through ducts to the four main bearings. The crank shaft is drilled to conduct oil to the six connecting-rod lower end bearings. Through a secondary line connecting with the main reservoir, oil is fed to the timing gears and to the pressure-adjusting valve in the gear case. An oil spray lubricates the piston-pin bearings, cylinder walls, and four cam-shaft bearings, as well as the valve-spring chamber, valve stems, valve-spring bearings, and push-rod bearings.

Details of the Continental Model "N" Red Seal Engine

Model "N" engine is an engine with four cylinders, 3¾" bore, 5" stroke. It is designed for trucks ranging from ¾ to 1½ ton carrying capacity. When fitted with a governor, the recommended governing speed is 1,300 r.p.m. Pistons and connecting rods can be removed from below. At 1,000 r.p.m., 23 h.p., at 2,000 r.p.m., 34 h.p., weight 410 lbs., with flywheel. Carburetor 1¼". Cooling: thermo-syphon. Three or four-point suspension.

Lubrication would be termed force-feed and splash system. The forced-feed system supplies oil to the crank-shaft main bearings and the timing gears. The splash system serves to lubricate the interior of the engine, such as the pistons, cam shaft, push rods, and connecting-rod bearings. The oil pump is a horizontal plunger-type pump operated by an eccentric from the cam shaft. The oil pressure is automatically controlled.

To grind the valves, see Index under "Valve grinding."

To take up connecting-rod bearings, remove the lower half of the crank case. Shims are used and it is very necessary to remove one or two—being careful to remove equal number on each side and not to have a bearing too tight.

If the bearings are too far gone to take up by removing shims, it is then necessary to fit new bushings (see repair subject).

The pistons and connecting rods can be taken out past the crank shaft.

Renewing piston rings is accomplished by lapping new rings to the cylinder (see Index under "Fitting piston rings").

Valve Timing

Valve timing of the model "N" engine is as follows: **Inlet opens** 17° 53′ past upper dead center and **closes** 29° 25′ past lower dead center. **Exhaust opens** 42° 36′ before lower dead center and **closes** 8° 20′ past upper dead center.

This gives an intake period of **191° 32′ and an** exhaust period of 230° 56′.

Remarks

The words "Red Seal," as used with these engines, represents the highest grade of motors manufactured by the Continental Motors Corpn., Detroit, Mich. Many passenger and truck model engines are manufactured. The model "7R" is a popular passenger car engine, and model "L4" (see Commercial Car Instruction) and model "N," below, are popular truck engine models.

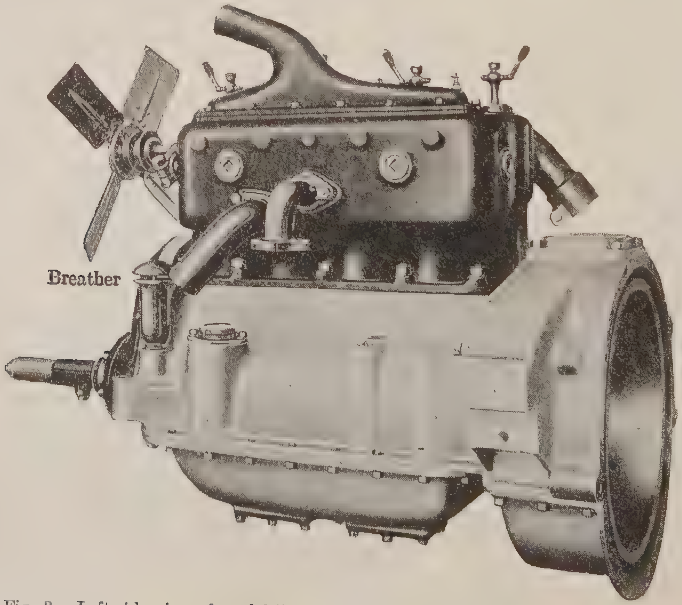

Fig. 3. Left side view of model "N" Red Seal Continental four-cylinder engine.

INSTRUCTION No. 13

CARBURETION: Early Carburetion Principle; Parts; Carburetor Principles; Gasoline; Priming Methods; Heating Methods; Vaporizing Gasoline; Size of Carburetor to Use; Gasoline Troubles; Gasoline Tank and Gauge; Fuel-Feed Methods; Vacuum Gasoline Feed System

EARLY CARBURETION PRINCIPLE

Meaning of carburetion: The mixing together of gasoline vapor and air is called "carburetion," and the device that keeps the two in proportion is called a "carburetor."

To get energy out of the gasoline it is necessary for it to be converted into a vapor and then mixed with a volume of air before it can be exploded in the cylinder.

There are two ways of producing this vapor, one being to expose a considerable surface of this liquid to the air, which is also caused to bubble through it and thus become impregnated with the gasoline vapor. This was the original method, and was called the "surface" type of carburetion.

The second method is to "spray" the liquid gasoline through a fine spray nozzle or jet into the mixing or vaporizing tube, into which air can be drawn to intermingle with the vapor.

The device in which this operation is performed is termed a "carburetor," and the operation itself is known as "carburetion," from the fact that the gasoline largely consists of carbon. The mixture might also be termed "carbureted" air.

Amount of gasoline and air: It has been found that the best explosive mixture, with the gasoline commonly used, is a proportion of 14 parts air to 1 part gasoline (this when maximum power is desired) and ranging to 17 to 1 (the latter for maximum economy), proportioned by weight of air and gasoline.

That is, 14 to 1, or rich mixture, is best for quick acceleration, or 15 to 1 or leaner mixture best for pulling with wide-open throttle, and 17 to 1, or still leaner mixture, for high-speed work (figures only approximate).

Pure gasoline vapor will not burn; it must be mixed with air before it can be used in an engine. To burn with the greatest rapidity and heat, the air must be in correct proportion to the vapor. The exact amount of air to be mixed with a certain amount of vapor depends on the quality of the gasoline, and other conditions. The carburetor, by which the proportions of the mixture are maintained, is so made that a current of air passes through it when the piston makes a suction stroke.

"Mixing Valve"—an Early Form of Carburetor

In the early days the method of mixing the gasoline and air in proper proportions was by means of a "mixing valve" (Fig. 1). It could also be termed a carburetor but without the float cut-off mechanism. The air was drawn in at "air intake," through valve (3), being opened automatically by suction of the piston, forming a vacuum in the crank case when going up (on a "two-cycle" engine), or when the inlet valve was open and the piston traveling down on suction stroke on a "four-cycle" engine. If, therefore, the gasoline needle valve was open, gasoline would also be drawn in, mixed with the air, and pass into the cylinder in a partially vaporized condition.

The mixing valve, also called a "generator valve," is still used to a small extent on two-port two-cycle engines. It takes the place of a check valve, as the valve (3) serves the same purpose.

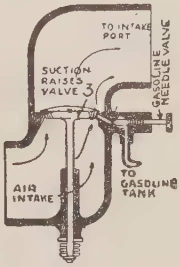

Fig. 1. Early form of a carburetor; a mixing valve.

Note the absence of any float arrangement. The gasoline is fed by gravity, and when the engine stops the gasoline needle valve must be cut off, otherwise the gasoline will drip.

Constant-Level Type of Carburetor

Fig. 2 explains the purpose, location, and parts of a simplified carburetor.

The gasoline tank is above the level of the carburetor; therefore the gasoline is fed to the carburetor float chamber by gravity.

The air goes through a passage, in which is a small pipe called a "spray nozzle," that sprays the gasoline so that it comes in contact with the air (see Fig. 2). The gasoline, being volatile, is taken up by the air, and the mixture goes to the cylinder.

The amount of air that may flow through the carburetor, and the quantity of gasoline that may flow out of the small pipe, are adjustable, so that for a certain amount of gasoline the proper proportion of air may be admitted.

When the mixture is not correct, that is, when there is too much or too little air for the gasoline flowing out of the small pipe, the running of the engine is affected, and it will not deliver its full power.

When there is too much air for the gasoline, the mixture is said to be "too poor" or "lean"; when there is too little air, the mixture is said to be "too rich."

The carburetor is connected to the inlet pipe, and no air or gas can enter the cylinder through the inlet valve without first passing through the carburetor.

The air drawn through the carburetor on the suction stroke enters it through the "air intake" and passes around the spray nozzle, drawing gasoline with it; the level of the gasoline in the float chamber then drops, and the float drops also and permits more gasoline to enter the float chamber.

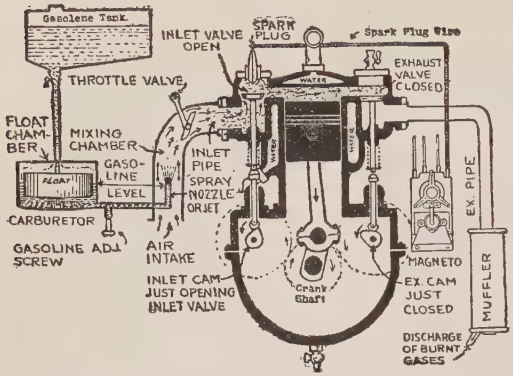

Fig. 2. Simplified illustration showing how the gasoline flows from the gasoline tank to the carburetor; how it is mixed with air and then drawn into the cylinder when the inlet valve is open.

It is in the "mixing tube," or "mixing chamber," as it is sometimes called, that the air is brought into contact with the gasoline. The "spray nozzle" projects into the mixing tube, so that it is in the center of the current of air.

How the gasoline is drawn into cylinder with the air: When the air is not passing through the mixing tube, the liquid gasoline stands just below the open end of the spray nozzle, but as soon as the current of air passes through, it sucks the gasoline out. The current of air sucks up the gasoline, very much as would a child trying to draw the last few drops of soda through a straw, drawing in really more air than soda.

The piston of the engine, on its suction stroke, produces the suction effect similar to a squirt-gun drawing in water.

The inlet valve must be open to permit the gas to be drawn into the cylinder—which is the case if the piston is on the suction or intake stroke, but in no other stroke.

The **adjusting screw** or **"gasoline needle valve"** regulates the amount of gasoline to be admitted into the mixing tube through the spray nozzle or jet. The regulation of this needle valve is very important, and after once being properly adjusted, a very slight turn one way or the other will affect the running of the engine.

The throttle valve, usually placed in the mixing tube, above the spray nozzle, governs the amount of gas which enters the cylinder on the suction stroke.

The throttle-valve lever on the carburetor connects with the throttle lever on the steering wheel. Moving the throttle lever on the steering wheel, in a certain direction opens the throttle valve on the carburetor, which increases the speed of the engine.

The more gas admitted by the throttle lever through the throttle valve, the more gas will enter the cylinder; hence more power or greater force on the power stroke results, thereby giving more speed to the piston of the engine.

Moving the lever in the opposite direction closes the throttle valve on the carburetor, reducing the amount of gas which enters the cylinder, thereby reducing the speed of the engine. The throttle valve is never entirely closed, but is set so that the engine will idle when the throttle lever on the steering wheel or accelerator is closed.

The float in the carburetor is provided merely to prevent the gasoline overflowing and running out of the spray nozzle, when the engine is not running. The float is adjusted so that the level of the gasoline will not quite reach the top of the spray nozzle or jet. Thus, as the float automatically governs the level of the gasoline in the float chamber and automatically cuts off the supply from the gasoline tank when the engine stops, it is termed a "constant-level type" of carburetor.

The floats are usually made of cork or hollow metal balls, which float in the gasoline inside of the mixing chamber. A needle point arrangement is connected with the float, which cuts off the gasoline flow when the engine stops.

The reason why engines must first be cranked, when starting a gasoline engine, is due to the fact that a charge of gas must be drawn into the cylinder and then compressed. Compressed gas is ignited by the electric spark; this produces the power stroke, and the power from this combustion of compressed gas, together with the momentum of the fly wheel, will keep the engine in motion until the next power stroke. The cycle operation of suction, compression, power, and exhaust is repeated over and over again.

An Early Constant-Level Type of Carburetor

Maybach conceived the idea of using **a float** to maintain a constant level of gasoline just below the spray-nozzle head, with a **main air inlet** below the nozzle, as shown in Fig. 3.

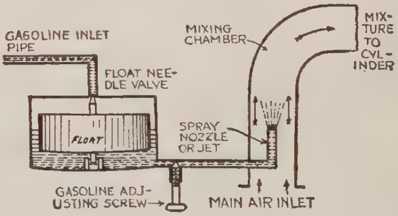

Fig. 3. Early type of carburetor with float mechanism. A "main air inlet" is provided.

The gasoline is drawn from the spray nozzle by a vacuum or suction effect produced by the piston. It is thus drawn through the mixing chamber and through the open inlet valve into the cylinder. At the same time, air is drawn into the mixing chamber at the main air inlet, but inasmuch as the greatest power of an engine is obtained by having a mixture of exact proportions of air and gasoline, it is clear that if the speed of the engine is increased, more gasoline would be drawn into the cylinder without sufficient air supply to mix with it. Thus too rich a mixture would be the result. If the air opening were enlarged to give a greater supply of air at high speeds, the result would be too great an air supply at low speeds, or too lean a mixture. This type of carburetor was evidently designed for a constant steady-speed engine.

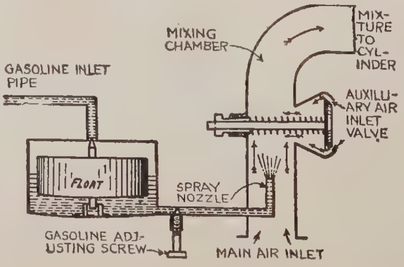

Fig. 4. In addition to a "main air inlet" an "auxiliary air inlet" is provided here.

An auxiliary air inlet was added to this type of carburetor by Krebs. Note that in addition to the main air inlet below the nozzle, an automatic auxiliary air valve was placed above the nozzle (Fig. 4).

At low speeds, the main air inlet was sufficient, but at high speeds, the suction effect being greater, the spring caused the auxiliary air valve to open, thus permitting more air to be drawn into the mixing chamber, and resulting in a better proportion of air and gasoline than the carburetor shown in Fig. 3. The greater the speed of the engine, the greater the suction effect, and consequently the greater the opening of the auxiliary air valve. At slow speeds, the air valve would remain closed and was thus automatic in action.

Another feature of the auxiliary air valve, is to break the gasoline up into as many fine particles as possible, so that the air will more readily mix with the gasoline and form a vapor. There are different methods of doing this which will be shown farther on.

Adjustable auxiliary air valve: The difficulty arising from the fact that the coil spring which held the auxiliary air valve closed at low speeds and was intended to open as the speed of the engine increased did not always function, because temperature changes would affect its sensitiveness and because the variations in the volatility of gasoline varied when cold and when warm, was overcome in a way by changing the adjustment of the tension on the auxiliary air-valve spring which was provided as shown in Fig. 5.

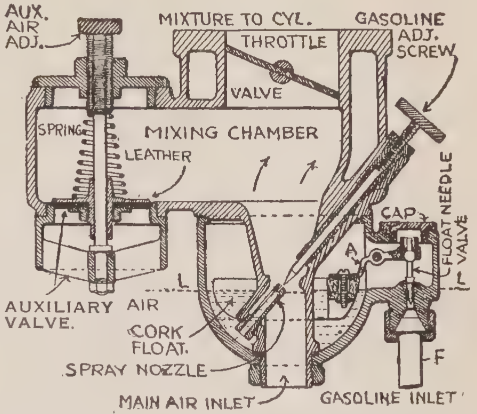

Fig. 5. Typical example of a carburetor using an auxiliary air valve.

The reader should closely observe the difference between the **main air inlet** and the **auxiliary air valve.** All carburetors have main air inlets, where air is drawn into the carburetor below the spray nozzle, thus mixing with the gasoline. This opening can be at the bottom or the side of the carburetor.

When an auxiliary air valve is used, it is usually placed so that air is drawn above the spray nozzle and thus combines with the mixture of gasoline and air. Many carburetors do not have auxiliary air valves.

PARTS OF A CARBURETOR

Before proceeding farther with the principle of different types of carburetors we will take up the subject of parts of a carburetor.

The concentric-float type of carburetor is the term applied to a carburetor where the float surrounds the mixing chamber and spray nozzle, as in Fig. 5. This makes a compact carburetor and maintains a constant gasoline level in the spray nozzle regardless of the angle at which the engine may be. On almost all concentric-type carburetors the float is made of cork.

The side-float type of carburetor is the term applied to a carburetor where the float and float chamber are placed to the side of the mixing chamber, as in Fig. 4.

Floats

Floats are usually made of light brass or copper in various hollow forms; the joints, if any, being carefully soldered or brazed, so that gasoline cannot enter the float itself. Floats are also made of cork, well shellacked, so that they will not absorb gasoline and lose their buoyancy. (See Fig. 5.)

The sole **duty of the float** is to maintain a predetermined or constant level of the gasoline in the carburetor. This level is generally a small fraction of an inch below the jet or nozzle opening.

The float chamber is that part in which the float operates; it is sometimes placed around the spray nozzle and sometimes to the side, as previously explained.

The float level: In different makes of carburetors, the level of the gasoline in the float chamber, and the gasoline in the spray nozzle, varies from about one-sixteenth to one-eighth of an inch below the top of the spray nozzle.

As gasoline flows from the main supply tank through the gasoline pipe or line into the float chamber of the carburetor, the float rises and the needle valve shuts off the further entrance of the fluid into the carburetor.

When the engine is running and using gasoline, the float in the carburetor is continually falling and rising slightly, always maintaining the approximate gasoline level in the float chamber.

There are many types of floats and float mechanisms, as will be seen in the illustrations of various carburetors in this instruction. By referring to Figs. 6, 7, and 8, the reader will observe several floats (**T**) and float needle-valve (**V**) arrangements.

Gasoline leaking into the float would increase its weight, thereby changing the proper gasoline level in the spray nozzle and causing the carburetor to flood and would thus give too rich a mixture.

Float Needle Valve

Float needle valve: The part **V** (Figs. 6, 7, and 8) explains how the float causes the float needle valve (**V**) to close the opening at the gasoline supply pipe (**F**) when the gasoline has reached the proper level in the float chamber, and how it causes the needle valve (**V**) to open the outlet at the end of the pipe (**F**) when the gasoline level is reduced. (**C**) is the opening leading to the spray nozzle.

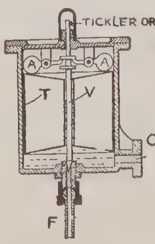

Fig. 6

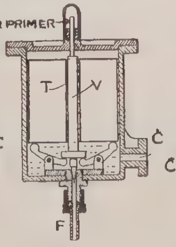

Fig. 7

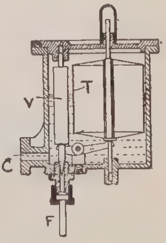

Fig. 8

Note that in Fig. 5 the float needle valve is to one side of the float. A glance will show how the float needle valve would be caused to open when the float drops below its level (L) and how it would cause the float needle valve to close when at the proper level. **Adjustment of the height of the float** can be made by slightly bending the arm (A) (Fig. 5).

A method of priming, or to supply an increased flow of gasoline at the spray nozzle when starting a cold engine, is sometimes found by what is termed "tickling" the carburetor, by raising the needle-valve rod through the float, as in Fig. 6, which projects above the carburetor and usually has a cap screwed over it to keep out dirt.

Another method is to close the main air inlet (Fig. 5), which is termed "choking" or "strangling" the carburetor, while the engine is being cranked. The fact that the air is shut off causes an increase of gasoline to be drawn in for the initial charge.

Dripping of gasoline from the bottom of a carburetor is usually due to grit or dirt getting under the float needle valve. Thus, when engine stops, instead of the needle valve seating properly and cutting off the gasoline supply from the supply pipe (F), it overflows at the spray nozzle and drips out of the main air inlet.

Remedy: By working the float needle valve up and down in its seat, which can be done by means of the rod above the carburetor float chamber (Fig. 6), or by unscrewing the cap (Fig. 5), the grit will very likely be removed. If this does not remedy the dripping, then the float should be readjusted, or possibly a new float needle valve is required.

Gasoline Needle Valve

The gasoline needle valve controls the flow of the gasoline to the spray nozzle, and the correct adjustment of it is necessary for the operation of the carburetor. It is also called the "gasoline adjusting screw" (see Fig. 5). Don't confuse this needle valve with the "float needle valve."

The regulation of this gasoline needle valve is very important and likewise very sensitive. After the carburetor is once adjusted by regulating the auxiliary air valve and the opening of this gasoline needle adjustment valve, the slightest turn one way or the other of this valve will make a difference in the running of the engine.

Types of gasoline needle valves are as follows:

1. Hand operated, as in Fig. 5.
2. Mechanically operated, by movement of a throttle through a cam arrangement by hand (treated farther on).
3. Automatically mechanically operated, by action of the auxiliary air valve, called a "metering pin" (explained farther on).

A main air inlet is on all carburetors, and, quite often, an auxiliary air valve also.

Auxiliary Air Valve

Auxiliary air inlet valve: The greatest difference in the air type of carburetor is in the construction, position, and action of the auxiliary air inlet, discussed farther on.

The auxiliary air valve is controlled automatically by the vacuum created by the engine piston, which draws air through the auxiliary air intake against a spring tension; for instance, see the auxiliary air intake in the carburetor shown in Fig. 5, page 97, the opening being controlled by the tension of a spring.

The air-valve spring: The weaker the spring the less vacuum it will take to draw the valve open, and it may be adjusted by means of a threaded sleeve (as in Fig. 5 and in various other ways).

The stronger the spring, the less air, hence a "richer" mixture. The weaker the spring, the more air, and hence a "leaner" mixture.

Another method for automatically opening and closing the auxiliary air intake is shown in Fig. 9. Note the action of the ball (L). Instead of a valve and a spring, balls are utilized instead. This carburetor is the **Kingston** air-valve type, with an auxiliary air inlet. Instead of using a spring to control the amount of air drawn into and through the auxiliary air valve, balls are used.

The **gasoline needle valve** is adjusted by hand. The float is concentric. Note the Venturi mixing tube. Another air-valve type of carburetor, with an auxiliary air valve controlled by one large ball placed in the main air inlet pipe of the carburetor is shown farther on.

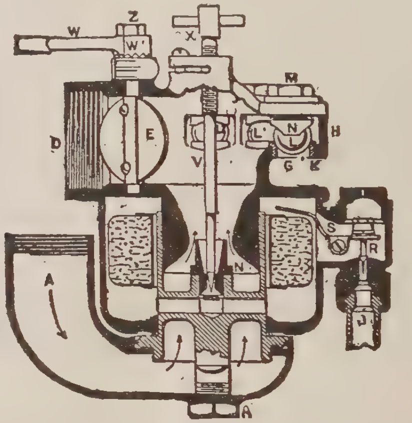

Fig. 9. Kingston air-valve type of carburetor. Note the balls in the auxiliary air valve which control the quantity of air entering the auxiliary air valve. Parts: **A**, main air inlet; **D**, outlet of mixture to engine; **E**, butterfly throttle valve; **G**, auxiliary air inlet; **L**, balls which rise as the suction increases or as the speed of the engine increases, thus admitting more air; **V**, gasoline needle valve; **X**, hand adjustment of needle valve; **W**, butterfly throttle lever connects with steering-wheel throttle lever; **N**, Venturi mixing tube.

The float is a cork float and concentric to the mixing chamber. S is an arm connected with the float needle valve, **R**. As the float rises, the arm forces the needle (R) to seat.

Explanation of the Venturi Action

If two buckets are placed side by side, both filled with water, with a one-inch opening cut in the bottom of each, one with a plain opening (A), as in Fig. 10, and the other with a "Venturi" opening (B), as in Fig. 11, the same volume of water would flow out of the Venturi one-inch opening in Fig. 11 more quickly than through the plain one-inch opening in Fig. 10.

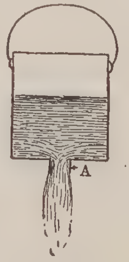

Fig. 10

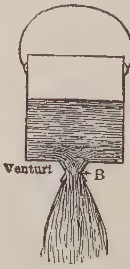

Fig. 11

Note the shape of the Venturi opening (B), in Fig. 11, then note a similar shaped tube in the mixing chamber in Fig. 9, where the arrow-points lead from (N).

The Venturi tube around the spray nozzle in the mixing chamber, is used in almost all makes of carburetors. The principle and purpose of the Venturi tube around the spray nozzle is to obtain a greater volume of air through a predetermined sized opening in quicker time. Another purpose of the Venturi tube is that the lowest pressure of the inrushing air will be at a point where it will cause the greatest suction in the spray nozzle.

Spray Nozzles or Jets

Spray nozzle: The fuel is discharged into the mixing chamber through the spray nozzle (also called **"jet tube"**). As its name implies, it is intended to deliver the liquid in the form of a fine spray, which is: (1) vaporized more or less; (2) mixed with the entering air, and (3) carried by the suction into the engine cylinder. The simplest form of spray nozzle is one having a single opening, as shown in Fig. 5 (page 97).

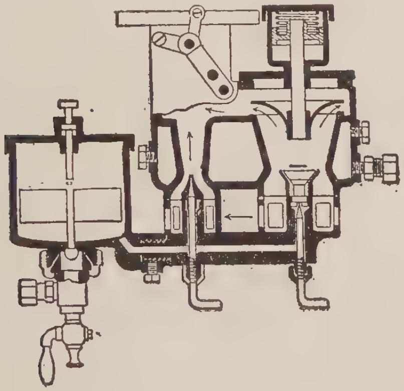

Fig. 12

Some carburetors have two spray nozzles or jet tubes, as shown in Fig. 12. Another type has what is called a "multiple jet" spray nozzle.

When a carburetor has more than one jet, it is particularly adapted to a multiple of cylinders of large size, and especially to six-cylinder engines.

The mixing chamber consists of an enclosure or passageway containing the nozzle. The gasoline and air are mixed within this tube in proper proportions and then drawn through the throttle into the engine.

Throttle Valves

There are three types of throttle valves: the butterfly, the rotary and the sliding.

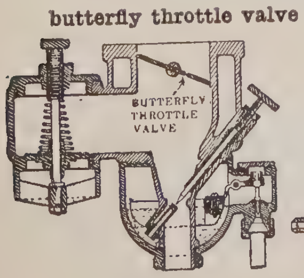

Fig. 13

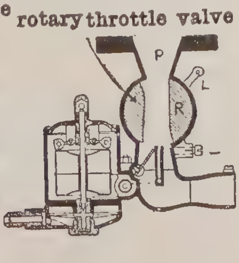

Fig. 14

Fig. 13. The throttle is placed in the mixture outlet, and the form that is shown is called a "butterfly valve." It is a disk of metal turning on pivots, so that it acts like the damper of a stove pipe. When wide open, the butterfly valve is edgeways to the flow of the mixture, but even in this position it presents resistance to the flow, which is something that should be avoided.

Fig. 14. The rotary type of valve. The passage of gas from jet to intake manifold through passage (P) is controlled by a rotary cylinder (R). It is now shown full open, but by moving throttle lever (L), it can be closed or partially opened as desired.

The butterfly throttle valve is the type of throttle used on almost all makes of carburetors. This type of throttle is shown in Figs. 13 and 9. The mechanism and method for controlling the throttle is shown in Fig. 11, page 33 and in Fig. 16, this page.

The "rotary" or "barrel" throttle valve (Fig.14), presents no resistance whatever.

The sliding throttle valve is another type which presents no resistance to the flow of gas. This type is now practically obsolete, although it was formerly used quite extensively when governors were used.

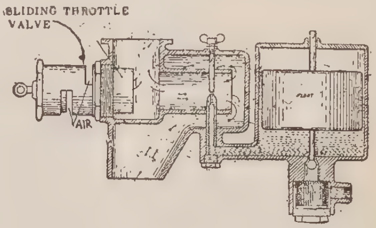

Fig. 15. The sliding throttle valve consists of a cylinder-type of throttle, but instead of being rotated, it is moved in or out of its passage, which controls the amount of gas passing to the intake manifold. As it is moved out, additional air is admitted through port holes. This type was the type formerly used with a governor.

Engine Speed; How Controlled

The method for controlling the speed of an automobile engine is by opening and closing the throttle valve on the carburetor by the hand throttle lever or foot accelerator.

A rod leading from the throttle lever on the throttle valve connects with a hand lever on the steering wheel. The driver then has the speed of the engine under his control at all times.

When running on a level and if more speed is desired, the throttle is opened by the throttle lever until the required speed is obtained. By closing the throttle, the speed is decreased.

Idling

The throttle valve is never entirely closed; the lock screw prevents the throttle from closing entirely. Therefore the engine will run slow, or "idle," as it is called, when the throttle valve lever on the steering wheel is closed and the car standing. To stop the engine entirely, throw off the ignition switch.

The Accelerator

This is the usual means for controlling the speed of the engine.

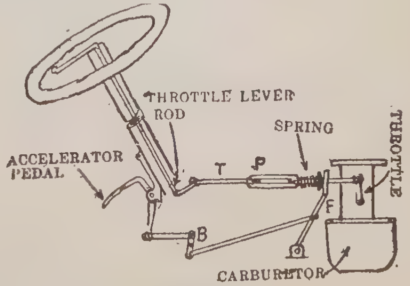

Fig. 16

The accelerator consists of a foot pedal which opens and closes the carburetor throttle valve independently of the hand-throttle lever. By referring to the illustration (Fig. 16), it will be noted that the accelerator will operate the throttle of the carburetor without moving the hand-throttle lever, by an arrangement as shown. When the foot-accelerator pedal is depressed, the rod (**F**) moves against a shoulder which is fastened to the throttle shaft. The end of the shaft (**T**) works free in a turnbuckle (**P**). Thus the throttle can be opened without disturbing the hand lever, or the hand lever can be operated without moving the foot pedal. The accelerator is used more than the hand-throttle lever. Its purpose is the same as the hand-throttle lever on the steering wheel: to open and close the throttle valve.

Fig. 17 illustrates the relation of the accelerator connections to the spark lever and its controls on the steering device. The Locomobile is shown as an example.

When pressed downward for increase, or released for decrease of speed, its action is instantaneous. When the accelerator is released, the engine immediately resumes the speed determined by the positions of the hand lever on the steering wheel. Although either the hand-throttle lever or the accelerator may be used to control the speed of the car, the use of the hand lever is advised for beginners. After confidence in driving has been gained, the more delicate action of the accelerator will be preferred.

The word "accelerate" means "to hasten." The term, therefore, is applicable here because it is quicker to operate throttling.

The Governor

There are no pleasure cars using the governor. Nearly all truck, tractor, marine and stationary engines use governors. See Index under "Governors." One governor, which is a "throttling" type, is the centrifugal ball type illustrated in Fig. 18**A**, the principle of which, is, no doubt, familiar to all. The "sliding" throttle in the carburetor is actuated by the movement of the sleeve controlled by the balls (**B**). The balls fly out as the speed increases, causing the throttle to close. Another principle is that of the "hit and miss type."

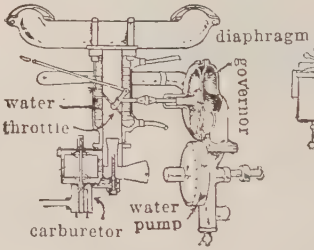

Fig. 18

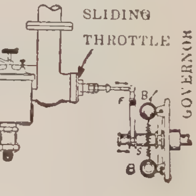

Fig. 18A

The governor formerly used on the **Packard** was termed a "hydraulic" governor of the diaphragm type, located directly above the water pump. It was operated by the pressure of the water in the water circulation system and consisted of a circular chamber divided by a flexible diaphragm of leather and rubber. On one side of the diaphragm was a water space through which the water of the circulating system passed. On the other side was an air space and a plunger head against which the diaphragm pressed. The plunger was directly connected with the throttle valve (Fig. 18).

CARBURETOR PRINCIPLES

Despite tremendous advancement made in internal-combustion engines during recent years, original methods of carburetion are still—broadly speaking—in practice.

The carburetor is still a comparatively primitive instrument, depending upon the suction of the piston during its descent on the inlet stroke to draw from a jet (spray nozzle) or jets—variable or otherwise—the necessary gasoline to mix with the air.

This jet can be of a fixed size or it can be variable in size. This spray of gasoline is at the mercy of the temperature, valve timing, exhaust, inlet, and combustion-head design.

Carburetors, as we know them at the present time, are divided into five classes:

(1) **Air-valve type.** In this the fuel issues through a fixed orifice and the additional air required when the throttle is opened is admitted through an auxiliary air valve.

(2) **Compensating-jet type.** In this an auxiliary fuel jet comes into action as the throttle is opened.

(3) **Metering-pin type.** In this the size of the gasoline orifice (jet) is increased automatically to increase the flow of fuel as the throttle is opened.

(4) **Expanding type.** In this there are a number of fixed orifices which come into action one after the other as the throttle is opened.

(5) **The "plain tube" or "pitot" principle.** A modern principle now being adopted extensively. The metering pins, dash pots, and auxiliary air valves are dispensed with. It derives its name, "plain tube," from the fact that both the air passage and the gasoline jet are of fixed size for all engine speeds. The action is to supply an increased supply of gasoline or rich mixture for acceleration and then to thin down to an economic mixture for normal engine speed.

Air-Valve Principle

The air-valve principle of the carburetor is the type previously shown in Fig. 3, page 96. In this type (see also Fig. 19), it is only possible to adjust the amount of gasoline flowing to the spray nozzle. It is therefore only suitable for engines which run at a steady, constant speed, as previously explained.

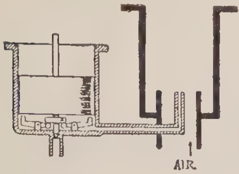

Fig. 19

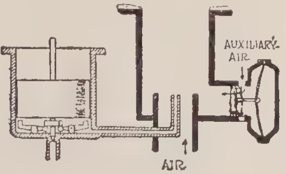

Fig. 20

The engine of an automobile, however, does not run at a steady speed; sometimes it is running fast and sometimes slow.

The speed of the air current passing through the carburetor depends on the speed of the engine; when the engine is running fast the speed of the air current through the carburetor is much greater than when the engine is running slow.

The greater the speed of the air current, the more gasoline it will suck out of the spray nozzle, and the adjustment of the gasoline flow that will give a correct mixture at a low speed will give a rich mixture when the air current moves at a higher speed. For this reason the air supply must also be varied in order to give a more combustible mixture.

Auxiliary Air Valve

To vary the air supply, different methods are used, but the one used most is the auxiliary air valve, and this is where the "air-valve type" carburetor derives its name (see Fig. 20).

The auxiliary air valve was designed for engines which run at changing speeds, so that an extra supply of air is admitted when the air current flows so fast that it would result in too rich a mixture.

The disadvantage of this type is that owing to the relieving action of the spring valve, it does not increase the proportion in proper ratio, and is hardly suitable for the present-day high-speed flexible engine.

There are several different models now manufactured, based on the principle of the auxiliary air valve only. In these, the problem is worked out in different ways; one manufacturer uses a "spring-controlled valve"; another hopes to get better results by regulating the movement of the valve by "two springs," instead of one; still another maker adds an "air dashpot" with the hope of getting finer regulation and a better functioning of the auxiliary air valve; another uses a "dashpot filled with gasoline"; and there are others who use metal "balls" to serve as the auxiliary valve, while others use what are known as "weighted air valves," in which the suction lifts balls, thus admitting the air which sweeps over the spray nozzle. While they all differ in the details of working out the design, all are, nevertheless, based on the basic principle of the auxiliary air valve as originally worked out, and shown in Fig. 4, and in Fig. 20 above. For simplicity in nomenclature we shall refer to this type as the auxiliary air valve type.

Relation of Acceleration to Gasoline Consumption

The rapid advance of high-speed and multiple-cylinder engines demands "quicker acceleration," meaning quicker "get away" or "pick up" of the engine.

Flexibility of control means practically the same thing, i.e., the capabilities of the engine to "pick up" from low to high speed and vice-versa. Rapid "acceleration" and "flexibility," both call for a sudden greater amount or percentage of gasoline to air. Quick acceleration therefore demands a surplus of gasoline for but a brief period, after which the normal supply will care for the engine. It may be but a matter of a few seconds, yet it is of importance that this additional supply be ready and in available form for that brief period.

To meet the sudden demand for gasoline, the added nozzle, or **multiple jet** has been introduced by some makers, so that when the suddenly opened throttle brings the auxiliary air valve into use, the valve in turn brings more gasoline into the mixture by opening the gasoline needle valve wider. This is termed the **"metering pin"** method. One maker does this by a "dashpot" on the auxiliary valve stem, the dash pot performing a regular pump stroke and forcing gasoline into the mixing chamber by way of a separate nozzle as the auxiliary air valve opens. Once open, the pumping action ceases, but the nozzle remains open for a more even demand for more fuel.

Proportion of air and gas: All of these methods of providing "acceleration" are based on the accepted belief that in carburetion, different mixtures of air and gasoline vapor are needed for different engine requirements. The days are past when the uniform-mixture argument dominated, the argument that the ideal carburetor was one that would give, say, a mixture of fifteen proportions of air to one of gasoline vapor for all speeds, "acceleration," "hard pulling" with open throttle, and high-speed work with open throttle, etc., etc. **The new rule** is that the amount of gasoline fed into the air volume must be changed according to demands. Thus a twelve-to-one or "rich" mixture might be best for quick acceleration; a fifteen-to-one or "leaner" mixture may be best for pulling with the throttle wide open; and a seventeen-to-one, or still "leaner" mixture may be desirable for particularly high-speed work. Therefore a "varying mixture" must be supplied.

The Compensating-Jet Principle

The compensating jet type of carburetor is where an **auxiliary fuel jet** comes into action, as the throttle is opened. Types of carburetors coming under this heading would be the Zenith; the Stromberg model "H" and the Marvel (see Index).

The Metering-Pin Principle

In the metering-pin type the size of the gasoline orifice, or jet, is increased automatically to increase the flow of fuel as the throttle is opened. In other words, as the throttle is opened, the metering pin (P, Figs. 21, 22, 23), which is similar to a gasoline needle valve, is moved so as to permit more gasoline to flow throught the spray nozzle or jet (J). Thus, instead of the gasoline needle valve (metering pin), being adjusted by hand, it is automatically adjusted by the speed of the engine, thereby permitting more or less gasoline to flow as the speed increases or decreases. This principle is called the "metering pin" principle, also the "pneumatic" principle, when operation is by air control.

Various methods are employed to operate this needle valve or metering pin as follows:

On the Schebler model "L" (Fig. 21), the metering pin (P) is connected with the carburetor **throttle lever** in such a manner that the metering pin (gaso-

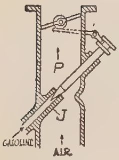

Fig. 21

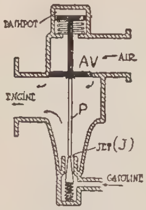

Fig. 22

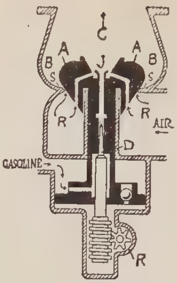

Fig. 23

Fig. 21. Schebler model "L." Metering pin controlled mechanically.

Fig. 22. Schebler model "T." Metering pin controlled by auxiliary air valve.

Fig. 23. Stewart model metering pin controlled by air suction.

line needle valve) is raised as the throttle is opened. See Index under "Schebler carburetors."

On the Schebler model "T" (Fig. 22), the metering pin (**P**) is connected to and controlled by the **auxiliary air valve.** As the throttle is opened, the speed of the engine increases, the suction becomes greater, and the air valve (**AV**) is sucked downwards, causing the metering pin (**P**) to give a greater opening at jet (**J**), thus admitting more gasoline.

On the Stewart carburetor (Fig. 23), the metering pin (**D**) is controlled by **air suction.** As the throttle is opened the suction becoming greater, the metering valve (**A**) (part in black) rises, enlarging the opening at the metering pin (**D**) and drawing more gasoline through jet (**J**). At the same time more air is drawn around the valve seat (**B**). A ratchet (**R**) is connected with a control on the dash for the purpose of enlarging the opening at the metering pin, so as to obtain a rich mixture when starting.

Example of a Carburetor with Both a Metering Pin and Dash Pot

The Rayfield uses a "metering pin," which is lifted as the throttle opens in the main jet (**N**) (Fig. 24), through a link arrangement, which establishes a right for it to be classified as a metering pin type. But it goes farther. It incorporates an auxiliary nozzle (**AN**) which also has a metering pin that is depressed when the auxiliary air valve opens. Thus, by having two distinct nozzles it establishes its right also to be classified as an expanding type of instrument.

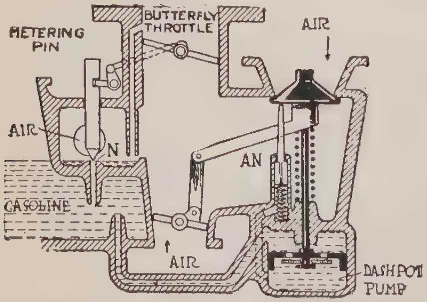

Fig. 24. The Rayfield carburetor principle with "metering pin" connected with the throttle and "dash pot," with auxiliary air intake.

But the Rayfield goes still farther, in that it combines a **pumping action** on the gasoline in the auxiliary nozzle (**AN**) whereby a very rich mixture is furnished for acceleration whenever the air valve is suddenly opened. This is accomplished by the piston on the lower end of the air-valve stem working in a "dashpot" filled with gasoline. Gasoline enters the dashpot above the piston and is admitted to the space below the piston by the disk valve in the piston. When the air valve suddenly opens, forcing the piston downward, this disk valve is automatically closed, forcing or pumping the gasoline upward through the dotted fuel passage into the nozzle (**AN**), where it is sprayed into the inrushing air. Only when the valve opens is this pumping function occurring; at other times the gasoline issues through this auxiliary nozzle according to the suction of the engine. Thus the **Rayfield is a compound** of two metering pins in conjunction with the pumping function for acceleration.

Expanding Principle

In the expanding principle, there are a number of fixed orifices which come into action, one after the other, as the throttle is opened. Types of this class of carburetors are shown in Fig. 25 and in the description of the "Master" carburetor (see Index).

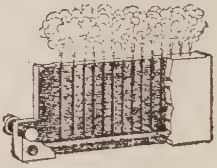

Fig. 25. The multiple jets of the Master carburetor.

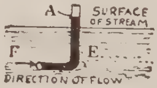
The Pitot or Plain-Tube Principle

The "Pitot" or "plain tube" type of carburetor differs from other principles. It is the principle now being used to a considerable extent, and derives its action as well as its name from a Pitot tube.

A Pitot tube is a very old instrument for measuring velocities of flowing streams of water, invented by Henri Pitot in 1730. It consisted of a vertical glass tube with a right-angled bend as shown at (**E**).



The impact of the flowing water against the open end (**F**) of tube (**E**) caused a column to rise above the surface of the stream as at (**A**), and by this small difference in height, the velocity of the stream was calculated. A similar principle, but to provide air, is embodied in the carburetor using this principle.

The Pitot tube is also used for measuring pressure in moving streams of gas or liquids. It can be used facing in any direction, but, as applied to the carburetor, faces down stream.

The Pitot tube has been used for years for measuring fire streams, chimney drafts, etc. In the carburetor it is simply used to provide air at sufficient pressure to force the fuel from the well to be enclosed in the carburetor.

The Pitot function as applied to a carburetor is simply to provide air at sufficient pressure to force the fuel from a well inclosed in the carburetor. The intake of the Pitot tube is inside the carburetor where the air pressure is quite low, but, owing to the Pitot action explained above, the pressure of the air delivered to the well from (**A**) is increased so that it is about as high as the pressure of the atmosphere.

See Index for explanation of a "plain tube" carburetor.

GASOLINE: PRIMING METHODS; HEATING METHODS; VAPORIZING GASOLINE

Before taking up the subject of various constructions and adjustments of carburetors, we shall first deal with the subject of gasoline, vaporizing gasoline, and fuel-feed methods.

Gasoline

The usual fuel for automobile engines is gasoline. Gasoline is distilled from mineral oil (petroleum).

When petroleum is heated, it gives off gases, just as water, when heated, gives off steam. When these gases are cooled, they become liquids, and are called gasoline, kerosene, benzine, naptha, etc.

The chief difference between them is their **"volatility."** When a liquid turns to vapor, or gas, it is said to be **"volatile."** Gasoline should be very volatile in order to insure easy and prompt starting, and to furnish power.

Temperature makes a great difference in the volatility of liquids; for instance, thick, heavy oil is not volatile at the ordinary temperature of the atmosphere, but is volatile when heated.

Gasoline is very volatile at the ordinary temperature of the atmosphere. It is so volatile that it must be kept in air-tight tanks, for it would entirely evaporate if left exposed to the air. Because of this volatility, gasoline must be handled with care to prevent fires and explosions. It should never be handled near an open flame.

A low grade of gasoline will produce poor results in any carburetor. Difficulty in starting is the main disadvantage in its use, as it is not as volatile as a high-gravity gasoline.

Inferior, or too much gasoline is generally indicated by a **black smoky exhaust** and a disagreeable odor. When a low-gravity gasoline is used some effective method for vaporizing it must be employed.

A test by hand: To ascertain how near kerosene you are getting, pour a little gasoline in the hand. When it evaporates slowly and leaves a greasy deposit, it is of a very low grade. When it evaporates rapidly and leaves the hand dry and clean, it is of a higher grade. This furnishes a fairly reliable test.

Testing gasoline with a hydrometer was the method used a few years ago. It is used as follows: Fill the glass tube with gasoline, and insert the hydrometer, which will float. The gravity of the gasoline is determined by the depth the hydrometer sinks in it. A scale is graduated on the upper portion of the hydrometer and the level of gasoline indicates the specific gravity. The scale usually runs from 60 to 80. Gasoline under 60 test ought not be used. It averages about 64 to 68, and the better grade is 72.

Gravity is no longer an accurate test of the merits of the fluid, the only really accurate test being from a maximum and minimum boiling-point. It is, of course, not practical for the average owner to make such tests, and the best rule is to purchase from a reliable distributor, who handles gasoline manufactured by responsible distillers.

Most of the gasoline today sold for motor-car use differs from that of several years ago in that it is not all of one grade, but is a compound or blend of the different petroleum elements; some of it being very light and volatile, while about one-fourth of it may have a boiling point higher than that of water, and is correspondingly difficult to convert into a vapor.

Gasoline of 56° to 64° Baume paraffine base is used almost universally in the United States east of the Rocky Mountains. Fuels of lighter gravity are also produced from asphalt base petroleum. In certain sections of the country gasolines of very low grade have recently been introduced, one-half being actual kerosene. With this fuel and the ordinary intake manifold it is almost impossible to make an engine operate properly either at closed or open throttle, unless the radiator is covered up and the cooling water is brought to a temperature of 160° to 180° F.

To use this fuel it is necessary that the whole carburetor and intake manifold system be thoroughly heated. Without this heat the carburetor setting will have to be changed and made richer than necessary, while the extra heavy part of the fuel, not vaporized, will burn slowly in the cylinder, forming carbon, and sooting up spark plugs, etc.

There is, of course, a period of time just after starting the engine cold, when the rich mixture will be necessary (and can be furnished by the dash control), but the control should be released as soon as the engine becomes warm.

It is also advisable, while the engine is cold, to avoid opening the throttle full, as the fuel vaporizes much more readily in the suction or partial vacuum which exists in the manifold while the throttle is partly or completely closed.

In very cold weather it is advisable, instead of readjusting the carburetor or using the dash control continuously, to cover part of the radiator surface, so that the normal temperature is maintained under the hood.

In some parts of the country there is so great a range in the constituents of the gasoline sold that the lighter or more volatile fractions may, in warm weather, boil in the carburetor, under normal operation of the car. In this case, the hot-air supply to the carburetor may be disconnected, while care should be taken that the gasoline supply line from the tank to the carburetor does not approach the exhaust pipe, cylinder walls, or other heating influence.

If the gasoline should catch fire, do not try to put it out with water, for as the gasoline will float on water, it will only spread the flames. Damp sand, flour, or a wet blanket will smother the fire.

Low and High-Gravity Gasoline

The proper gravity of gasoline to use is governed by conditions. In the summer a low gravity vaporizes much more easily than in the winter; therefore the engine starts easier.

A great many claim that the low gravity gives results as good as or better than high-gravity. Probably it does, as there are more heat units per gallon, but as a matter of easy starting and absence from carbon deposit, the high gravity is preferable, unless the carburetor has been properly adjusted, and priming and heating methods are provided.

With the high gravity we have a high "flame" rate (mixture burns rapidly), whereas, with the low gravity, we get a higher combustion heat, but slower "flame" rate. With a high flame rate the mixture burns rapidly—pressure rises quickly and imparts a powerful push at the commencement of the stroke, but falls away equally quickly as the stroke progresses.

With low-gravity gasoline, the reverse occurs. The explosion generates slowly and does not impart a violent shock, but with a retarded flame rate, and the pressure predominates through a much greater proportion of the stroke. The results are obvious. With high speed, as in racing, the high gravity is best. For medium speeds, where steam-engine-like power is required, combined with fuel economy, low gravity is best—providing the carburetor has been readjusted for the low-gravity fuel and proper heating arrangements are provided.

Owing to the great amount of **carbon in low-gravity gasoline** it is very necessary that the carburetor be properly adjusted.

The starting will be more difficult with low gravity, but with the use of a primer and a hot-air arrangement, this trouble can be overcome.

It is a well-known fact that **an engine,** especially an old one with loose bearings and slack pistons, **will run much more quietly on low-gravity gasoline.** This is due to the slow flame rate; the pressure is gradual on the piston head and presses rather than slams.

How Unvaporized Gasoline Thins the Lubricating Oil

Gasoline vapor that is not completely consumed in the engine does one of three things: it either passes out into the exhaust in an unburned state and is wasted, is deposited in the form of carbon within the cylinder, or condenses and runs down past the pistons into the crank case.

The first of these is the most direct loss, but the other two are equally important in the long run. A carbonized engine is of itself inefficient. Carbon makes the engine miss, makes it overheat and preignite. All of these things are sure to shorten the life of the engine.

When the unburned fuel runs down past the piston, it destroys the seal between piston rings and cylinder, removes the oil film which is to protect the surface of the cylinder, piston, cam, and crank shaft bearings from friction and wear, and, lastly, dilutes the lubricating oil in the crank case to such an extent that in time it becomes worthless.

Manufacturers are advising now that the crank case be drained even more frequently than ever before for this very reason. As cold weather approaches, the necessity for frequently refilling completely with new oil will become more imperative. Either the motorist is forced to drain out his oil and refill with fresh at an increased outlay, or he must suffer the consequences of an engine damaged by insufficient lubrication.

Starting Engine

Remember, when you start an engine by closing the air intake and thus choking off the air, that pure raw gasoline is being drawn into the cylinder. For this reason, a **heating method** of some sort should be attached to every carburetor, so that the gasoline will become heated and vaporized as quickly as possible, thus avoiding the use of the choker for any length of time.

Priming Methods

On a cold morning, **after the engine and all parts have become chilled,** we find that the ordinary grade of gasoline now in use does not vaporize readily until it is heated. Considerable cranking of the engine is sometimes necessary in order to ignite the cold, damp, unvaporized gasoline.

There are several methods of overcoming this; one being to use a higher grade of gasoline. But even with the higher grade, which is difficult to obtain, on a really cold day the starting will be somewhat difficult with some makes of carburetors. For these reasons, **priming,** by injecting raw gasoline into the cylinder, is necessary.

Examples of various priming methods are exexplained in Figs. 1–6:

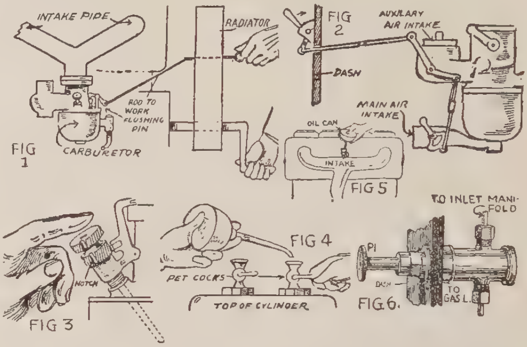


Fig. 1. Method of priming by depressing float, thus opening the float needle valve, and providing an excess of gasoline to be drawn into cylinder.

Fig. 2. A damper is provided in the main air-intake pipe. When closed, the suction provides more gasoline than air. Sometimes the tension of the spring on the auxiliary air valve is regulated from the dash or steering post.

Fig. 3. Priming the carburetor by opening the gasoline needle valve. This method is not advisable, however, because the adjustment valve is a very sensitively adjusted part of the carburetor, and will upset the proper working of the carburetor after the engine is heated up. If this method is employed, be sure to mark a notch on the head of the valve, so that it can be turned back to its original adjusted position.

Fig. 4. Priming with gasoline through priming cups.

Fig. 5. The oil-can primer, where gasoline is injected into the intake manifold. Simple and effective when other methods fail.

Fig. 6. The spray primer; a small injector pump. The suction part of the pump is connected to the gasoline supply pipe between the tank and carburetor. The other part connects to the intake manifold; one stroke of the plunger sprays a charge into the manifold. The Imperial Brass Co., of Chicago, manufactures a pump primer of this type, as also does the Bay State Pump Co., 102 Purchase St., Boston.

When an engine fails to start during cold weather and you are positive there is a good hot spark, an effective method is to pour boiling water over the carburetor and inlet pipe. A resort to the "choker" or "damper" principle, however, usually results in starting the engine.

The "damper" or "choke" method is shown in Fig. 7. Instead of lowering the float, the air intake is closed. This causes an increased suction of gasoline and is called "choking" the air supply.

Too much priming, however, will fill the float chamber so full, that gasoline will run out of the spray nozzle, giving a rich mixture, on which the engine will not start; it will then be necessary to open the switch and close the throttle, and to crank the engine a few times to draw in more air. Then close the switch and crank again, when the engine ought to start if there is a good spark.

In either method explained, remember that **a good hot spark must be provided** in order to ignite this raw gasoline, because it is harder to ignite when cold than after it is warmed up.

Note. In order to facilitate **easy starting** next time, by hand or motor, it is advisable to open the throttle just before stopping the engine, in order to draw in a good charge of gas. This is done by speeding the engine up with the clutch out, and leaves a **charge in the cylinder** for starting later.

After the engine is started, some means should be employed for heating the gasoline so it will vaporize quickly and thus prevent raw gasoline being drawn into the cylinder.

Vaporizing Gasoline

Gasoline gives off more vapor at about 170° Fahr. It is the vapor mixed with air which is most desired. With the proper mixture there is more uniform power and flexibility.

Carbureting means breaking up the gasoline into infinitesimally small particles, mechanically, without heating, which is called "spraying." This is the best method, but is very difficult to accomplish, owing to the different amounts of gasoline passing from the spray nozzle, and on account of the variation of the throttle, or of the speed.

If a low gravity of gasoline is used, it is necessary to heat and vaporize the mixture, because it is practically impossible to break it up; but if it is a high-gravity gasoline, it generates into gas or vapor more quickly. In other words, it is the vapor that we must obtain, which is possible with high-gravity gasoline. In using high-gravity gasoline, however, it must be remembered that it will not stand as much heating as low-gravity gasoline, for if too much heat is used, it makes the mixture so rare that the actual amount of gasoline that goes into the cylinder is so small and at such a low flash point, that it ignites quicker, and will burn and expand more like powder. It will do its work and cool before the piston gets well under way. Furthermore the pressure on the piston does not last as long.

Owing to the low-gravity gasoline now being used, the mixture is not a true vapor. Instead of forming a gaseous mixture, it condenses inside of combustion chamber and manifold. Therefore a plentiful supply of heat is required.

As previously stated, the use of **low-gravity gasoline** requires more heating or vaporizing than a high grade. It might be compared with the firing of a furnace with soft coal. If soft coal is properly fired and is properly mixed with air, it will produce the most heat without producing very much smoke. Just so with a low grade of gasoline. If properly vaporized, it will work fairly well, otherwise carbon deposit and smoke will be the result.

High-gravity gasoline may be compared with hard coal. It is very easy to get the proper mixture of air with the high-gravity gasoline, because it is so very "volatile"—meaning that there is more vapor, and less vaporizing is necessary, and that it will "carburet" more readily. Therefore it will work satisfactorily in most any carburetor construction. Just so with hard coal. It will burn with less smoke and produce an equal amount of heat even though you burn it in an open shovel, and makes very much less carbon.

On stationary and high-duty marine engines a low gravity fuel is used, as kerosene and oil, but before it can be used it must be "vaporized."

A correctly heated carburetor runs on less gasoline than an unheated one, therefore in such a case a closer adjustment of the gasoline needle valve or a smaller jet is necessary.

An engine requires **more gasoline in winter than in summer,** as the gasoline does not vaporize and readily mix with the air until warm.

Heating Methods

What we desire to heat is the gasoline, so that it will vaporize and enter the cylinder in the form of gas, or mixed vapor and air instead of raw gasoline mixed with air.

We might classify heating methods under four classifications as follows:

1. **Heating the air** which is drawn into the air intake of the carburetor, and which mixes with the gasoline as it is drawn into the cylinder.
2. **Heating the mixture** as it is drawn into the cylinder.
3. **Heating the air and the mixture.**
4. **Heating the carburetor.**

Fig. 7. **Float principle:** When gasoline and air are drawn into the cylinders by suction of the piston, the float automatically lowers, thereby opening the float needle valve and permitting more gasoline to enter the float chamber. When the engine is not running the float chamber fills up, causing the float to rise, thereby closing the float needle valve. This prevents more gasoline entering, which would cause overflowing and dripping. If the float happens to become loose or lowered more than intended, it would not cause the needle to cut off the gasoline supply—hence dripping would result. (Note the dotted lines indicate the gasoline level.)

Heating the Air

The illustration (Fig. 7) is that of the early model "Y" Kingston carburetor, used on the Ford. (See the Ford instruction for the later models.)

The air is taken in at the "air-valve" opening. A hot-air pipe is shown connected, which admits warm air to be drawn in from around the exhaust pipe. This is a good example of **how the air is heated** before being drawn into cylinders. It will be noted that there is no auxiliary air valve on this carburetor.

Priming method: The damper or "choker" or "primer" method (Fig. 7), for priming or feeding the engine more gasoline for starting is operated by closing the damper or "air valve." This is used principally during cold weather.

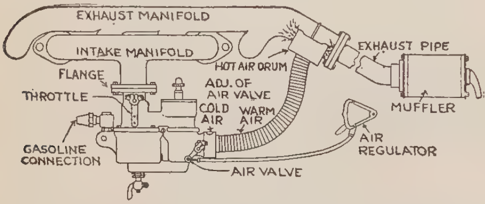

Fig. 8

Another example of **heating the air** drawn into the carburetor and also a method of admitting cool air is shown in Fig. 8. This is practically the same principle as in Fig. 7. Hot air is drawn into the main air-supply opening of the carburetor. A **hot air drum,** also called a "stove," is fitted around the exhaust pipe, not close, but placed so that air can be drawn in where the arrows indicate. A flexible tube then permits the air to flow to the air opening of the carburetor.

A valve is provided, called the **"air valve,"** also called a "damper" or "choker," which can be opened or closed by the "air regulator" lever, usually placed on the steering column or dash. This lever operates a butterfly type of valve in the air opening of the carburetor.

Choking air supply to start engine: When starting the engine, this air valve is closed, cutting off the air supply to the carburetor and causing an increased suction of gasoline to enter the cylinder (or an extremely rich mixture). This gives the initial priming for starting. Immediately the engine is started, the air valve is slightly opened to admit air. As the engine becomes warmed up, the air valve is opened more and more until fully open, or, in other words, to where the engine runs without missing or jerking which is common during cold weather. It is well known that engines will miss when first starting, due to the gasoline particles being unevaporated, which, in turn, is due to lack of heat. But after the engine is warm, the gasoline becomes vaporized and the engine runs without missing. The idea is to run on as much air as possible at all times. Therefore open the air valve to the point where missing will not occur.

By this method, warm air will be drawn into the carburetor whenever the air valve is open. But after the engine is thoroughly warm, and especially in summer, the air valve is opened more fully, thus permitting more air to be drawn in and mixed with cool air taken in at the "cold air" opening.

Temperature regulator: After the engine is well warmed up, it ought to have more air, and the more air used, the less gasoline required.

If warm air is drawn into the carburetor after the **engine is very hot,** then the mixture would be made too rare or lean.

We also know that gas expands in direct proportion to the degree to which it is heated. Therefore, when **heated too much,** the gas is unduly or prematurely expanded to such an extent that it **loses** a certain percentage of **its energy.** Furthermore, the piston will draw in a smaller amount of gas during each stroke.

The best degree for general running appears to be somewhat below the boiling point of water, i.e., between 170° and 200° Fahr.

Therefore some means of **admitting cool air** must be employed which will mix with the warm air. This would be termed a "temperature regulator."

Adjustable temperature regulator: It will be observed, in Fig. 8, that the cold-air opening is a fixed opening and the amount of cold air drawn through the air valve is not adjustable. The amount of warm air drawn in, however, is governed by the air regulator. The arrangement shown in Fig. 9 is slightly different. The cold-air opening is adjustable.

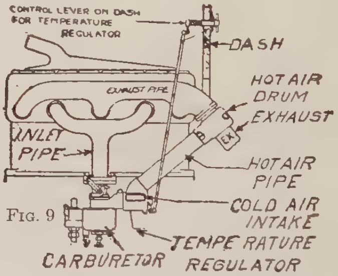

Fig. 9

The temperature of the warm air entering the carburetor can be regulated by opening the cold-air intake, thus permitting cool air to be drawn in. The use of this opening is governed more or less by the temperature. In summer, the opening is usually wide open, but closed more or less during cold weather.

Heating the Carburetor Mixture

There are various methods employed for heating the mixture, as it enters the cylinder, as follows:

1. **The hot-spot method** or heating the inlet manifold by placing it adjoining the exhaust manifold, as in Figs. 10 and 11.
2. **Passing hot exhaust gases** through a jacket surrounding the inlet manifold (Fig. 12).
3. **By circulating hot water** through a jacket around the inlet manifold (Figs. 13 and 14).
4. **By circulating hot water** through a jacket around the carburetor (Fig. 15).
5. **By passing exhaust gases** through a jacket around the carburetor (Fig. 16).
6. **By heating the mixture** with an electric resistance (Fig. 17).
7. **By a method termed a "fuelizer,"** as used on the Packard (Fig. 18).

The various methods mentioned above will now be illustrated and described. The reader should observe, however, that these examples refer to "heating the mixture" after the air has been taken into the carburetor through the main air inlet and mixed with the gasoline.

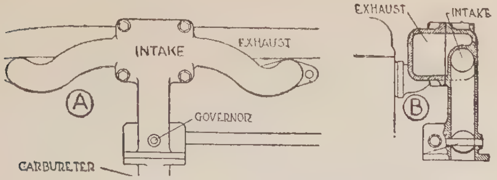

Fig. 10. "Hot-spot" heating of mixture by placing the exhaust manifold adjoining the inlet manifold. Only a part of the inlet manifold is heated: the upper part. The idea here is to prevent condensation of fuel. The liquid particles, when they reach the top of the vertical passage, do not swing to the left or right with the gas, but go straight, since they are heavier, until they strike the hot spot.

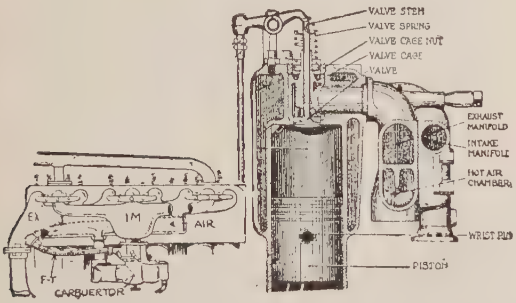

Fig. 11. Buick's exhaust heating of mixture. Note the exhaust manifold which adjoins the inlet manifold (**IM**). The lower part of the exhaust manifold (hot-air chamber) is divided from the exhaust (above). Air passes through the lower chamber which is heated. Hot air is also drawn into jacket around the upper part of the carburetor by a flexible tube connection (**FT**).

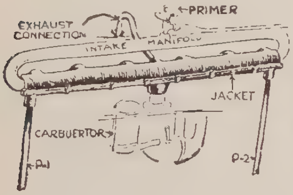

Fig. 12

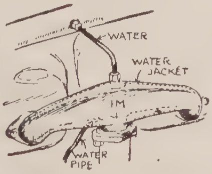

Fig. 13

Fig. 12. Franklin exhaust method of heating the mixture. Note the jacket which encloses the intake manifold through which exhaust gas passes. A cut-off is provided when the engine becomes very warm. **P1** and **P2** pipes are left open.

Fig. 13. Stutz hot-water-heated intake manifold.

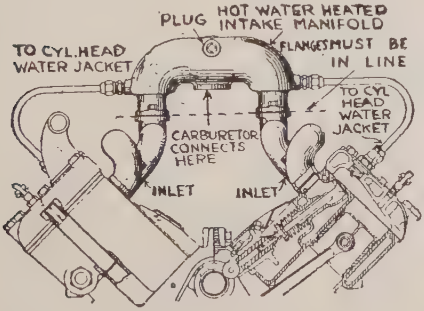

Fig. 14

Fig. 14. Hot-water heating of mixture as employed on the Oldsmobile eight-cylinder "V"-type engine. Note the hot water circulates through a jacket around the inlet manifold. This principle is more effective than heat around the carburetor. Exhaust gases can be passed through this jacket instead of hot water, which will heat the mixture quicker, and is more generally used.

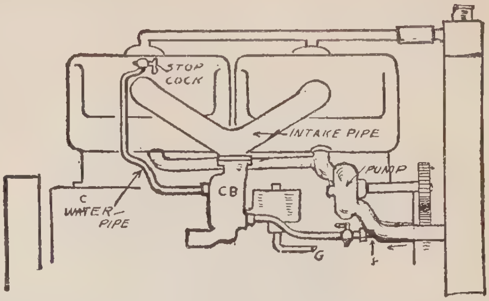

Fig. 15. Hot-water heating of carburetor. The usual method of connecting the hot water to the carburetor water jacket is to connect the upper water connection to the cylinder water jacket or pipe, and the lower one to the suction end of the pump (between radiator and pump). See that the connections are made in such a way that water will drain out of the carburetor jacket when the system is drained. Place a shut-off cock in the line for use in extremely hot weather.

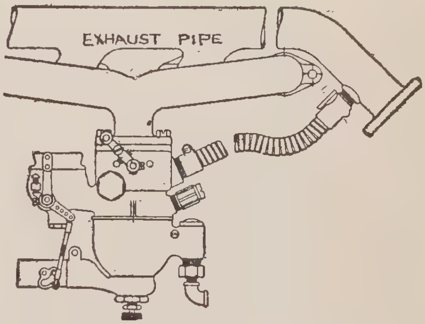

Fig. 16. Exhaust-gas heating of carburetor. The exhaust gases from the exhaust pipe can be carried to the carburetor water jacket, by tapping the exhaust pipe and connecting a flexible or copper tube to the water jacket. It is advisable to use as large a pipe as possible—say ½″, as it has a tendency to clog up. The other opening of the water jacket is left open by a ⅜″ or ½″ copper-pipe connection extending to the lower part of the engine for emission of gases.

Packard "Fuelizer" for Heating Mixture

The pipe marked "By-Pass" (Fig. 18) carries a minute quantity of gas direct from the carburetor to the fuelizer, a small combustion chamber surrounding the intake manifold.

MAIN PASSAGE FROM CARBURETOR
USUAL COLD WET MIXTURE

Fig. 18. Packard fuelizer.

The gas is ignited by means of an independent spark plug in this chamber, as shown, and circulates at a very high temperature through the fuelizer chamber which surrounds the intake manifold. At the bottom of the fuelizer chamber are two small holes through which the superheated exhaust of the fuelizer enters directly into the main inlet manifold.

Thus the main inlet manifold temperature is raised by direct mixing with the fuelizer exhaust as well as from the heat developed in the fuelizer chamber.

The result is that all gas passing through the main manifold is thoroughly dried, sufficiently heated, and broken up into a completely combustible fuel. Any grade of commercial gasoline, after receiving this treatment, explodes without a trace of carbon and without depositing lower grade fuels.

The circulation of gas through the fuelizer pipe and chamber is maintained by the same cylinder suction which draws gas through the main manifold. However, the circulation of gas through the fuelizer starts below the butterfly valve of the carburetor and exhausts into the main inlet manifold.

When the butterfly valve is closed, engine suction is very heavy upon the fuelizer; it receives a maximum supply of gas and gives off a maximum heat.

On the other hand, the farther the butterfly valve is opened, the less becomes the suction of the engine by the way of the fuelizer, because it is easier for the engine to suck the gas by way of the main manifold. This automatically decreases the heat given off by the fuelizer directly in proportion to the decreasing need of the engine for heat.

When the engine is being started, or idling, the fuelizer is going at maximum. But when the engine reaches an ideal combustion heat, because of high-speed traveling, or heavy low-gear work, the fuelizer automatically shuts off until it is again needed.

The Lexi-Gasifier

The following illustration and explanation is taken from the instruction book of the Lexington series "S" model. The air is not heated, but is drawn in cold.

Incorporated in the Moore multiple exhaust system manifold is a device that converts all the heavy portions of the fuel not vaporized by the carburetor into gas, which is taken up by the air stream and carried into the engine cylinders to do useful work instead of going down the cylinder walls, destroying lubrication. All of the highly volatile portion of the fuel, in passing through the carburetor, is vaporized and is carried by the air stream into the engine cylinders. The heavy portion, or "high-end point," after passing the throttle valve, is deflected into the hot grid back of the manifold, by the bend in the pipe immediately above the carburetor.

The system is so designed that all six of the exhausts play on the back of the grid, keeping it quite hot. All heavy particles of fuel falling into this grid are instantly converted into gas, which rises and is carried by the air stream directly into the engine cylinders. Its action is similar to pouring gasoline on a hot stove.

EXHAUST
HOT GRID
COLD AIR FROM CARBUERATOR

Fig. 18**A**. Lexington gasifier.

This device is not to be classed with the hot-spot manifolds, which heat the carburetor mixture (both air and fuel). Heating the air expands it, and prevents the cylinders from taking in the maximum amount of oxygen units to mix with the fuel, thereby weakening the explosions.

In the Lexi-Gasifier the air passes in almost cold, taking with it the gasified fuel, providing the maximum oxygen units in a given space for this fuel. This excess of oxygen and gasified fuel produces a greater pressure in the cylinders, hence more power.

After all, the power obtained from the internal combustion engine is the difference in temperature of the incoming mixture and the temperature to which we can raise this after burning.

Cadillac "61" Carburetor Thermostatically Controlled

The carburetor on the type "61" Cadillac is provided with thermostatic control for the tension on the auxiliary air-valve spring and also for regulating the effectiveness of the accelerating pump.

THERMOSTATICALLY CONTROLLED AIR VALVE WHICH OPENS AS THE HEAT INCREASES
FLOAT VALVE
FLOAT

Fig. 18B. The Cadillac carburetor is provided with thermostatic control on the auxiliary air-valve spring and also for regulating the effectiveness of the accelerating pump.

Referring to Fig. 18B showing a sectional view of the carburetor, it will be noted that the manual setting for the air valve is employed as usual, but superimposed on this manual setting is a **thermostat** which alters the tension of the air-valve spring in accordance with temperature requirements.

On a cold engine the spring tension is increased, thereby causing increased resistance to the opening of the auxiliary air valve.

In warmer weather the effect is the reverse, thus tending to make the mixture leaner.

The thermostat on the accelerator pump (not shown in the illustration), which is located in the fuel chamber, operates a shutter which covers and uncovers a vent, thus increasing the effectiveness of the pump when the engine is cold, and decreasing it when the engine is warm. In other words, when the vent is open the accelerator pump has little or no effect, but when it is closed the accelerator pump or throttle pump will force gasoline through the spray nozzle, when the throttle is opened quickly for acceleration. When the throttle is opened slowly the pump has practically no effect on the gasoline. The throttle pump is interconnected with the throttle, and its function is to force compressed air into the float bowl. When the thermostat comes into effect and opens the vent, the air, of course, cannot be compressed, and consequently the pump operation is materially reduced.

It is claimed that the introduction of these two thermostats materially reduces the warming-up period of the engine. (*Motor Age.*)

Heating the Air and the Mixture

A combination of heating the mixture and heating the air is shown in Fig. 19. The exhaust manifold adjoins the inlet manifold which heats the mixture as it enters the cylinders. Warm air is drawn around the upper part of the carburetor, admission of which is controlled by a throttle which keeps the upper part of the carburetor warm. Warm air is drawn in the main air supply which heats the air. **A temperature regulator,** controlled from the dash, admits cool air into the main air supply when the engine is thoroughly warmed up.

COLD AIR DOOR (CONTROLLED FROM DASH)

Fig. 19

For starting, the lower air opening of the carburetor can be closed entirely, which "chokes" the air and causes gasoline to be drawn into the cylinder until the engine starts. This system is used on the Nash trucks and is an ideal system.

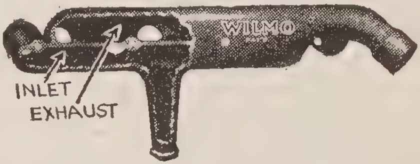

Fig. 20. Wilmo exhaust-heated intake manifold, designed for Fords and other cars. An example of method for heating the mixture just before it passes into the cylinders. The carburetor connects with the lower, or inlet part of the manifold; the exhaust is the upper part, with a plate between. By completely vaporizing the gasoline, no residue is left to seep into the crank case to thin the lubricating oil. The Whittier Co., 2415 So. Mich. Ave., Chicago, Ill., are the manufacturers, who claim for it an increase in mileage on a Ford.

Remarks on Water and Exhaust Heating

If the intake manifold is heated with water, the temperature is not so liable to cause overheating, as the temperature seldom goes above 170° to 200°, especially if a thermostatic principle is used.

When the engine is cold, after standing all night, the water does not heat as quickly as if exhaust-gas heated, but when the engine is run and warmed up and left standing, the water will remain warm for some time and will quickly heat again. The water is quite often circulated around the carburetor and inlet manifold and in connection with a temperature regulator and heated air intake. A water heating system can be used only with engines using a force or pump water-circulating system.

When the intake manifold is heated by the exhaust, the temperature is liable to increase to a high degree, if the engine is run continuously for a long period. The latter system, however, will heat the mixture more quickly than the water system, when the engine is cold. Therefore means for admitting cool air and some means for cutting off the exhaust gases from the manifold jacket ought to be provided, especially in case of the long-continued running of the engine.

HOW TO DETERMINE THE SIZE OF CARBURETOR TO USE

The size of the carburetor should be determined by the area of the valve opening on the engine, and not by the cylinder displacement, as the former is a true measure of the engine capacity. A carburetor cannot deliver more charge to a cylinder than the area of the valve opening will allow to pass.

A large carburetor with too much passage area cannot cause an engine to deliver more power than it would with one having a passage equal in area to that of the valve opening. Too large a carburetor would not only waste fuel, but would reduce the power of the engine by furnishing a weak mixture.

If the carburetor is too small the engine will not develop its rated power, as it could not deliver a full charge at high speed.

When a carburetor is small for the engine, it **becomes very cold** while in operation, as the amount of heat necessary to effect the vaporization of the gasoline is more than is available from the entering air or than could be secured through the metal carburetor by conduction. The temperature of the metal part of the carburetor becomes so low that water condenses on it, and, in some cases, is in the form of frost. These results are produced by the use of a carburetor too small for the engine. To meet these conditions, some makers provide means for heating the air supply, as previously shown.

It follows that the **carburetor of proper size** should have its passage area equal to the valve opening of the engine. In multiple-cylinder engines this area is equal to the valve opening multiplied by the number of suction strokes which take place simultaneously, determined from the sequence of cranks.

It will spell failure to fit a carburetor with a large jet and opening to an engine in which the exhaust closes very early, because the surplus gas cannot be expelled as completely as with an engine having a very late-closing exhaust valve.

Carburetor sizes are determined by the opening leading to the manifold. These openings are slightly larger than the indicated size of the carburetor.

For example: The opening on three different makes of carburetors varies as follows: **1-inch:** Schebler, 1 3/16″; Rayfield, 1¼″; Stromberg, 1 3/16″; **1¼ inch:** Schebler, 1⅜″; Rayfield, 1½″; Stromberg, 1 7/16″; **1½ inch:** Schebler, 1⅝″; Rayfield, 1¾″; Stromberg, 1 11/16″.

In fitting a carburetor to the manifold, the carburetor opening should be slightly smaller and never larger than the opening in the intake manifold.

S.A.E. flange openings are as follows: **1-inch carburetor** has 2⅜″ between bolt-hole centers; **1¼ inch carburetor** has 2 11/16″ between bolt-hole centers; **1½″ carburetor** has 2 15/16″ between bolt-hole centers.

GASOLINE TROUBLES

The tank of a fuel system is always provided with a small hole, usually drilled through the filling cap, as at (V), Fig. 1, by which air may enter to replace the gasoline as it is drawn off. If this hole becomes clogged with dirt, the gasoline in flowing out will tend to create a vacuum, and the flow will stop.

The outlet pipe should project slightly above the bottom of the tank, so that water and dirt may settle, and not be carried to the carburetor. A filter screen should also be provided.

A temporary repair for a slight leak in a gasoline tank can be made by applying ordinary soap. Such a repair may last till the defective part can be soldered. Leaks at gasoline taps can generally be cured by screwing up the nut securing the tap plug, or by grinding in the tap with crocus and oil.

If gasoline drips from the feed line, examine connections (A) and if it **drips from the carburetor** it is probably due to the float needle valve failing to seat properly. Gasoline leaks are sometimes difficult to locate.

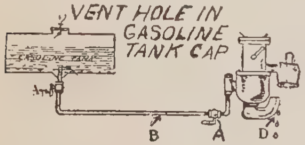

Fig. 1

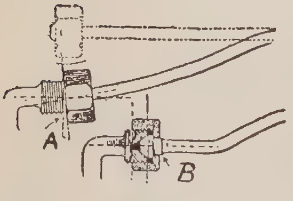

Fig. 1A

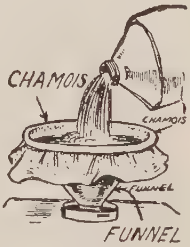

Fig. 2

If gasoline fails to flow to the carburetor, see that (V), Fig. 1, is open. If this is open, then examine the filter screen at the bottom of the tank. If this is open, then remove pipe (B) and blow it out. If this is open, then take the carburetor apart and see if it is clogged up with waste or sediment.

Gasoline feed-pipe connections should have special unions. See Index under "Pipe connections." The threads are very fine and can easily be crossed. Therefore use every precaution not to "cross-thread" when joining a gasoline pipe coupling as at (A) (Fig. 1A). In (B) the threading is straight and correct.

Gasoline rots rubber rapidly and should not be conveyed through a rubber hose, nor should joints be packed with rubber. Shellac or soap may be used when screwing joints together, as it helps to make them tight.

Draining: The lowest point of the gasoline line on a vacuum-feed system is the bottom of the gasoline tank. On a gravity feed system it is at the carburetor. A strainer made of brass wire mesh is usually at the lowest point, and should occasionally be removed and cleaned.

Water in gasoline is indicated generally when the engine runs irregularly and finally stops. This will often prevent starting of the engine. Water is frequently present in gasoline, and, particularly when the tank is low, is liable to get into the pipes and carburetor. The drain cock at the bottom should be opened occasionally to let off the water and sediment.

In cold weather, this water is liable to freeze, preventing the action of the carburetor parts. Ice in the carburetor can be melted only by the application of hot water (or some other non-flaming heat) to the outside of the float chamber.

To prevent water getting into the gasoline and freezing during cold weather, thereby clogging the flow, strain through a chamois.

Gasoline ought to be strained. Many carburetor troubles would be avoided if more care were taken to free gasoline of all dirt before its entrance into the tank, and, later, into the carburetor (Fig. 2).

It is said that **static electricity will be generated** when straining through a funnel and chamois, and a spark is liable to ignite the gasoline. If the funnel is grounded to the tank this cannot occur.

Old gasoline left in the carburetor for some time, when the car is not in use, will lose its strength. If the engine should not start easily, then drain the float chamber.

Stale gasoline: After standing for many days, even in a tight tank, gasoline will become dead and slow to ignite. This is partly due to evaporation, and partly to chemical changes that take place.

A strainer should be on all gasoline tanks or lines, as water and sediments being heavier, always settle at the bottom.

Addresses of carburetor manufacturers, classified under the type of carburetor they manufacture, are given elsewhere; see Index under "Address of carburetor manufacturers." For detailed information catalogs are of value.

Broken gasoline pipe can be temporarily repaired by wrapping with tape.

Another method of repairing a broken gasoline pipe is to scrape the tube near the break and to wind about 1″ of clean copper wire on each side and over the break, and then to solder carefully.

Air leaks cause missing. If the engine persists in missing and this is not due to faulty ignition, then look for air leaks in the inlet manifold. Examine gaskets and see if a crack is in the intake casting—providing the trouble is not in the ignition.

Leaks in the intake pipe gasket are a very common cause for missing at low speeds. This is best detected by letting the engine run at the missing speed. Take a squirt-can full of gasoline and squirt around all the intake-pipe joints. If you detect any difference whatsoever in the running of the engine, there is a leak.

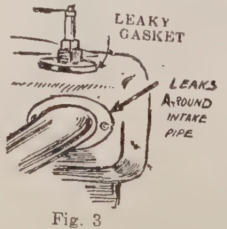

Fig. 3

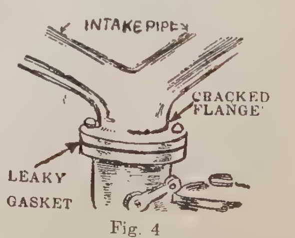

Fig. 4

Cracked flanges (Fig. 4) can be repaired by having them welded by oxy-acetylene process. See Index under "Gaskets," for the kind of gasket to use.

GASOLINE TANK AND GAUGE

The main gasoline tank used on the Studebaker six is shown in Fig. 5. Note the connection to the vacuum tank, also the **gasoline gauge** mechanism. As the tank is filled, the float rises, which causes the bevel gear on the float-rod to turn the rod connected with the gauge needle.

The words "main gasoline tank" apply to the gasoline tank which contains the greater amount of gasoline and is usually suspended at the rear of the car.

The auxiliary gasoline tank is a smaller tank placed on the inside of the dash when the vacuum system is used, as explained farther on.

Gasoline feed pipes are usually made of copper tubing or brass pipe 5/16″ outside diameter and 7/32″ inside diameter.

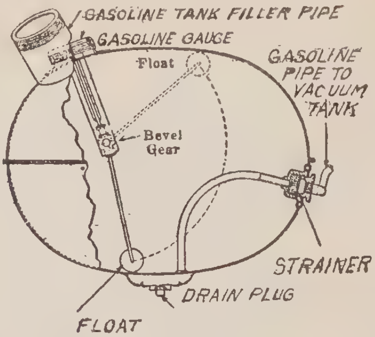

Fig. 5

GASOLINE-TANK SHUT-OFF COCKS

On many cars there is a reserve of gasoline carried in the tank. This reserve is not usually partitioned off. The shut-off cock controls the reserve. An example is the shut-off cock used on the King car.

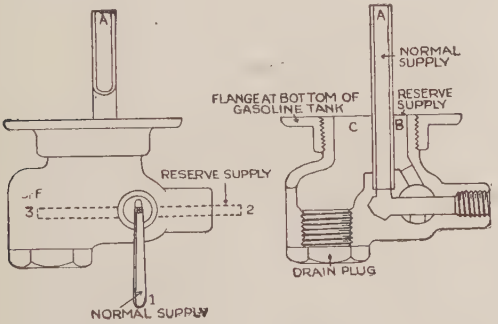

Fig. 5B

Fig. 5C

Figs. 5B, 5C. Gasoline-tank shut-off valve as used on the King car, as an example.

The capacity of the tank is 18 gallons. When the shut-off cock is turned **down** as shown in (1) (Fig. 5B), before the gasoline will flow to the vacuum tank there must be a sufficient amount of gasoline in the tank to run through tube (**A**). Therefore when the gasoline level is below the top of tube (**A**) with the shut-off cock down, the supply of gasoline will not flow to the vacuum tank, although there are two gallons in the tank.

Reserve: By turning the shut-off cock to a horizontal position, as at (2) (Fig. 5**B**), the reserve amount of gasoline is permitted to flow through pipe (**B**) (Fig. 5**C**). This reserve amount is 2 gallons.

To shut off the supply: Turn shut-off cock to position (3) (Fig. 5**B**) and the gasoline will run through opening (**C**).

To drain the tank: Unscrew the drain plug.

There are other similar methods employed on different cars; for example, see page 112 under the heading, "A three-way valve located on the top of the gasoline tank," as used on the Packard.

FUEL FEED METHODS

There are **five methods for feeding gasoline,** some of which are not in use. They are as follows:

1. By **gravity.**
2. By **exhaust pressure.**
3. By **combined gravity and exhaust pressure.**
4. By **forced air pressure.**
5. By **vacuum and gravity.**

The vacuum and gravity method is used most; the air-pressure feed is used by some of the larger cars, and the gravity feed is used on the Ford.

Gravity Feed

A tank is placed above the level of the carburetor so that the gasoline flows from tank to carburetor by gravity (Fig. 6). The tank can be placed at any point on the car, providing it is above the level of the carburetor.

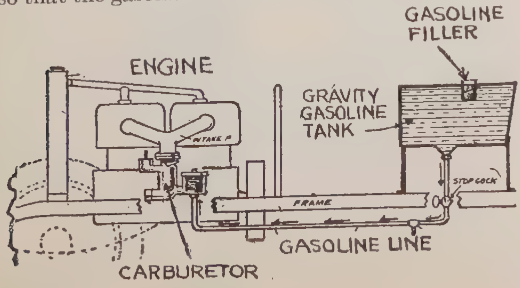

Fig. 6

The disadvantage of this where the tank is not close to the carburetor lies in the fact that when ascending hills, or on the side of an incline, the gasoline may fail to flow through the pipe.

Exhaust-Pressure Feed

With this system (Fig. 7), the tank is placed in the rear. A hand air pump is connected to obtain the initial pressure in the tank. After the engine is started the exhaust gases pass through a check valve to the tank, creating a pressure, which forces the gasoline to the carburetor.

A small pipe is used for the exhaust passage. The pipe being exposed to the air, the gases are cooled and prevent a flame. A check valve prevents the gas passing back, as it can pass in but one direction.

Disadvantage: The pressure is liable to interfere with the proper operation of the float. This system is practically obsolete.

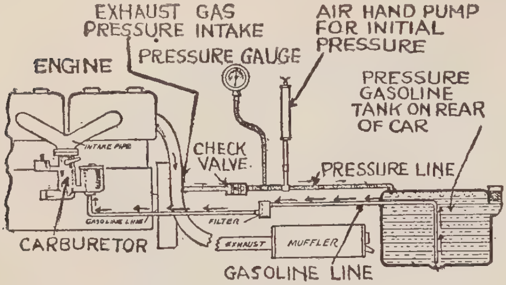

Fig. 7

Gravity and Exhaust-Pressure Feed

Gasoline is forced by exhaust pressure from the tank to an auxiliary tank, placed above the level of the carburetor. The gasoline then flows to the carburetor by gravity. The auxiliary tank is small and is placed close to the carburetor, so as to make sure that the gasoline will always feed (Fig. 8). This system was used in the early days of motoring, but not to any great extent.

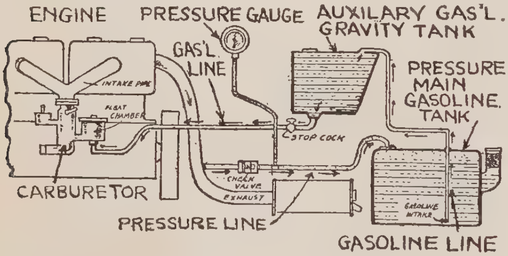

Fig. 8

Air-Pressure Feed

A modern gasoline air-pressure feed is that shown in Fig. 9, which represents the Packard system. A similar method is used on the Cadillac and on the Locomobile.

General principle: The supply of gasoline is carried in the tank at the rear of the frame. The gasoline is supplied from the tank to the carburetor by **air pressure** (at 1½ to 2½ lbs.) provided by an air pump attached to the engine front-end cover and driven by the forward extension of the generator shaft.

Fig. 9

The carburetor is mounted above and between the cylinder blocks, and receives the heat generated by the engine, which assists in the vaporization of the gasoline.

The gasoline tank is located on the rear of the frame. The capacity of the tank on all models is twenty gallons, including about a three-gallon reserve.

A three-way valve located on the top of the gasoline tank connects with outlet pipes leading to each side of the tank. Turning the valve handle to the right permits the gasoline to be completely drained from the right side of the tank and vice versa. When gasoline has ceased to flow, turn the valve handle to its opposite extreme regardless of the previous running position, in order to obtain the reserve supply. Turning the handle straight up shuts off the gasoline.

Caution: If the gasoline tank has been completely drained and is replenished with less than a five-gallon supply, turn the valve handle to the left, which is the side of the tank which receives the first three to five gallons, otherwise, the gasoline will not flow.

Air pressure for supplying gasoline to the carburetor is furnished by an air pump attached to the crank-case front-end cover, and driven by an eccentric mounted on the generator shaft.

The air is drawn from outside the crank case and forced under pressure to the gasoline tank. To **increase** the pressure, remove the plug at the top of the pump cylinder and unscrew the smaller plug at its base. To **decrease** the pressure, the small plug should be screwed down.

The hand or auxiliary pump on the instrument board provides a means of obtaining initial air pressure before the engine is started, providing the gauge on the dash shows that there is no air pressure in the gasoline tank.

To obtain pressure by hand, unscrew the handle to the left. When the plunger is free, operate the pump until pressure shows on the gauge. Do not pump higher than 2½ lbs. pressure.

Note. When air pressure is used, if the carburetor has a small float, the pressure should not be over 2½ or 3 lbs. With a larger float, the greater area will withstand more variation in pressure.

If the gasoline gauge does not respond to the hand pressure pump, it is probably caused by the tank outlet valve being shut off.

Caution: Having finished operating the pump, push the plunger in, and be sure to lock it in place by screwing the plunger handle to the right.

The plunger leather of the pump should be oiled occasionally with neat's-foot oil. Mineral oils improve the operation of the pump only temporarily, and tend to dry up the leather.

A gasoline pressure gauge on the instrument board is connected directly with the supply line at the gasoline strainer housing. The gauge indicator should show from 1½ to 2½ lbs. pressure when the engine is running.

If the pressure gauge indicates that **the pump is not maintaining the proper pressure** in the tank, proceed as follows:

Inspect the gasoline-tank filler cap, seat, and gasket to make sure that they are in good, clean condition and free from nicks.

Be sure that the filler cap is tightly seated. If the trouble is not found by this method, examine all connections on the air pressure and gasoline supply lines to make sure that there are no leaks. A good method of locating leaks in the air line is to put pressure in the tank and go over the line carefully with soap suds.

If it is determined that all pipes and connections are absolutely air-tight, raise the air pressure by adjusting the pump as described above.

THE STEWART VACUUM GASOLINE SYSTEM[1]

It will be noted in Fig. 1 below that gasoline is fed by gravity to the carburetor in the usual manner, by an auxiliary gasoline tank, which is combined with a vacuum system of drawing the gasoline from the main gasoline tank. In other words, the same gravity principle of feeding gasoline to the carburetor is utilized with the auxiliary or gravity tank placed on the inside of the dash (usually) above and near the carburetor, so that the gasoline will feed to the carburetor at all times, regardless of the angle or position of the car.

The difference in this system is that of drawing the gasoline up to this tank, as the main gasoline tank is below the level of the gravity tank. Instead of air being applied to the gasoline in the main tank to force the gasoline to the gravity tank, it is sucked by a vacuum process through pipe (**D**) to the vacuum chamber (12); thence it flows through trap or flapper valve (6) to the gravity tank, thence to the carburetor.

This vacuum is created by suction at the intake manifold through pipe (**C**), connected at (**N**). (Although the connection of pipe (**C**) is shown in the center of the manifold at (**N**), the usual plan is to connect it near the end of the manifold, as the vacuum is greater at a point closer to one of the cylinders.) We know that a great suction takes place in the intake manifold when pistons are working; this suction is utilized to create the vacuum, as will be explained below.

Principle of Operation

There are two chambers: the upper or vacuum chamber and the lower chamber or gravity feed tank. See Fig. 2.

When there is no gasoline in either chamber, the float and levers (**E**) and (**F**), to which the float is connected, **close** the valve (**B**) which admits air

Parts: (4) inlet from gasoline tank (**D**); (5) toggle lever operating valves; (6) flapper valve (**H**) (Fig. 2); (7) suction line to intake manifold; (8) vent for air; (9) vent valve (**B**) (Fig. 2); (10) outer supply chamber; (11) float (**G**); (12) gasoline in float chamber; (13) shut-off valve to carburetor; (14) primer supply pipe; (15) drain valve (**J**) (Fig. 2).

---

[1] Another fuel system is the G. G. Fuel System, Zorzi Corporation, 1737 Broadway, New York.

into the vacuum chamber and at the same time opens the valve (A) connected with the suction pipe (C) which is connected with the intake manifold.

If the engine is working (by crank or power), a vacuum is then created in the upper chamber which closes the flapper (H) (by suction), thereby making the upper chamber absolutely air tight, which creates a vacuum and causes the gasoline to be drawn from the main gasoline tank to the vacuum or upper chamber.

As the gasoline enters the upper or vacuum chamber the float rises, and through levers (E) and (F), connected to the float, the valve (A) to the intake manifold is closed, thereby cutting off further suction and at the same time valve (B) is opened, which permits air to enter the vacuum chamber, through the air-vent tube.

Air entering the vacuum chamber causes flapper (H) to open, which permits the gasoline in the vacuum tank to flow into the lower chamber or gravity tank, thereby causing the float to lower as the gasoline flows out.

As the float lowers, the operation of levers (E) and (F) is again brought into action, and valve (A) is again opened and (B) closed, which again causes (H) to close, and the vacuum and suction take place again. It will be noted that the lower chamber is always open to air circulation through the "air-vent tube," otherwise the gasoline would not flow by gravity to the carburetor.

The primer (14) (Fig. 1) is a connection used by some of the car manufacturers for connecting with the hand pump on the dash, for priming the engine to start during cold weather.

Installation

The top of the vacuum tank must be above the level of the gasoline in the main gasoline tank when full, even when the car is going down a steep grade.

The bottom of the vacuum tank must be not less than 3″ above the carburetor; 5/16″ copper pipe is used.

Do not install the tank directly over the generator or wiring terminals, on to which gasoline could leak.

Never tap through a water jacket, if the intake manifold is provided with one. Always tap the intake manifold at a point as close to the intake of one of the cylinders as possible. Be careful in bending tubing. **The air vent** must be placed at as high a point as possible under the hood. The best location for the tank is on the engine side of the dash.

On eight- or twelve-cylinder "V"-type engines with two inlet manifolds, a "Y" connection is made at (C) on top of the tank, with both manifolds tapped.

Care and Repair of Stewart Vacuum-Feed System

Some of the various troubles which might arise and the remedy for them are explained in the following paragraphs.

Vent-Tube Overflow

The air vent allows an atmospheric condition to be maintained in the lower chamber, and also serves to prevent an overflow of gasoline in descending steep grades. If once in a long while a small amount of gasoline escapes no harm will be done, and no adjustment is needed. However, if the vent tube regularly overflows, one of the following conditions may be the cause:

(a) The air hole in the main gasoline tank-filler cap may be too small or may be stopped up. If the hole is too small or if there is no hole at all, the system will not work. Enlarge the hole to ⅛″ diameter, or clean it out.

(b) The vacuum tank may not be installed quite high enough above the carburetor. If the bottom of the tank is not 3 inches above the carburetor, raise the tank.

Gasoline Leakage

If gasoline leaks from the system, except from the vent tube, it can do so only from one of the following causes:

(a) A leak in the outer wall of the tank may exist. If so, soldering up the hole will eliminate trouble.

(b) The carburetor connection in the bottom of the tank may be loose. If so, it should be tightened.

(c) There may be a leak in the tubing leading from (D) or (C) (Fig. 2).

Failure to Feed Gasoline to Carburetor

This condition may be due to causes other than the vacuum system. To test; after flooding the carburetor, or "tickling the carburetor," as it is commonly called, if gasoline runs out of the carburetor float chamber, you may be sure that the vacuum feed is performing its work of feeding the gasoline to the carburetor.

Another test is to take out the inner vacuum tank, leaving only the outer shell. If you fill this shell with gasoline and the engine still refuses to run properly, then the fault clearly lies elsewhere and not with the vacuum system.

If the failure to feed is in the vacuum tank, one of the following may be the cause:

(a) The float (G), which should be air-tight, may have developed a leak, thus filling up the float with gasoline and making it too heavy to rise sufficiently to close the vacuum valve. This allows gasoline to be drawn into the manifold, which in turn will choke down the engine.

(b) The flapper valve may be out of commission.

(c) Manifold connections may be loose, allowing air to be drawn into the manifold.

(d) The gasoline strainer or tubing may be clogged up. Look to this first.

Remedies

(a) **To repair float:** remove top of tank (to which float is attached). Dip the float into a pan of hot water, in order to find out definitely where the leak is. Bubbles will be seen at the point where the leak occurs. Mark this spot.

Next, punch two small holes, one in the top and the other in the bottom of the float, to permit discharge of the gasoline. Then solder up these holes and the leak. Test the float by dipping in hot water. If no bubbles are seen, the float is air-tight.

In soldering the float, be careful not to use more solder than required. Any unnecessary amount of solder will make the float too heavy.

To overcome the condition of a leaky float temporarily until you can reach a garage, remove plug (W) at the top. In some cases the suction of the engine is sufficient to draw gasoline into the tank, even with this plug open, but not enough to cause it to continue to be drawn into the manifold. If, however, you are not able to do this, close up plug (W) with the engine running. This will fill the tank. After running the engine until the tank is full, remove plug (W) until gasoline gives out. Continue repeating these operations until a repair station or garage is reached, when the leaky float can be remedied.

(b) **A small particle of dirt getting under the flapper valve** (H) might prevent it from seating airtight, and thereby render the tank inoperative.

In order to determine whether or not the flapper valve is out of commission, first plug up the air vent; then detach the tubing to the carburetor from the bottom of the tank. Start the engine and apply a finger to this opening. If suction is felt continuously, then it is evident that there is a leak in the connection between the tank and the main gasoline supply, or else the flapper valve is being held off its seat and is letting air into the tank, instead of drawing gasoline.

In many cases this troublesome condition of the flapper valve can be remedied by merely tapping the side of the tank, thus shaking loose the particle of dirt or lint which has clogged the valve. If this does not prove effective, remove the tank cover, as described below. Then lift out the inner tank. The flapper valve will be found screwed into the bottom of this inner tank.

To Fill the Tank

To fill the tank, should it ever become entirely empty: With the engine **throttle closed** and the **spark off**, turn the engine over a few revolutions. This takes less than ten seconds, and will create sufficient vacuum in the tank to fill it.

If the tank has been allowed to stand empty for a considerable time and it does not easily fill when the engine is turned over, this may be caused by **dirt or sediment** being under the flapper valve (H).

Or, perhaps, **the valves are dry.** Removing the plug (W) in the top and squirting a little gasoline into the tank will wash the dirt from this valve, and also wet the valves, and cause the tank to work immediately. This flapper valve sometimes gets a black carbon pitting on it, which may tend to hold it from being sucked tight on its seat. In this case the valve should be scraped with a knife.

To Clean the Tank

Remove the top of tank and take out the inner shell or vacuum chamber. This will give access to the lower chamber from which dust or dirt may be removed. Clean the tank every three months.

To Remove the Top

After taking out screws, run the blade of a knife carefully around the top, between the cover and the body of the tank, so as to separate the gasket without damaging it. The gasket is shellacked.

Auxiliary vacuum pump: On some cars (Hudson), a small hand vacuum pump is provided on the dash. If the vacuum tank should become empty, it would not be necessary to turn the engine over, but merely to operate a pump connected by a check valve to pipe (C), which will create sufficient vacuum to draw gasoline from the main tank.

RELATION OF THE INLET MANIFOLD TO CARBURETION

Engine manufacturers endeavor to make **a manifold which will have the least number of curves,** and be as straight and as short a path for the gas to travel through as possible.

The **ideal inlet manifold** is one in which no unnecessary resistance is offered to the flow of the mixture.

An inlet manifold for a six-cylinder engine which will deliver an equal mixture to each cylinder has been a problem with manufacturers. If the distance is too great, the gas tends to condense.

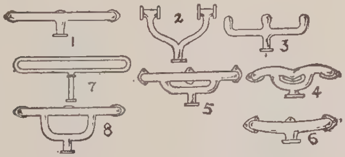

Fig. 3. Types of inlet manifolds.

The inlet manifold in use today is smaller in diameter than formerly, owing to the poor grade of gasoline in use. The fuel is harder to "break up" and will not vaporize readily. It condenses and clings to the inner walls of the manifold. By having smaller intake manifolds, the mixture is sucked through at a greater speed, which in a way prevents this condensation.

With too large an intake, using the present low-grade fuel, after a hard pull, the engine tends to "choke" and miss until it runs a short distance on a closed throttle.

Water jacketed or exhaust-heated manifolds are now the approved method. On many engines the intake manifold is cast right into the cylinder.

FITTING CARBURETOR TO MANIFOLD

Carburetors are **attached to the inlet manifolds,** either with a horizontal connection (Fig. 4) or a vertical connection (Fig. 5).

When fitting a carburetor, a gasket must be placed between the carburetor flange and the flange on the intake pipe, and it is very important that an air leak does not occur, otherwise the mixture is changed.

The best form of gasket is copper, interlined with asbestos. Multibestos or similar material can also

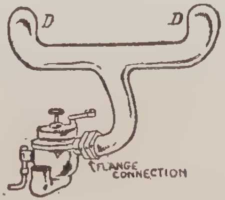

Fig. 4.—Carburetor Attached Horizontally.

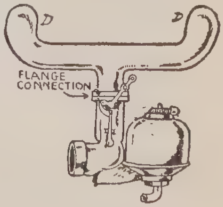

Fig. 5.—A Carburetor Attached to the Intake Manifold Vertically

be used, coated on each side with shellac. Leather could also be used here, but would not answer elsewhere, because it would get too hot. If material is used which has a rough edge, it is important to watch that none of it gets into the carburetor pipe.

At the point (**D**) where the inlet manifold covers the inlet ports, a copper gasket must be used and drawn tight to prevent air leakage. Be sure there are no air leaks where the carburetor joins the intake pipe, and where the intake pipe connects to the engine.

The air inlet of the carburetor, if exposed to dust and dirt, should be placed so that dust may not be drawn in.

The inlet manifold, connecting the carburetor to the inlet-valve port chamber, should present no resistance to the flow of the mixture. Sharp bends or turns will make it harder for the mixture to pass.

When fitting a carburetor, be sure there is no vibration. If there is, the result will probably be a broken flange connection. If there is vibration, place a small iron hanger from a nut on the engine frame to the carburetor, to steady it and also to take the strain off the intake pipe.

COMPRESSION RATIO

Compression ratio is defined as the volume of gas in a cylinder when the inlet valve has just closed, divided by the volume of gas in the cylinder after the compression stroke has been completed. Consider the engine as shown in Fig. 6: the inlet valve has just closed and there is one cubic foot of gas in the cylinder.

In Fig. 7, the compression stroke has been completed and the gas has been compressed until its volume is only ¼ of a cubic foot (the volume of the combustion space). The compression ratio is then 4, because **1 cu. ft.÷¼ cu. ft.=4.**

The final compression pressure (just before ignition takes place) in an automobile engine depends on two main things, namely, **the compression ratio and the pressure of the gas when the inlet valve has just closed,** as shown in Fig. 6. (It is obvious that the greater the pressure in Fig. 6, the greater the pressure that will result in Fig. 7.) The pressure in Fig. 6 is equal to the pressure of the atmosphere; therefore the lower the atmospheric pressure, the lower will be the compression pressure. A further consideration is that the **explosion pressure** (immediately after ignition), which gives the engine its power, depends on the **compression pressure before ignition.**

Conclusion: A low atmospheric pressure will cause a low compression pressure, which in turn will cause a low explosion pressure, and therefore the power of the engine will be reduced.

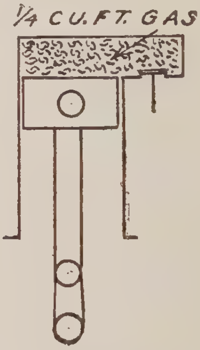

Fig. 7

Fig. 6. Inlet valve has just closed; Fig. 7. Compression stroke completed; the compression ratio is 4 to 1.

EFFECT OF ALTITUDE ON CARBURETION

Atmospheric conditions have much to do with the action of a carburetor. For example, an engine which would run satisfactorily at a low altitude, say at sea level, would lack power and would overheat at a high level, as, for instance, at Denver, Colo., where the elevation above sea level is approximately 5,280 feet, or one mile high.

This is due to the fact that at sea level, the air exerts a pressure of approximately 15 lbs. per square inch. This means that a column of air one inch square in cross-section and 50 miles high weighs approximately 15 lbs. It has been fairly well established that atmosphere blankets the earth for a depth of about 50 miles.

Therefore if we go higher, we begin to shorten this column of air responsible for this pressure; we therefore have not so much weight of air above us, and consequently the pressure corresponding to the reduced weight is also reduced.

Thus, if, at Denver, the height above sea level is 1 mile, there would be only 49 miles depth of air in the column to establish this pressure, and a column of air 49 miles high weighs less than a column 50 miles high, so that we find the atmospheric pressure at Denver is just a trifle over 12 pounds per square inch. As we go still higher, the pressure begins to fall off.

The drop in pressure amounts to approximately one half-pound per square inch for each rise of 1,000 feet. This, however, is not strictly accurate, nor is there a distinct and invariable relationship between the two, for it depends upon barometric variations, the amount of moisture in the air, etc., which, as we know, will cause the barometer to vary even though it remain in one place.

This reduction of air pressure as a result of increasing altitude has an effect on the power of the engine.

First it affects the compression, reducing it at a rate corresponding to the reduction in atmospheric pressure, as explained above. Thus at sea level, an average Ford engine would have a compression pressure of 64 lbs. per square inch, as measured by a pressure gauge, and after ignition, the explosion pressure would be 256 lbs. per square inch; while in Denver, owing to the low atmospheric pressure, the compression pressure would be only 48.5 lbs. per square inch, and after ignition, the explosion pressure would rise to only 194 lbs. per square inch. It is the latter pressure which determines the power of the engine, and since it has decreased from 256 lbs. per square inch to 194 lbs. per square inch, the engine will deliver much less power.

Second, we know that at sea level the composition of the air by weight is approximately 25 parts of oxygen to 75 parts of nitrogen, and the combination is a mechanical mixture, not a chemical one.

It is the oxygen that we rely upon to support combustion of the gasoline. Thus if the oxygen is reduced in value to that of the fuel, the mixture is affected.

The higher we go, the less the percentage of oxygen in the air. Therefore, unless the carburetor is readjusted to suit the changed conditions, we get an over-rich mixture, slow combustion, and overheating.

The point, then, is to open up the air intake, giving more air, rather than to cut down on the needle valve of the carburetor, reducing the gasoline supply.

Where carburetors are fitted with adjustable air valves, then the air-valve adjustment should be opened wider for altitude work.

Where carburetors have no air adjustment, use smaller jets for altitude work.

At the top of Pike's Peak, which rises to an altitude of 14,000 feet above sea level, the atmospheric pressure of the air is only 8.5 lbs. per square inch; therefore the compression pressure will drop to 30 lbs. per square inch (as measured by a gauge) and the explosion pressure will be only 120 lbs. per square inch, thus causing a very great loss of power.

Furthermore, water boils at a lower degree (Fahrenheit) at higher altitudes, for example at 14,000 feet above sea level water boils at 185° F., owing to less atmospheric pressure, whereas at sea level, water boils at 212° F.

Altitude	Atmospheric Pressure	Boiling Point of Water	Compression Pressure (as measured by a Gauge) on Engine with Compression Ratio of 3.6
Sea Level	15 lbs.	212° F.	64 lbs.
1,000 feet	14.1 lbs.	210° F.	59.5 lbs.
2,000 feet	13.6 lbs.	208° F.	57 lbs.
3,000 feet	13.1 lbs.	206° F.	55.4 lbs.
4,000 feet	12.5 lbs.	204° F.	51.2 lbs.
5,000 feet	12.3 lbs.	203° F.	49 lbs.
6,000 feet	11.6 lbs.	201° F.	46.5 lbs.
7,000 feet	11.2 lbs.	199° F.	44.3 lbs.
8,000 feet	10.8 lbs.	197° F.	42.1 lbs.
9,000 feet	10.4 lbs.	195° F.	40 lbs.
10,000 feet	10 lbs.	193° F.	37.9 lbs.
14,000 feet	8.5 lbs.	185° F.	30 lbs.

Note. The Ford engine has a compression ratio of 3.6.

INSTRUCTION No. 14

CARBURETOR ADJUSTMENTS: Mixture; Troubles and Remedies; Float Adjustments; Tools for Repairing Carburetors; Examples of Principle and Adjustments of Leading Carburetors

The principle of carburetion is treated in instruction No. 13. It will be advisable to start at the beginning of the subject and master the fundamental principles before taking up the subject of adjustments.

Kerosene carburetors are treated under the subject of "Tractors." See Index.

The first and most important thing to learn about any carburetor is to let it alone as long as it is working properly. Never tamper with the carburetor until you are quite sure that it is at fault.

There are two essentials necessary before an engine will run: first, gasoline; second, a spark. The gasoline must reach the inside of the cylinders and a hot spark must be there at the proper time to ignite the gas. If you have both, something is bound to happen, even though it is but a single explosion.

Next, remember that even though you have a spark and gasoline, the engine will not run properly if the gas does not enter the cylinder at the right time and if it is not in a proper gaseous form, or a correct "mixture." See "Digest of Troubles" for various reasons why an engine will not start, etc.

MIXTURE

At low speeds the mixture should be richer than at high. At low speeds more heat is lost to the cylinder walls, more compression is lost by leakage, and the combustion can therefore be slower, thus sustaining the pressure. **At high speeds** the compression is higher, due to less leakage and less loss of heat. A lean and highly compressed charge burns faster and hence gives better pressures and fuel economy than a richer one.

The quantity of mixture an engine will take, varies greatly with the speed and pull. **At slow speeds,** the volume, at carburetor pressure, is equal to the cubic content of the cylinders multiplied by the number of intake strokes.

At high speeds of one thousand revolutions or over, the quantity may drop to less than one-half the amount, depending on the design of the valves, inlet piping, and passages. This reacts upon the compression, and hence on the mixture desired for best results.

The design of the engine has a bearing on the carburetor design, which explains the well-known but seemingly mysterious fact that a carburetor giving good results on one engine sometimes fails to maintain its reputation when applied to one of different design. **The system of ignition** used also has a marked influence on the proper working of an engine, as a hot spark is most essential.

Proportions of air and gasoline. Different mixtures of air and gasoline are needed for different engine requirements. It is no longer the belief that a uniform mixture is correct for all speeds. The new rule is, that the amount of gasoline fed into the air must be changed according to demands, and that if a 12 to 1, or rich, mixture is best for quick acceleration, a 15 to 1, or leaner, mixture may be best for pulling with the throttle wide open, and a 17 to 1, or still leaner, mixture is best for particularly high speed work. Therefore, a varying mixture must be supplied.

Atmospheric conditions have much to do with the action of a carburetor. An engine seems to run better at night. Taking an engine from sea level to an altitude of 10,000 feet involves using air in the engine cylinders at atmospheric pressures ranging from 14.7 lbs. down to 10.1 lbs. to the square inch. In other words, the higher the altitude, the lighter is the air, and thus more air for the carburetor is required.

To Test the Mixture

If there are doubts in the mind of the operator as to whether the mixture is too rich, one method of ascertaining **the correct proportion of air and gasoline** is to shut off the fuel at the tank and open the throttle.

If the mixture passing into the cylinder is too rich, the engine speed will increase as the level of the gasoline in the float chamber is lowered, since this operation weakens the mixture considerably.

If the mixture is thought to be too weak, the float chamber can be flooded while the engine is running, and if this causes the engine to speed up, it may be taken as an indication that the mixture is not rich enough.

The proportionate amount of gasoline to air is essential. The novice usually gives the carburetor too much gasoline by opening the adjustment valve too wide, thereby causing "too rich a mixture." Too much gasoline will not run the engine any better than not enough. It must be remembered that only a very little gasoline is required in proportion to the air needed.

Use air. It is advisable to run the engine with as much air as possible, which means a "lean" mixture. This not only means economy of gasoline, but prevents soot deposit and pitted valves (providing good lubricating oil is used).

Of course, when first starting, or when cold, more gasoline is absolutely necessary, but as soon as the engine warms up, cut down on the gasoline and run on more air. Most carburetors, now-a-days, are fitted with air regulators and heated intake manifolds for this purpose.

An engine will run on less gasoline, and more air, the warmer it gets. This accounts for the necessity of the air adjustment.

Rich and Lean Mixture

A rich mixture is one in which the proportion of gasoline abnormally exceeds the amount of air. It may be due to faulty adjustment of the gasoline needle valve, float, or air valve. The expression, "mixture too rich" means that too much gasoline is present in proportion to air, or, technically, that there is insufficient oxygen to support its combustion.

An over-rich mixture will cause an engine to overheat and thereby give rise to a number of troubles, such as preignition, accumulations of carbon on the pistons and cylinder heads, steaming water in the radiator, and loss of power and "loping" or choking up on slow speeds.

The cause of mixture being too rich may be: Too much gasoline at needle valve; punctured float; float valve not working properly, owing to bent needle, or presence of foreign matter in valve seat; too much priming; primary air passage clogged or partially obstructed; air valve not open enough, spring too strong or air opening choked.

A mixture is poor or lean when it contains too much air and not enough gasoline, a condition often due to a faulty adjustment of the needle or air-valve, float, a leak in the inlet pipe, the spray nozzle, float valve, or feed pipe partly clogged, or water in the gasoline.

A poor mixture will make the engine miss when running idle at slow speeds, and at high speeds it will not only cause misfiring, but the missing will be accompanied by coughing and "popping" in the carburetor. Both this and explosions in the muffler may also occur.

The cause of mixture being too weak may be: Too much air, not enough gasoline; carburetor passages or jet clogged; throttle valve out of adjustment; insufficient flow of gasoline; tank valve closed; vent hole in gasoline tank cap stopped up; break in gasoline supply; bad gasoline, originally, or from standing; water in gasoline; carburetor cold; gasoline cold and unvaporized; gasoline supply exhausted. The ignition system not working properly will also act in a manner similar to too lean a carburetor mixture.

Smoke Indications of Carburetor Mixture

If the engine is fed too much gasoline, black smoke, smelling of raw gasoline, will usually be in evidence, issuing from the exhaust. Care should be taken to distinguish this from the excess of heavy blue smoke which is indicative of too much engine lubrication.

Whenever any considerable quantity of smoke of either color comes from the exhaust, the engine may miss explosions through fouled spark plugs.

If the mixture is too rich, the engine will have a tendency to slow up and "choke" or "load up" when the throttle is opened wide, and will run at a higher speed when it is partially closed.

Another indication of the mixture being too rich will be shown in its speeding up perceptibly, if the auxiliary air valve of the carburetor is held open, or additional air is admitted in any way between the carburetor and the cylinders.

Such being the case, the exhaust gases, if ignited by holding a piece of burning paper near the end of the exhaust pipe, will burn with a large red flame, similar to that of a bunsen burner when the air is mostly cut off.

Loping. Another indication of too rich a mixture is that when "idling," the engine will run in a loping manner, as if actuated by a governor; more air and less gasoline is needed.

"Loading up" when running slow or idling is due to the fact that the air comes into the carburetor so slowly that the gasoline particles are not broken up fine enough, and condensation takes place. Thus the gasoline is taken in in a more or less liquid form, and combustion is very poor. That is one reason why as much heat as possible should be applied to the air intake of the carburetor. Also, the engine should not be allowed to tick over slowly for any length of time when the car is standing idle. It not only wastes fuel, but the manifold will load up with raw fuel, and acceleration will be anything but good when you attempt to get under way.

By opening the relief cocks in the cylinder heads (if provided), while the engine is running, one can judge fairly well, by the color of the flame, when the mixture is correct. At each explosion a jet of flame will shoot out of the cylinder through this relief cock.

If the mixture is too poor (too much air for the gasoline), the flame will be light yellow.

If the mixture is too rich (not enough air for the gasoline), the flame will be red and smoky. Black smoke will also come out of the muffler, smelling of raw gasoline.

If the mixture is correct, the flame will be light blue or purple, and hardly visible.

Note. This test is not absolutely reliable, because, when the relief cock is open, air is drawn into cylinder which tends to change the mixture.

"Back Firing" or "Popping" in the Carburetor

Back firing. There seems to be much confusion in the use of the terms "back kick" and "back fire," the latter being very often used to describe what happens when, in starting an engine, it suddenly reverses its direction of rotation to give a "back kick."

Generally speaking, "back-firing" is caused by a weak mixture which burns so slowly that the flame continues until the opening of the admission valve again, when it ignites the incoming charge in the intake pipe and shoots back to the carburetor. While an over-rich mixture will also burn slowly, it rarely ever will cause back-firing.

Another cause of back-firing is, of course, the faulty timing of the valves, or, in fact, a badly leaking valve. As a general rule, back firing is due to one or more of the following causes: (1) very slow explosion or weak mixture; (2) very late explosion; (3) a spark occurring during the intake stroke; (4) the intake valve being partially open during the power stroke; (5) premature ignition.

Slow combustion is caused by a lean mixture; **late combustion** is caused by a weak or retarded spark. Nos. 1 and 2 are the usual causes, while Nos. 3 and 4 happen infrequently.

Back-kicking is usually caused by preignition in starting the engine, which is due usually, as is well known, to too much "advance" in the spark timing.

"Popping back" or "spitting" in the carburetor is quite a common occurrence with carburetors when first starting the engine on a cold day. But after the engine has been run for a brief period it will become warmed up and the gasoline will begin to vaporize properly and run without popping back.

If the "popping back" continues, then the mixture is too weak and more gasoline is required. By giving the auxiliary air-valve spring a slight increase of tension, or by opening the gasoline needle valve a notch or so, or by closing the "choker," or closing the "damper" at the air intake, more gasoline will be supplied to the carburetor until the popping stops, which it will probably do when the engine is warmed up.

Do not use the "choker" any more than absolutely necessary. It permits raw gasoline to be drawn into the engine, a part of which passes to the crank case and thins the lubricating oil.

Never run an engine in a closed garage, because carbon monoxide, a deadly poisonous gas, is present in the exhaust of gasoline engines. Too rich a mixture increases the amount of carbon monoxide given off.

Carburetion during Cool Weather

Since, at the present day, low-gravity gasoline is being used, the engine will have a tendency to miss explosion and run in jerks or uneven explosions, especially when starting.

This is due, principally, to **insufficient heat** properly to vaporize the gasoline to prevent condensation. After the engine becomes thoroughly warmed up, the "missing" usually disappears. When the weather is warm the engine starts easier, because gasoline will vaporize more readily and is easier ignited. Therefore during cool weather three things are essential: a good **hot spark,** a **quick method of heating,** and a **choker** or primer for enriching the mixture to start on.

For starting. There are different methods employed to inject a rich mixture into the cylinder in order to start the engine at all on a cold day. The common method is to close the main air intake, which causes raw gasoline to be drawn into the cylinder, which would be termed "choking" the air supply. After the engine is started, it is then only a matter of running the engine until warm enough to vaporize the gasoline, at the same time gradually opening the choke or air valve, until the regular amount of air is being used.

There is a disadvantage, however, in priming an engine, and that is, the raw gasoline drawn into a cool cylinder is not all utilized for combustion, but part of it forms carbon, due to lack of oxygen, which is not being supplied, as the air is choked. The result is a deposit of carbon on the head of the piston, in the combustion chamber, and on the spark plug. Therefore the air should be supplied as quickly as possible. The problem is, then, to heat the gasoline as quickly as possible, so that vapor and air are used instead of raw gasoline.

The "choker" or some method of supplying a richer mixture, however, is usually necessary for starting. If the choker principle is used, it is closed only until the engine starts, then gradually opened. In fact, by using an exhaust-heated intake manifold to heat the mixture, and also drawing warm air through the air passage of the carburetor, the amount of raw gasoline injected into the cylinders will be considerably less than if it is not heated. Therefore this system will provide a quicker vaporizing or heating of the mixture and a saving of fuel, with less carbon deposit in cylinders.

Additional Pointers on Cold-Weather Starting

Don't expect the engine to warm up in a minute any more than you expect a kettle to boil as soon as it is set on the stove. It takes time to heat.

Take into consideration the fact that cold solidifies the lubricant in the transmission, rear axle, and other parts of the car. Therefore it requires greater energy on the part of the self-starter to revolve the engine. If the clutch is in, when starting, and gears are in neutral, the transmission counter-shaft gears are directly in this oil and are revolved when cranking. After a car has been standing over night in a cold garage or sufficiently long at the curb to become thoroughly chilled, **throw out the clutch** when cranking. This eliminates the drag of the transmission gears plowing through the solidified grease.

A good hot spark is important, especially in winter. Be particular to see that the battery is always charged. A quick method of starting should be provided in order to save current.

CARBURETOR ADJUSTMENTS IN GENERAL

The parts to adjust in the carburetor depend upon the type of carburetor. This subject is therefore best treated by giving examples of carburetors of different types, such as the air-valve type, metering-pin type, plain-tube type, etc.

Carburetors are usually adjusted to the best advantage when the engine has been run and all parts are warmed up. If a carburetor is adjusted when the engine is cold, it will be noticed that it will need readjusting when warm, that is, in order to get a perfect adjustment.

When carburetors are adjusted when warm, sometimes, especially on a cold day, the engine will not hit just right when first starting; it will miss and not run even or smooth until it has run a few moments and is heated up; then it runs satisfactorily.

Another point to remember is to be sure the ignition is right and you have a good hot spark, and the spark plug gaps set about .025″. **If too close,** the engine will operate unevenly at idling speeds and miss at higher speeds; **if too wide,** it will miss when accelerating at very low speeds or hard pulls. A weak spark causes late combustion. (See Index for "Adjusting spark-plug gaps.") Also remember, that if trouble, lack of power, etc., develops with the engine missing, it is well to be sure that the trouble is in the carburetor and not due to other troubles. See "Digest of Troubles," for suggestions of how to diagnose troubles.

The best way to adjust a carburetor is to arrange so that the engine may be run loaded while the adjustment is being made. One way to do this is to adjust the carburetor while the car is in motion on the road.

To test the carburetor for adjustment, run throttled down for two blocks. When there is a clear space ahead, suddenly press the accelerator pedal down. The engine should pick up smoothly, to as high speed as you care to run at. If the engine chokes, stalls, misses or labors, or backfires at the carburetor or at the muffler explosions, it shows the carburetor is out of adjustment.

Adjusting the Air-Valve Type of Carburetor

The three principal parts of a carburetor used for making adjustments on the air-valve type are: the **auxiliary air valve,** the **gasoline needle valve,** and the **float needle valve.**

For the average carburetor, having an "auxiliary air valve" and a "needle-valve" adjustment, the following rule for adjusting will apply.

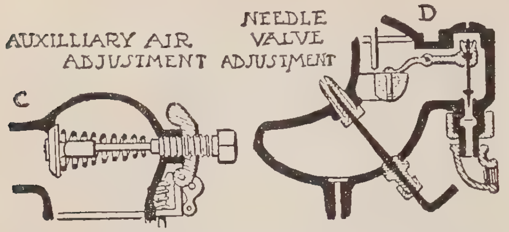

Fig. 1. Showing principal parts of an air-valve type carburetor for adjustments.

First, run the engine at what will be nearly its maximum speed in ordinary use, with the throttle open considerably and the spark rather late. This speed, of course, will be considerably less than the maximum speed of the engine when running idle.

Second, turn the main gasoline needle-valve adjustment, until the mixture is so weak that there is popping in the carburetor.

Third, note this position and then turn this adjustment until so much gas is fed that the engine chokes and threatens to stop.

Fourth, set the adjustment half-way between these two points, which will be very near the correct position. Turn the adjustment slightly in one direction and then in the other until the point is found where the engine seems to run the fastest and smoothest.

Fifth, gently and gradually cover the auxiliary air inlet of the carburetor by placing the hands partly over the valve, if necessary, in order partially to exclude the air. If the engine slows down, the spring should be weakened, since not enough air is allowed to enter the carburetor.

Sixth, next try opening the auxiliary air inlet slowly and gradually by pushing the poppet off its seat with the finger or the end of a pencil. If the engine speeds up, there was not enough air and the spring should be loosened, while if it slows down, the mixture is correct or a little too lean, according to the degree to which the speed is affected. If it is found to be too lean, the spring needs tightening.

Seventh, after the auxiliary air inlet has been adjusted, open the throttle again and adjust at high speed, as this adjustment may now require to be altered.

In the air-valve spring lies the chief difficulty in making carburetor adjustments, if the carburetor is provided with an automatic auxiliary air valve. This spring should be of such length and of such gauge wire, diameter, and number of convolutions as to provide the requisite progressively increasing resistance to opening, while at the same time exerting little or no pressure upon the valve when it is against its seat.

Adjustment: The needle valve should be set for slowest running with the air valve held lightly against its seat, and then the spring adjustment should be backed off until the slightest further increase in throttle opening causes the valve to leave its seat.

From this point on the only proper adjustment for the air valve becomes a series of tests for spring strength without alterations being made in its normal length; that is, with the adjustment backed off in accordance with the instruction just given. If the spring tension with increased throttle openings is too light, and "spitting back" in the carburetor continues in spite of the increased opening of the gasoline needle-valve adjustment, it is a pretty sure indication that the air-valve spring is too weak and that a stronger one should be obtained from the factory. These can usually be obtained in several sizes or degrees of tension to suit varying engine and climatic conditions.

Too strong a tension on the auxiliary air-valve spring will result in too much gasoline and not enough air (too rich a mixture), because the valve will be more difficult to open by suction. **Too weak a spring tension** will give too much air or too lean a mixture.

When adjusting a carburetor on a "V"-type engine, a good plan is to adjust each block of cylinders separately.

TO OBTAIN A SLOW, EVEN PULL OF ENGINE WITHOUT MISSING

Factors which, in addition to proper carburetor adjustment, assist an engine in pulling slowly and firing regularly at low speeds are:

1. **Good compression,** which includes proper clearance of pistons, good piston rings, and no air leaks at the inlet manifold, carburetor gaskets, valve caps, or spark plugs, etc. If there is an air leak in one cylinder it will affect the other cylinders.
2. **Proper valve clearance, properly seated valves, and correct valve timing** are very important.
3. **Proper ignition timing**—not too far advanced; when running slow, retard the spark.
4. **Interrupter points should be set correctly** with a clear, flat surface at the points.
5. **Be sure there is a good hot ignition spark** which will fire a charge at a wide-open throttle and also at low speed. A defective coil, condenser or resistance unit will produce a spark, but not one of sufficient volume to ignite the gas properly. See Index for these subjects, including how to test a fully charged battery.
6. **Properly set spark-plug gaps.** About .025″ is the average gap. Good spark plugs are also important.
7. **Cooling water** must be at least 90° F.; 140° F. is better.

These details are essential to secure a flexible and smooth-running engine.

Indication of Correct Carburetor Adjustment

1. Run the engine until warmed up.
2. Close the throttle with spark between half advance and fully retarded position. The engine should then run evenly.
3. The car should run 6 to 7 m. p. h. smoothly on high gear.
4. Run one-quarter to one-half mile at 12 to 13 m. p. h. The engine should run evenly.
5. With the car running 7 to 8 m. p. h., open the throttle wide suddenly. The car should accelerate smoothly.

Indications of Incorrect Adjustment

The following indicate a lean mixture:

1. The engine starts hard.
2. The engine backfires through the carburetor when opening the throttle suddenly.
3. The engine refuses to idle.

The following indicate a rich mixture:

1. Spark plugs foul quickly.
2. Exhaust gas causes one's eyes to burn.
3. Black smoke issues from the muffler.
4. Engine operation is uneven, causing "loading up" or "loping," as previously explained. On a Ford, a rich mixture will cause the rear axle to have an uneven hum which is distinctly heard at 13 m.p.h.

POINTERS ON GOOD CARBURETION[1]

Good ignition, good compression and good spark plugs are necessary for perfect carburetor performance.

Valve stem guides: When the carburetor is properly installed and the engine refuses to idle, look for defective guides. To locate these defects, squirt gasoline from an oil can at the bottom of the guides while the engine is running. The tendency of the gasoline is to travel upwards through the loose guide, and each cylinder will begin firing as the gasoline takes the place of air which was previously passing through the guide.

Remedy: New valves should be installed or the valve guides should be bushed. A great deal of imaginary carburetor trouble can be traced to valve springs being weakened and to unequal tension having developed.

Air leaks in intake manifold: When the engine refuses to idle, test for air leaks, by removing the hot-air tubing from the intake and with a squirt-can apply gasoline freely around the manifold connections. If an air leak exists the engine will either speed up or choke down entirely. Air leaks are often responsible for poor mileage, loss of power, and over-heating trouble.

The cause of an engine galloping is found in unequal explosion in the cylinders, caused by leaking valves and pistons, or by leakage past the intake guides. It may also be due to improper carburetion, allowing some of the cylinders to be fed liquid gasoline. The spark-plug points should be the same distance apart; likewise there should be no partial short circuit anywhere in the distributor wiring, and all brush segments in the distributor should be cleaned so that the brush may make equal contact with all of them.

Popping back in the carburetor usually indicates a weak mixture, not enough gas; it may also indicate a sticking valve, or possibly a leaky intake valve which might be due to lack of clearance between the stem and push rod. It could also be due to improperly timed ignition or to short circuit.

Exploding of the gases in the muffler, caused by an intermittent spark, generally is due to lack of adjustment of the breaker points, to sticking of the breaker mechanism, to a loose or badly worn distributor brush, or to loose or short-circuited wires or connections.

The proper spacing of spark plugs is very essential. There are very few motors that should have a gap set closer than .025″.

If gaps are set too close, the engine will not idle properly, as there will be a loping at low throttle. The action is something similar to too rich a mixture. Under these conditions the results will be the same with either a lean or rich mixture.

If spark-plug gaps are set too wide, the engine will have a tendency to cut out at high speed. To ascertain if it is due to the carburetor mixture, enrich the mixture by closing the damper, suddenly accelerate the engine, then open the damper for the leanest mixture, and again accelerate the engine. If the same condition exists with both the "rich mixture" and the "lean mixture" test, you will know that it is not carburetor trouble, as both rich and lean mixtures have been encountered by these operations

If spark-plug gaps are set too close, it will cause the car to jerk at low throttle. The same condition will occur if there is a weak spark, a safety gap in the magneto set too close, or an exposed wire, which will cause the spark to jump across.

If the engine runs smooth on the level but misses on a grade or under extreme pulling conditions, it is an indication of ignition trouble, which is likely to be located in the coil or magneto, due to a defective condenser, or to a punctured armature or coil winding. This could also be traced to an improper mixture.

To determine whether the trouble is ignition or carburetion, release the clutch when missing occurs, leaving the throttle wide open. If the engine speeds up instantly and does not miss, it is ignition trouble. If the engine does not speed up readily and continues to miss, it indicates an improper mixture.

Poor compression is another cause of trouble which is often blamed on the carburetor and shows up more at low engine speeds. It will cause the car to jerk at speeds below fifteen miles an hour and make it impossible to get good idling with any mixture. The cylinders with poor compression will not draw in as much mixture as those with good compression. It will force out on the compression stroke a portion of the mixture taken in on the suction stroke. This trouble is caused by valves not seating properly, valve tappets set too high, or poorly fitting pistons or rings.

To test this out, see if the engine will rock on all cylinders by using the starting crank. This should always be tested before making a carburetor installation.

To "rock" means to have a good compression, which offers resistance to the piston when it is going up on compression stroke.

If the engine heats up excessively, look for a late spark or poor water circulation. If the magneto or distributor is set late, the engine will heat and will also cause a power loss, and you will be unable to get a spark knock with spark advance on a hard pull. Overheating could also be caused by an air leak or too lean a mixture.

When the engine backfires, it is caused by too lean a mixture. If it backfires continually and you are unable to overcome it by adjustment of the carburetor, you will know that a valve is sticking open. Exhaust valves closing too early will also cause the motor to heat.

---

[1] From instruction on **Master Carburetor.**

The impression is prevalent that engine knocks are caused by a poor mixture. This is in fact very rarely the cause, as in the case of overheating, caused by a very lean mixture. When the engine knocks, look for carbon deposit, the spark being too far advanced, loose pistons causing a slap, loose bearings or wrist pins. Do not lay it on the carburetor.

Lubrication: To obtain the greatest possible mileage from an engine it is particularly essential to get the full expansion forces of the gases exploding in the combustion chamber. This is possible only when the best grade of lubricating oil is used. The perfect lubrication of an engine means considerably more than the mere elimination of friction between the moving parts.

The oil should form a perfect seal between the piston and the piston rings and the cylinder walls. This seal is all important in the saving of fuel, for it is very evident that if only a small fraction of the pressure is lost, a corresponding amount of fuel must be used to enable the engine to do the same amount of work. The fuel passing by the rings into the crank case will eventually dilute the oil to such an extent that it will be entirely robbed of its lubricating value. It is therefore essential to replace this oil with a fresh supply at least every two thousand miles.

When vacuum systems are used, there are occasional instances where trouble is experienced by gasoline being drawn direct from the vacuum tank to the intake manifold, causing the engine to load badly. This is due to a leaky check valve in the vacuum system caused either by dirt or a punctured float. The result is that the vacuum tank fills, permitting gasoline to be drawn through the vacuum tube direct into the manifold. To determine if this trouble exists loosen the vacuum tube connection at the manifold; when the engine starts loading, draw the pipe out of connection about one-eighth of an inch while the engine is running. If the valve leaks, you will notice gas being drawn through the tube. If there is an air leak existing at the vacuum-tank connection, the tank will not supply enough fuel to the carburetor under heavy pulling conditions.

In making carburetor installations it is often necessary to use elbow fittings, which will necessitate tapping the flange for vacuum connections. In such cases do not tap the intake manifold too close to the outlet of the carburetor throttle, as this will reduce the vacuum in the manifold when the throttle is suddenly opened to such an extent as to interfere with the proper functioning of the vacuum tank. The bottom of the vacuum tank should be at least two inches higher than the gasoline level in the float chamber of the carburetor.

Vacuum tanks should be drained and cleaned at regular intervals. The carburetor is blamed quite often for vacuum-tank trouble. However, do not lay your trouble to the vacuum system until you have proved that it lies there.

When the car runs perfectly at low throttle or ordinary speeds and will accelerate quickly without backfiring, **but will backfire at high engine speeds** or on hills with wide-open throttle, look for some restriction in the flow of fuel from the tank to the bowl of the carburetor (providing you are sure the spark-plug gaps and ignition are all right). If the line is free from restriction, remove the screen and wash with gasoline. If there is no restriction up to this point, see that the vent hole in the main gas tank filler cap is not plugged up and trapping the flow of gasoline in the line.

FLOAT TROUBLES AND ADJUSTMENTS

When a carburetor drips, it usually indicates that the float or float-valve mechanism is out of adjustment. This prevents the float needle valve from properly closing. For instance, the float may be loose at the float screw; the gasoline then reaches a higher level than the spray nozzle or jet, with the result of an overflowing at the spray nozzle.

There are several causes for a dripping carburetor: either the float needle valve does not seat, due to sediment under it, or perhaps it is worn.

If sediment is the cause, the needle valve can be turned a few times on its seat and will probably clear the obstruction. On some carburetors, the float needle valve is in the form of a rod running through the float.

If the leak is not in the float needle valve, then it is probably due to the float being set so that it does not cut off in time to prevent overflowing at the jet. Or, in the case of a metal float, there may be a small hole in it, preventing it from floating; another cause may be that the mechanism is loose.

A simple method of testing a carburetor float mechanism is shown in Fig. 1.

In making this test, unscrew that part of the carburetor which will permit access to the float and float mechanism. Then prepare a device consisting of a can with a wire handle, a piece of copper tubing soldered to the bottom of the can to form an inlet, a piece of rubber tubing, and a nipple or short piece of metal tubing with a coupling adapted for attachment to the carburetor. The gasoline flows to the carburetor from the can, when it is held above the carburetor. By watching the float chamber fill with gasoline, the height the gasoline reaches at the time the float valve cuts off can be ascertained. If the height of gasoline in the carburetor is not sufficient, then the float must be raised slightly so that it will cut off later; if the height is too great, which can be determined by the gasoline flowing out of the jet, then the float must be slightly lowered, so that it will cut off earlier.

Owing to the variation in the suction of different engines on a carburetor, it is often found that a slight variation of the fuel level or a slight change in the size of the spraying nozzle will add greatly to the efficiency of the engine. The first thing to do, then, before attempting the adjustment of a float is to learn whether or not the float needs adjustment, by seeing if the gasoline is at the proper height in the jet when the float cuts off the gasoline.

To locate a suspected leak in a float of the hollow metal type: If the float is immersed in very hot water, the gasoline will be vaporized sufficiently to force its way out through a puncture and the spot may be located by watching the bubbles. The float should, of course, be removed from the water the instant bubbles cease appearing. The remedy is to solder the hole.

Testing the Float Height

On most makes of carburetors, the float needle valve is intended to cut off the gasoline when the level of gasoline in the float chamber reaches a level of about ⅛″ below the top of the nozzle or jet tube. Therefore this height, or the height recommended by the manufacturer, ought to be maintained.

Float adjustment: There is usually an adjustment provided directly above the gasoline float needle valve, which will regulate the height of the float. If not, then on some makes of carburetors (see Fig. 1) the float arm can be bent up or down, which will regulate the height of the float, and this in turn governs the float needle valve cut-off.

If the leak is due to a faulty seating of the float needle valve, then it will be necessary to put in a new needle valve or to reseat it.

Gasoline Level in the Jet

It is advisable to not tamper with the float unless you know positively that it is out of adjustment. This can be determined, if continually leaking, by making the test suggested above. Carburetors with floats similar to the Stromberg type "H" are provided with float adjustments. A Zenith carburetor is used as an example.

Zenith (Fig. 2): The level of the gasoline is maintained in the float chamber so that the gasoline stands 3 millimeters below the top of the jet, or about 7/64″. To regulate the level, note the washers (L), Fig. 2.

Master: The float weights are set about 1/32″ from the bottom of the float lid.

Schebler: In model "L," the top of the cork should stand 1 1/16″ from the top of the bowl in the 1-inch, 1¼-inch, 1½-inch and 1¾-inch. In the 2-inch model "L" carburetors this measurement is 1⅛″ and in the 2½-inch model "L," 1⅝″. These measurements should be made when the float valve is seated. In the Model R, the height of the cork float should be 23/32″ from the top of the bowl when the float valve is seated. In models D and E, the cork float should be level and rest 1/16″ above the top of the nozzle in the ½-inch, ¾-inch, and 2-inch sizes, and 1/32″ on the 1-inch, 1¼-inch, and 1½-inch sizes. Model H is 19/32″.

Fig. 2. This illustration shows the level of gasoline in the float chamber and in the jet of the Zenith carburetor. If the float level was above the jet, the gasoline would run out of the jet.

Note: When changing the float level, great care must be taken to bend the arm in such a manner that the float will be at the proper height, yet perfectly level.

Stromberg: Note the level of gasoline in the float chamber in the Zenith (Fig. 2). This illustration will give the reader an idea as to the relation of the level of the gasoline in the float chamber to that in the jet. On the Stromberg Model "H," it should be about one inch from the lower edge of the glass. This can be adjusted by removing the dust cap and loosening the nut; if the gasoline is too low, screw adjustment up; if the gasoline is too high, screw adjustment down.

On Stromberg carburetors models "L" and "M" the height of gasoline should be 1″ below the top of the float chamber.

The adjustment on the Stromberg "K" type can be adjusted only by "bending the arm," as previously explained, which governs the float level.

Rayfield: The float level is correctly set at the factory and does not ordinarily require adjustment; but if it should, then the correct gasoline level should be maintained in the middle of the window in the side of the float chamber.

Cork floats are coated with varnish, but after long periods of time this coating may come off and the cork may become gasoline soaked, making it heavy and thus causing the float needle valve to fail to cut off properly. A mixture for coating is as follows: 1 lb. of glue, 1 teaspoon glycerine, 1 quart water. Let this come to a boil and add formaldehyde for quick drying. When coated, suspend the float by a string until dry.

Ford carburetor (Kingston and Holley): See Instruction on the Ford car.

TOOLS REQUIRED FOR REPAIRING CARBURETORS

Tools for repairing the Ford carburetor are given below as an example. Many of these tools can be used for repairing other carburetors. Special tools and wrenches can be obtained of the various carburetor manufacturers.

2 oz. hammer; ¼″ screw driver; ½″ screw driver; No. 52 drill; hand drill; adjustable wrench; pair pliers; flexible 6″ scale; 8″ mill file; wrench for inserting spray nozzle (H.), 3Z 4675; wrench for inserting float-valve seat (H. and K.), 3Z 4120; seating tool for inlet needle (H. & K.), 3Z 4114; float-setting tool and low-speed-tube nut wrench (H. & K.), 3Z 3223; low-speed-tube clearance gauge (H.), 24Z 2390; gauge for gasoline level (H.), 24Z 2393; float gauge and adjusting tool (H. & K.), 24Z 3990.

Tools with a "Z" number may be purchased from the nearest Ford branch.

Note: "H" means Holley carburetor; "K" means Kingston, as used on the Ford. Other numbers and letters are Ford stock numbers.

Carburetor Repair Bench

A space should be set aside for testing and repairing the carburetor, and no greasy or dirty tools should be used, as it is important that no dirt gets into the assembly.

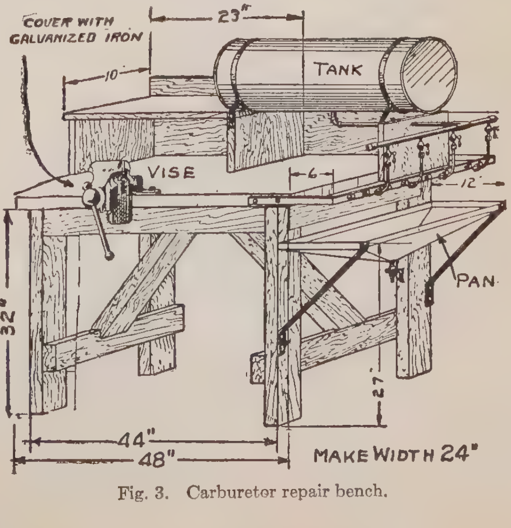

Fig. 3. Carburetor repair bench.

A suggestion for a repair bench is shown in Fig. 3. A bracket is provided to hold the carburetor in a level position. A tank 6″ above the level of the bracket is connected to the carburetor by means of a series of standard Ford feed pipes. Note the four gasoline pet cocks and connections which permit four carburetors to be tested at one time. Below the bracket a pan is provided to catch any drippings.

To guard against fire due to static electricity, the bracket should be connected to the drip pan by some metallic connector.

The carburetor is secured to the bracket and the feed pipe is attached to the carburetor from the connections (shown on the right) in the regular way. Here the gasoline level may be checked and the carburetor may be watched to see that it does not leak at the float valve.

A 4″ machine vise with jaws opening 5¼″ should be provided to hold the carburetor during the repair operations.

LEADING CARBURETORS—PRINCIPLE AND ADJUSTMENT

Owing to the fact that innumerable improvements are constantly being made in carburetor construction, it is impossible in this instruction to describe all the actual adjustments of all carburetors.

Repairmen are advised to secure instructions for adjustment of all the leading makes of carburetors from the manufacturers and to keep them on file (see Index for "Addresses of carburetor manufacturers").

Schebler Model "R" Carburetor

This carburetor may be termed an air-valve type of carburetor, with an automatically operated gasoline needle valve controlled by the auxiliary air valve.

Note that the gasoline needle valve (metering pin I) is operated automatically by movement of the auxiliary air valve. A concentric-type cork float is used.

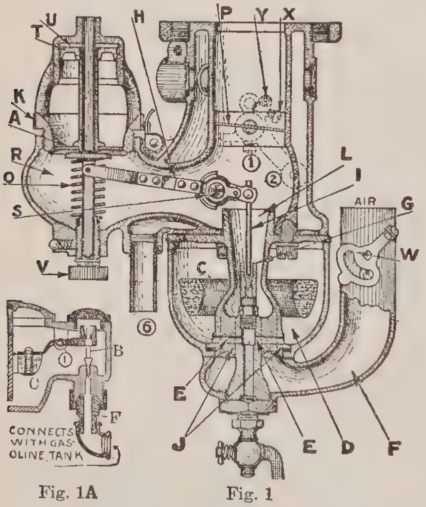

Fig. 1A Fig. 1

Fig. 1. Schebler model "R" carburetor.

Fig. 1A. Showing how the float gasoline needle-valve (B) cuts off and opens the gasoline passage (F) by the rise and fall of the float (C).

The parts consist of a float chamber (D), the cork float (C), and a float needle valve (B). These three parts control all flow of gasoline into the carburetor as it is needed by the engine.

That part of the carburetor where the gasoline and air are mixed consists of a mixing chamber (L), a spray-nozzle (G), and a needle valve (I).

The parts which automatically regulate the amount of gasoline required from the float chamber to provide the proper mixture consist of an auxiliary air valve (A) and lever (H), connected with needle valve (I).

Principle of operation: Gasoline flows from the tank through the gasoline pipe into the float chamber (**D**).

As the gasoline rises in the float chamber (**D**) it raises the cork float (**C**) with it, which, through a lever connection, automatically closes the needle valve (**B**) and shuts off the flow of gasoline from the tank to the carburetor. Of course, as the gasoline is drawn from float chamber (**D**), the float (**C**) drops and raises valve (**B**), admitting more gasoline.

The suction of the pistons draws the gasoline from the float chamber (**D**) through the passages (**E**) into the nozzle well (**G**), and past the needle valve (**I**) into the mixing chamber (**L**). As the needle valve (**I**) is raised and lowered, more or less gasoline is allowed to spray into the mixing chamber (**L**). At the same time the suction of the pistons draws from the warm-air intake (**F**) and the passages (**J**) warm air into the mixing chamber (**L**). As the suction of the swiftly moving pistons is very strong, the air is drawn through the mixing chamber (**L**) with great velocity, and there, coming into contact with the gasoline spray from the nozzle well (**G**), it vaporizes the gasoline.

This vaporized mixture is then drawn by the suction of the pistons past the throttle valve (**P**) into the cylinders. The quantity of combustive vapor flowing past the throttle valve (**P**) is regulated by the position of this throttle valve, and the position of this throttle valve is regulated by the driver either from a pedal called the "accelerator" or a throttle lever on the steering post. Opening the valve (**P**) admits more combustive vapor to the cylinders, and consequently increases the speed and power of the motor. Closing it has the reverse effect.

At high speed it is obvious that the suction through the mixing chamber (**L**) and the warm air passages (**J**) greatly increases, and as it increases beyond the capacity of these passages to supply air, a strong suction is brought to bear upon the auxiliary air valve (**A**). At a certain speed this suction is sufficient to draw this valve down against the coil spring (**O**). As the valve is drawn down, air rushes into the auxiliary air passage (**R**), and thence past the mixing chamber (**L**) into the cylinders.

Auxiliary air valve: To take care of this extra supply of air there must be an extra supply of gasoline automatically furnished. This is taken care of as follows: As valve (**A**) is depressed against the spring (**O**) it operates the lever (**H**), which is hinged at the point (**S**). As the lever (**H**) is depressed by the valve (**A**) it opens needle valve (**I**) admitting more gasoline to the mixture. It will be seen that this extra supply of gasoline is always directly in proportion to the air supply through the valve (**A**).

Dash-pot action: It is obvious that if means were not taken to prevent it, the valve (**A**), which is under the tension of the spring (**O**), would close very abruptly if the speed of the engine was suddenly checked. It would also tend to open very abruptly if the speed of the engine was suddenly increased, as, for instance, if the accelerator was suddenly opened. Furthermore, the suction of the cylinders is to a certain degree intermittent between the strokes of the pistons, and this intermission between the strokes would ordinarily tend to cause the valve (A) to flutter or vibrate if means were not taken to prevent it. The fluttering or vibratory action of the valve (A) would result in an unsteady flow of gasoline vapor to the cylinders, which would cause a vibratory or jarring effect in the engine. Any such action is prevented by a device (U) called a dash pot. Its function is automatically to insure a steady and stable supply of gasoline vapor to take care of varying engine speeds under all circumstances. To hold the valve (A) steady and to check its sudden closing or opening and to overcome its tendency to vibrate, it is attached directly to a plunger (T), which operates on a cushion of air in the dash pot (U).

To adjust the carburetor (Fig. 1): Turn the auxiliary air-valve cap (K) clockwise, or to the right (right means "rich") until you can turn it no farther. Then turn to the left or counter-clockwise (left means "lean") through one complete turn. Start the engine and then continue to turn (K) to the left or counter-clockwise until the engine hits perfectly on all cylinders, at the slowest speed possible. Advance the spark lever two-thirds or three-fourths ~~the~~ way on the sector and then suddenly open the throttle lever or accelerator wide. If the engine back-fires on this quick acceleration, turn the spring adjusting screw (V) up until the carburetor works perfectly.

By turning the screw (V) up or inward, it is turned against the spring (O), which increases its tension, thus preventing valve (A) from admitting air into the carburetor too freely.

Turning (K) to the right, or clockwise, lifts the needle valve (I) out of the nozzle well (G) and permits more gasoline to spray into the mixing chamber.

When (K) is turned to the left, or counter-clockwise, it lowers the needle in the nozzle and shuts off the gasoline. It should be remembered that it is desirable, from both points of economy and power, to drive the car with the leanest mixture possible.

The throttle valve should be adjusted so that when the hand throttle is closed, the engine will idle and run evenly on all cylinders. This can be ascertained by the regularity of the impulses in the exhaust when both the spark and throttle levers are set at their lowest positions. If the engine, however, should run too fast, or should stop when the throttle is at lowest position, adjustment is necessary. Directions for this are as follows:

Loosen the set screw (X) which locks the adjusting screw (Y) where the throttle shaft enters the carburetor. Place throttle in lowest position. If the engine runs too fast, unscrew adjusting screw (Y) so that the butterfly throttle valve (P) is closed a little tighter. If the engine runs too slow, screw in the adjusting screw so that the valve is held a little more open. Lock adjusting screw (Y) with set screw (X) after adjustment.

Schebler Model "L" Carburetor

This carburetor may be termed an "air-valve type" of carburetor with a mechanically operated gasoline needle valve. Note that the gasoline needle valve (B) is raised and thus opened mechanically by movement of the throttle lever which is connected with a cam arrangement (C). As the throttle lever is opened, the cam action raises the arm (J) connected with the gasoline needle valve, thus raising the needle valve from its seat (S) and admitting more gasoline at the jet.

To adjust the carburetor: First, make adjustments on the auxiliary air valve (A) so that it seats firmly, but lightly; then close the needle valve by turning the adjustment screw (B) to the right until it stops. Do not use any pressure on this adjustment screw after it meets with resistance. Then turn it to the left about a turn and a half and prime or flush the carburetor by pulling up the priming lever (C) and holding it up for about five seconds. Next, open the throttle about one-third, and start the engine; then close the throttle slightly and retard the spark and adjust the throttle-lever screw (F) and needle valve adjusting screw (B) so that the engine runs at the desired speed and hits on all cylinders.

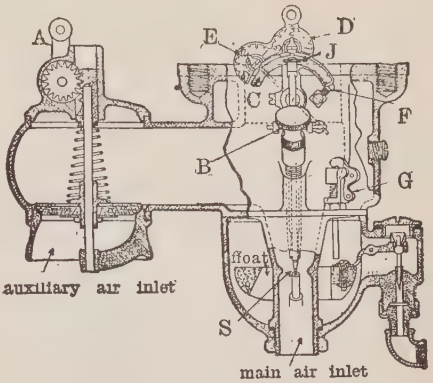

Fig. 2. Schebler model "L" carburetor.

After getting a good adjustment with the engine running idle, do not touch the needle valve adjustment again, but make intermediate and high-speed adjustment on the dials (D) and (E). Adjust pointer on the first dial (D) from figure No. 1 toward figure No. 3, about half-way between. Advance the spark and open the throttle so that the roller on the track running below the dials is in line with the first dial. If the engine back-fires with the throttle in this position and the spark advanced, turn the indicator a little more toward figure No. 3; or if the mixture is too rich, turn the indicator back or toward figure No. 1 until satisfied that the engine is running properly with the throttle in this position, or at intermediate speed. Now, open the throttle wide and make adjustment on dial (E) for high speed, the same as adjustments for intermediate speed on dial (D)

Note: In the majority of cases, in adjusting this carburetor, the tendency is to give too rich a mixture. In adjusting the carburetor, both at low, intermediate, and high speed, cut down the gasoline until the engine begins to back fire, and then increase the supply of fuel, a notch at a time, until the engine hits evenly on all cylinders. Do not increase the supply of gasoline by turning the needle valve adjusting screw more than a notch at a time, in low-speed adjustment, and do not turn it after the engine hits regularly on all cylinders.

In making the adjustments on the intermediate and high-speed dials, do not turn the pointers more than half-way at a time between the graduated divisions or marks shown on the dials.

Stromberg Model "H"

This carburetor would be termed a compensating-type carburetor, because, as previously stated, an auxiliary full jet comes into action as the throttle is opened.

For low speeds the gasoline is taken from the spray nozzle (C), in a venturi tube, through which hot air passes. Regulation of amount of gasoline is by needle valve (A) (Figs. 3 and 4).

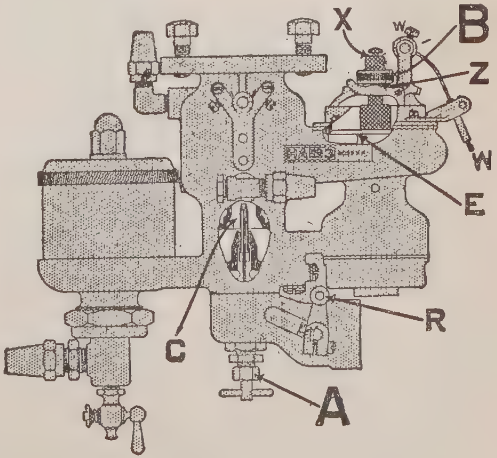

Fig. 3. Stromberg model "H" carburetor.

For high speeds, the nozzle in the center of the air valve is automatically regulated by opening of the air valve thus supplying the necessary volume of gasoline for high speed.

Adjustment for high speed is by (**B**), which controls the amount of flow of gasoline on high speed by regulating the time when the needle valve begins to open. The needle valve opens only when (**B**) comes in contact with (**X**). (**B**) is raised by a throttle opening at high speed. There is usually about 1/32″ clearance between (**B**) and (**X**).

Low-speed adjustment is controlled by the needle valve (**A**). If too rich, as indicated by the engine "rolling" or "loading," turn (**A**) up, thus admitting less gasoline and making the mixture leaner. If the mixture is too lean, turn (**A**) down, thus admitting more gasoline and a richer mixture.

High-speed adjustment: Advance the spark, open the throttle. If the mixture is too lean on high speed, screw (**B**) up until desired results are obtained. If the mixture is too rich, screw (**B**) down.

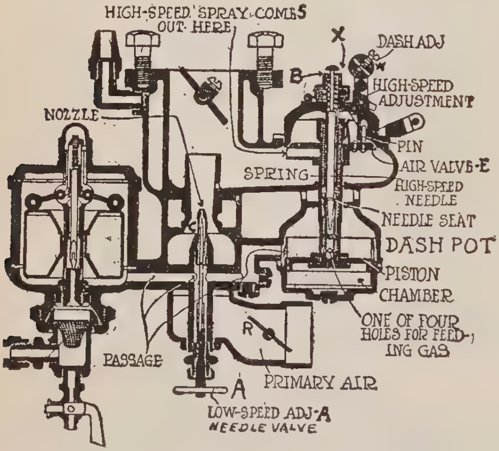

Fig. 4. Sectional view of Stromberg model "H" carburetor.

Nozzle: Before changing a nozzle, check up closely on the ignition system, and examine all manifold and valve-head connections for air leaks, as it is absolutely impossible to make a carburetor operate properly if the ignition is not in good condition or if there are air leaks in the engine.

If, however, with the engine in normal condition, it is necessary to turn the needle valve (A) down more than two and a half turns, and still the engine will not idle, it indicates that the primary nozzle is too small and that a larger one should be used.

If it is impossible to get enough gas on high speed except when nut (B) is so high that there is no clearance at (X) on idle, a higher number needle valve should be used.

If there is too much gas on high speed when nut (B) is turned down as far as it will go, a lower number needle valve should be used.

To change the primary nozzle (C), take out the needle valve (A) and remove nozzle with a regular screw driver. To remove the taper valve on high speed, pull up the steering post control, unscrew nut (B) all the way, and lift valve out. This valve and nut (B) are assembled together and should be ordered in that way. Do not attempt to take these apart or to change the taper.

Never change the nozzle more than one size at a time. The nozzle opening gets smaller as the number gets larger; thus a No. 59 is smaller than a No. 58.

High-speed needle valves deliver more gas as the number gets larger; thus a No. 7 will give more gas than No. 6.

Always install the carburetor with the float chamber towards the radiator.

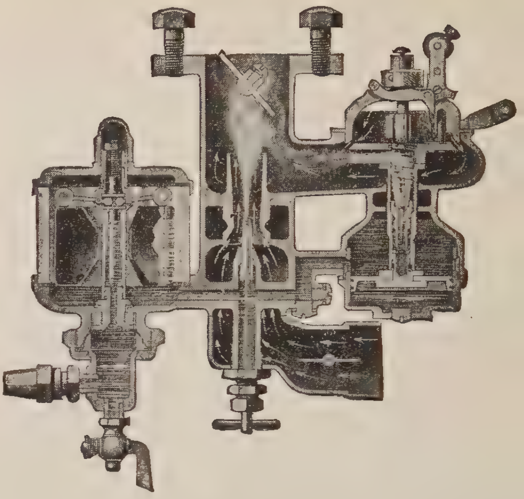

Fig. 5. Phantom sectional view of model "H" Stromberg carburetor, showing high-speed needle and primary nozzle in action. Note the path of the gas.

Marvel Model "E" Carburetor

The Marvel model "E" is a double jet, "compensating type" of carburetor, with the application of exhaust heat to a jacket surrounding the throttle chamber and venturi tube, the amount of heat being automatically controlled by the throttle opening. Outside the float mechanism this carburetor has but one moving part, the auxiliary air valve. (See Figs. 6 and 7.)

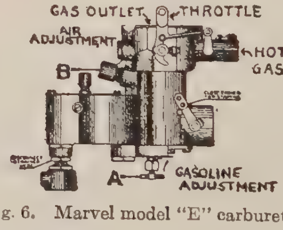

Fig. 6. Marvel model "E" carburetor.

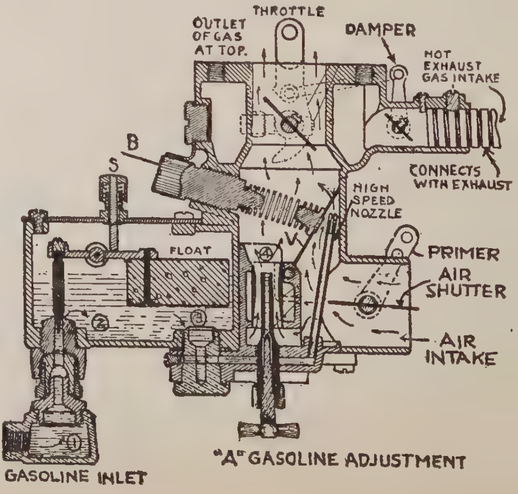

Fig. 7. Sectional view of Marvel model "E" carburetor.

Two jets are used, a primary low-speed jet and a secondary high-speed jet which is brought into action by the opening of the auxiliary air valve.

When the engine is idling, the hinged auxiliary air valve (V) (Fig. 7) rides on its seat against the bore of the mixing chamber, thus closing off the air passage past the tall high-speed nozzle jet, rendering it ineffective. At this time the air passes up through the small venturi surrounding the low-speed jet.

As the suction of the engine increases the auxiliary air valve is opened against the spring pressure, and the second jet (high speed), comes into action.

A choker valve (see air shutter) in the main air intake allows a rich mixture to be obtained for starting. This device may be controlled from the dash, so that when the engine is cold it may be closed to prevent back-fires, and may be gradually opened up as the engine warms up.

The feature of this carburetor, previously mentioned, is the **exhaust-heated jacket.** The heat is controlled by a damper connected to the throttle lever, which damper can be set to give any degree of heat desired. This is of particular importance, as the quality of gasoline is yearly becoming heavier and heavier. This heat damper, therefore, can be set to admit sufficient heat to secure good vaporization of heavy fuel on low throttle, and then, as the throttle is opened, the heat is automatically cut off, thus insuring maximum power at the higher speeds where heat is not necessary to good carburetion. By such an application of heat the entering air is not preheated, and this naturally results in greater thermal efficiency and power due to a maximum cylinder filling at each stroke of the pistons.

Adjustment: start by turning needle valve (A) to the right until it is completely closed. Then adjust the air adjustment (B) until the end of the screw is even with the end of the ratchet set spring above it.

Next, open (A) (gasoline needle) one turn, start the engine as usual, using the strangler button (S) to get a rich mixture at first. Allow the engine to settle and warm up; then gradually cut down on (A) until the engine runs smoothly.

Next, turn air screw (B) to the left, a little at a time, until the engine begins to slow down. This indicates that the air-valve spring is too loose. Turn it back to the right just enough to make the engine run well.

To test the adjustment, advance the spark and open the throttle quickly. The engine should "take hold" instantly and speed up at once. If it misses, or "pops back" in the carburetor, open needle valve (A) slightly, turning to the left. If this does not give results, the air screw (B) may be tightened a little by turning slightly to the right. It should be borne in mind that the air valve should be carried as loosely as possible, and that the adjustment for "pick-up" may be obtained by carrying more gas with needle valve (A), rather than to tighten up the air valve too much.

The best possible adjustment is secured when air adjustment (B) is turned as far as possible to the left and needle valve (A) to the right, providing the engine runs smoothly and picks up quickly when the throttle is open. The speed of the engine is governed by the small set screw in the throttle stop. If the engine runs too fast, turn the screw to the left; if too slow, turn the screw to the right.

Marvel Carburetor Connected to a Buick

The illustration (Fig. 8) is that of the gasoline system of the Buick six-cylinder, enclosed-model car. Note the vacuum gasoline feed system connected with the intake manifold and carburetor.

The Buick exhaust heating method of the mixture, by means of the exhaust manifold surrounding the intake manifold is shown.

A gasoline gauge is shown on the dash, the purpose and explanation of which is as follows:

A visual gasoline gauge is located on the dash of the closed models only and is a mechanically operating device which registers at all times the quantity of gasoline remaining in the main gasoline tank attached to the rear of the car.

It consists of a cork float, a piano wire, and a graduated registering dial. The cork float (F) is fastened to the tank base extension by means of an arm bent at the proper angle, which rises and lowers as the gasoline level changes.

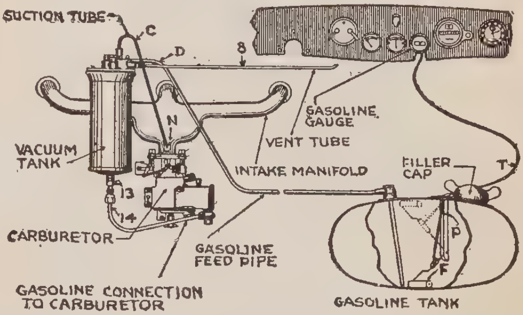

Fig. 8. Fuel system of the Buick in which the Marvel carburetor is used.

The piano wire (P) is attached to the float arm by means of a clip, and as the float rises and lowers it forces the wire to oscillate in and out of the tank through an aperture in the tank base which is fastened to the tank, from which a flexible tubing or casing (T) extends to the gauge on the dash inside of which the piano wire oscillates.

The graduated dial or drum is enclosed in a housing which fastens to the instrument plate, and the gasoline level is registered by the longitudinal motion of the wire. The drum is supported by pivot pins, and a constant tension is maintained with a hair-spring adjustment, set in such a manner as to permit the drum to rotate. The registering figures are placed on the outside of the drum and show through a small aperture in the face of the instrument conveniently located on the dash.

Rayfield Models "G" and "L" Carburetor

Rayfield carburetors are made in two types: model "G" and "L," the difference being that model "G" has a water-jacket.

In both models the **air-valve adjustment has been eliminated,** high and low-speed adjustments being made through the control of the fuel.

Both models are of the **two-jet type,** one jet feeding at low speed and both at high speed. The principle of this carburetor is explained in Fig. 24 and on page 102.

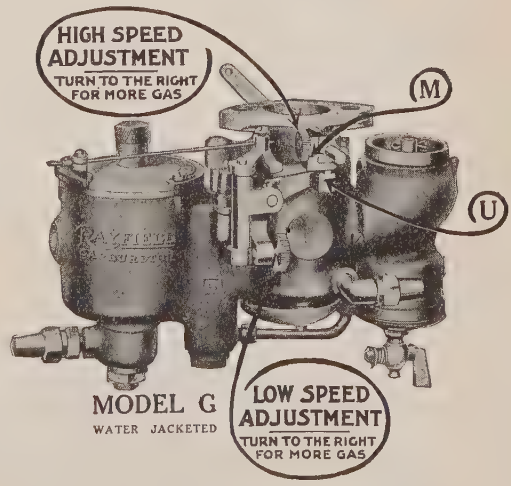

Fig. 9. Side view of Rayfield model "G" carburetor.

There are three air openings, one fixed and operating in conjunction with the low-speed nozzle and the other two having automatic valves linked together and operating simultaneously.

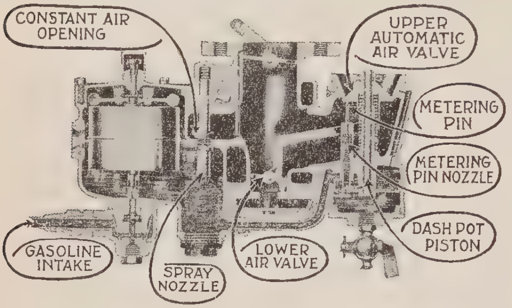

Fig. 10. Sectional side view of Rayfield model "G" carburetor.

The high-speed nozzle is controlled by a metering pin actuated by the upper automatic air valve. The stem of the valve is connected to a piston working in the dash pot, from which a passage communicates with the float chamber; the dash-pot chamber has direct connection with the high-speed nozzle.

When the throttle is opened, the tendency of the air valve to open suddenly and excessively, and to flutter, is checked by the dash-pot piston, which at the same time forces an extra supply of fuel into the nozzle and enriches the mixture for acceleration; the slow opening of the air valve increases acceleration by causing strong suction on the nozzles.

When adjusting a Rayfield, bear in mind that **both adjustments are turned to the right for a richer mixture,** as indicated on the adjustment screw heads.

The Rayfield dash control connects with the carburetor by a wire. When properly used, this will render starting easy, furnish a richer mixture when the engine is cold, and maintain a correct mixture under extreme atmospheric changes.

Raising the dash control lifts the spray needle and supplies a richer mixture. When it is raised full distance, a direct passage is opened, permitting raw gasoline to be drawn from the fuel chamber of the carburetor to the engine. The control button (or lever) should be down for running, except when a richer mixture is desired.

The automatic air valve should be closed when the engine is not running, or when throttled down.

The low-speed adjustment is to be used only when the engine is running idle and positively must not be used in adjusting high speed. Never adjust a carburetor unless the engine is hot and the water jacket of the carburetor warm.

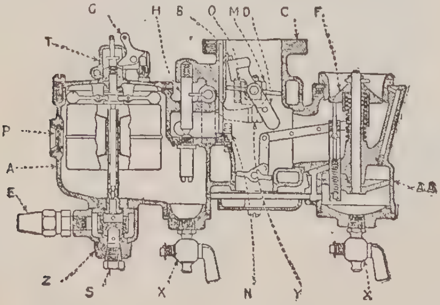

Fig. 11. Simplified illustration of the Rayfield. Note that two air valves, with a dash pot for acceleration, are used. (**A**), float chamber; (**AA**), dash pot; (**B**), stop screw; (**F**), automatic air valve; (**H**), nozzle needle; (**N**), low-speed adjustment; (**M**), cam; (**O**), high-speed adjustment; (**S**), drain cock; (**Y**), block.

Adjusting low speed: With the throttle closed and the dash control down, close the nozzle needle by turning low-speed adjustment to the left until block (**U**) (Fig. 9), slightly leaves contact with the cam (**M**). Then turn to the right about three complete turns. Start the engine and allow it to run until warmed up. Then with retarded spark, close the throttle until the engine runs slowly without stopping. Now, with engine thoroughly warm, make final low-speed adjustment by turning low-speed screw to the left until the engine slows down and then turn to the right a notch at a time until the engine idles smoothly. If the engine does not throttle low enough, turn stop arm screw (**A**) (Fig. 12) to the left until it runs at the lowest number of revolutions desired.

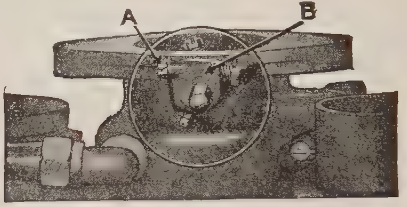

Fig. 12. (**A**) stop arm screw; (**B**) stop arm; turn screw (**A**) to left to throttle engine lower.

Adjusting high speed: Advance spark about one-quarter. Open the throttle rather quickly. Should the engine back-fire, it indicates a lean mixture. Correct this by turning the high-speed adjusting screw to the right about one notch at a time, until the throttle can be opened quickly without back-firing. If "loading" or choking is experienced when running under heavy load with throttle wide open, it indicates too rich a mixture. This can be overcome by turning the high-speed adjustment to the left.

To start the engine when cold: First close the throttle and pull the dash control all the way up. Second, when the engine starts, open the throttle slightly and push the dash control one-quarter of the way down. Third, as the engine warms up, push the control down gradually; when thoroughly warm, push the control all the way down. When the engine is warm it is necessary to pull the dash control only part way up for starting.

Hot-water connection is connected with the suction end of the pump (between radiator and pump). The connection on the other side connects with the water jacket of the engine or upper water pipe. A shut-off cock is provided for hot weather. See that these connections are made so that water will be drained out of the carburetor jacket when the system is drained.

Attach a hot-air stove to the exhaust pipe and connect to the constant air elbow of carburetor by a flexible tube. Connections are 5/16″ outside diameter tubing for gasoline and water connections.

Rayfield Model "M" Carburetor

The model "M" Rayfield (Fig. 13) is a smaller type, incorporating the features of the Rayfield model "G" without the dash pot. Fig. 14 shows the principle of the primer incorporated within the carburetor.

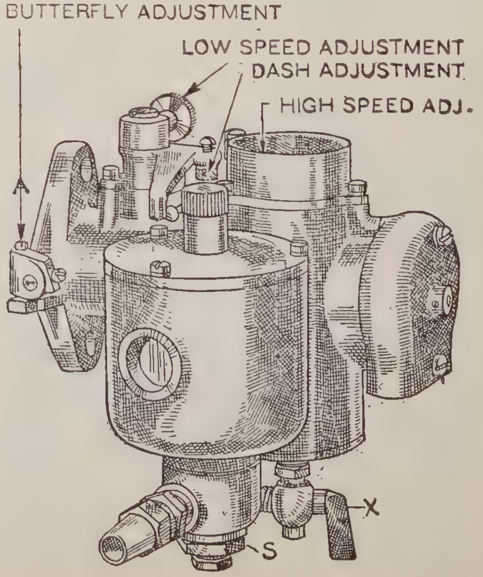

Fig. 13. Rayfield model "M" carburetor.

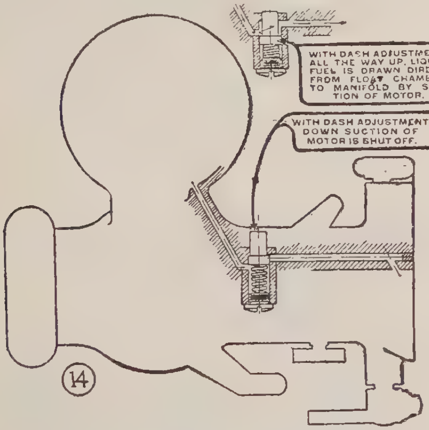
To adjust this carburetor, bearing in mind all the precautions cited previously, proceed as follows: The **low-speed adjustment** is turned to the right for a rich mixture, to the left for a lean.

With the engine running idle and the dash control down, turn the low-speed screw to the left one notch at a time. Between each movement of the thumb screw, the engine should be accelerated and allowed to come back to its idling speed. In this way a very exact adjustment can be obtained. If the slow-speed adjustment is obtained by turning the screw down all at once, a very accurate setting will not be obtained. When this screw has been turned down until the engine manifests a marked falling off in speed, it is a sign that the correct position has just been passed a notch or two. During the accelerating periods, the engine will commence to miss and spit back when the lean mixture is reached.

The intermediate and high speed is made accessible by removing the hot-air elbow from over the main air valve. It is well to observe a little precaution at this point. The high-speed screw should not be moved more than one-eighth turn at a time. This screw produces very effective results in the action of the carburetor, and its movement should therefore be correspondingly regulated. The economy of the engine is affected in a very pronounced manner by turning this screw.



WITH DASH ADJUSTMENT ALL THE WAY UP, LIQUID FUEL IS DRAWN DIRECT FROM FLOAT CHAMBER TO MANIFOLD BY SUCTION OF MOTOR.
WITH DASH ADJUSTMENT DOWN SUCTION OF MOTOR IS SHUT OFF.
⑭

Fig. 14. Internal primer on the Rayfield model "M."

Johnson Carburetor

The Johnson is a "gravity air-valve type," with a single concentric jet, in which an air valve is made up of a sleeve rising and falling by suction and gravity in a cylindrical passage above the jet.

There are **three stages of vacuum:** one is the space between the throttle and strangle tube; the second, in the strangle tube itself; the third, in the space below the plate on the bottom of the air-valve sleeve. By removing the location of the idling adjustment (in Fig. 15) the gasoline flow (for idling) is brought in a zone of greater vacuum and hence better idling.

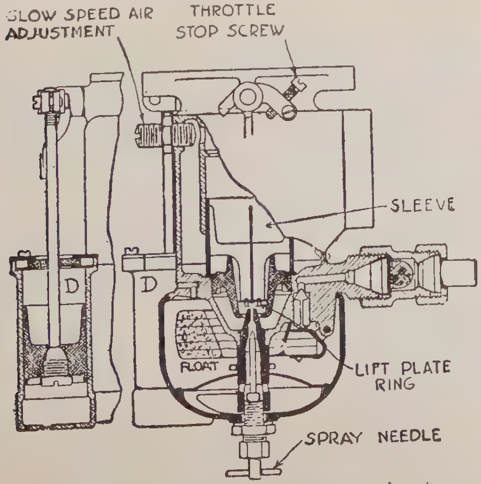


Fig. 15. Adjusting, old style Johnson carburetor.

Indications of incorrect adjustment: (A), lean mixture; (B), engine difficult to start; (C), "popping back" on quickly opening throttle; (D), engine knocks when throttle is opened quickly; (E), engine will not idle.

Many mechanics can adjust this carburetor for high speeds, but sometimes find difficulty in adjusting for low speeds or idling. The correct procedure of **adjustment is as follows:** (1) retard spark; (2) close the slow-speed air-adjustment screw (Fig. 15); (3) warm engine; (4) see that the intake pipe manifold, where it connects to the carburetor flange, does not leak air; (sometimes a water-jacketed intake manifold will become "air-locked" and water will not circulate, depriving it of heat; open "plug"); (5) accelerate the engine by opening and closing the throttle rapidly; if the mixture is too rich, acceleration will be sluggish; if too lean, it will "pop back" considerably; the spray needle adjustment should be set between these two points; (6) retard the spark and close the hand throttle; adjust the throttle stop screw until the engine runs very slowly, regardless of whether it operates evenly or not; (7) open the slow-speed air adjustment until the engine idles evenly, if possible; if it runs too fast, close down the throttle stop-screw; the adjustments on the stop-screw and the low-speed screw should be made simultaneously; (8) it may be found that the low-speed air adjustment cannot be opened at all; in this case the low-speed mixture is too lean; possibly the low-speed air adjustment can be opened more than 3½ turns, when the mixture is too rich; do not touch the spray-needle setting, but **proceed as follows:**

Disassemble the carburetor: A small ring, shown in Fig. 15, is attached by two lugs to what is known as the lift plate. This ring is somewhat curved, and if the slow-speed air adjustment can be opened more than 3½ turns without obtaining good idling, the curve is excessive and the ring should be slightly flattened. If on the other hand the air adjustment cannot be opened, the ring is too flat and should be slightly curved. The standard setting is 3/32″ from the edge of the ring to the lift plate to which it is attached.

Adjusting (Model "A"): (1) Turn both idle screw and high-speed needle (Fig. 16) to their seats, and set the throttle stop in approximately the correct position for closed throttle; (2) open the high-speed needle 1½ turns. This permits the engine to be started. Warm the engine up by running a few minutes; (3) place the spark lever in full retard position, and open the throttle until the engine turns at a speed equivalent to about 20 to 25 miles per hour; (4) turn high-speed spray needle to the right until the engine speed decreases; (5) then turn the spray needle to the left until the engine speed increases and then decreases from a rich mixture; (6) turn again to the right to a point midway between the extremes; this is the correct mixture and will give the best results for all throttle positions; (7) adjust the throttle stop screw to the desired idling position; (8) if uneven firing occurs, correct either by unscrewing the idling jet to enrich the mixture or by screwing up the idling jet to give a leaner mixture. The average setting is one-half turn from the seat. This adjustment must be made with the spark and throttle levers fully retarded.

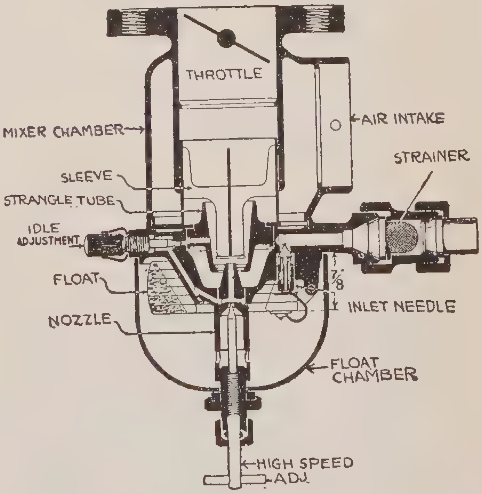

Fig. 16. Johnson model "A" carburetor.

The float should set evenly all around, the bottom being ⅞″ from the float-chamber seat, as shown in Fig. 16.

Principle of the Zenith Carburetor

We shall first consider a simple type of carburetor or mixing valve as an example, to lead up to the principle of the Zenith. This consists of a single jet (G), placed in the path of the incoming air, and fed from the usual float chamber (F) (see Fig. 17).

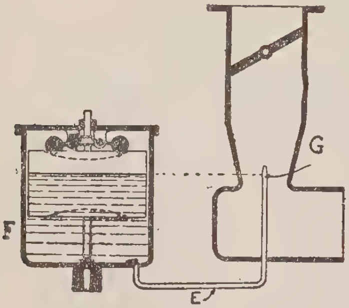

Fig. 17. A simple type of carburetor; jet (G), fed from float chamber.

As the speed of the engine increases, the flow of the air increases, but the flow of gasoline from the jet increases faster, causing the mixture to become richer and richer. The mixture is practically constant only between narrow limits and at very high speed.

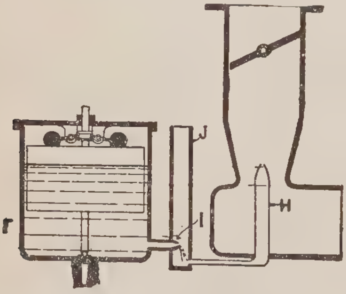

Fig. 18. Spray nozzle (H), receives gasoline from well (J), instead of from float chamber.

A second type of carburetor (Fig. 18) is shown in which the spray nozzle receives its gasoline from the well (J).

The gasoline in the well is fed by gravity only through compensating jet (I), and is not affected by the suction, as the well is open to atmospheric pressure. The flow of gasoline is therefore constant at all engine speeds. While the flow of air increases with the engine speeds, the mixture also becomes poorer and poorer as the speed increases.

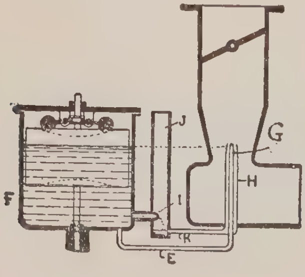

Fig. 19. A combination of Figs. 1 and 2.

It will readily be seen that the second type produces the opposite effect from the first, while a combination of the two, as shown in Fig. 19, will result in a constant mixture, when jets are properly chosen.

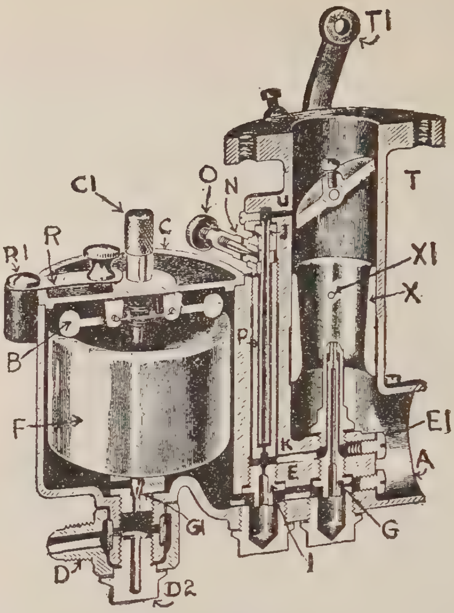

Fig. 20. The standard Zenith carburetor model "L" for 4 or 6-cylinder engines, made in five sizes ranging from 1″ to 2″ size of opening to the intake manifold. This type is used extensively abroad.

This construction, further illustrated in Fig. 20, admits of the addition of the priming tube (J) (Fig. 20) extending into the secondary well (P) and opening at the point (U) (Fig. 20) of the closing butterfly (T). With the butterfly partially open, the suction at this point (U) is powerful and draws the well full of gasoline into the cylinders, effectively priming the engine. Also, by the introduction of this secondary well, which measures the gasoline used in running idle, a perfect mixture is obtained at very low engine speeds.

The level of the gasoline in the float chamber is set at the factory and need not be changed. In case this becomes necessary, the gasoline level is as shown in Fig. 19.

The setting or adjusting of the Zenith carburetor is the choosing of the proper size of choke tube or venturi, and gasoline jets and secondary well.

The choke tube or "air nozzle" (X) is held in place by a screw and can be easily changed when the butterfly throttle has been removed. Its object is to obtain a correct gas velocity around the jets. A choke too small will restrict the flow of air and prevents the motor from receiving enough mixture for high speed. A choke too large will cause irregularities when running fully open, and when slowing down.

The main jet (G) is easily removed after unscrewing the lower plug. This jet is of the ordinary type and has a predominating influence at high speeds.

The compensating jet (I), corrects the action of the main jet, and has a predominating influence at low speeds, as when climbing a hill.

The throttle adjusting screw will regulate the opening of the throttle for slow speed and the position of the screw (O) will regulate the quality of the mixture at that speed; in screwing in this piece the mixture will get richer, and in unscrewing it, the mixture will get leaner.

Adjustments: If the engine does not slow down or idle, or if it "lopes," that is, speeding up and slowing down as if fitted with a governor, it is evidently getting too much gasoline. (1) adjust air screw (O); (2) look for air leaks at manifold and other joints; see that jets are tight on seat; (3) look for water accumulation in the passages; remove plugs under the carburetor and clean (I) and (G).

If engine does not pull properly going up hill: (1) the engine may be cold or insufficiently heated; (2) the mixture may be too lean or too rich (irregular running results in the latter case); try a larger or a smaller compensating jet (I), using the one which gives best results; try this also with jet (G) and adjust the choke tube to a corresponding size.

If the car does not attain its proper speed: (1) mixture may be too lean; try adjusting slow speed (O); if the trouble is chronic, try larger main jet (G); (2) if the mixture is too rich, try regulating air intake at (Z) (Fig. 24); if the trouble is still chronic, try a smaller-size main jet (G).

When trying a new jet, the choke tube (X) must also be changed. The choke can be removed from the upper part of the barrel by removing screw (X1) and the throttle valve. If it is stuck, remove the cap and jet at the lower part of the carburetor and use a brass rod to drive it out.

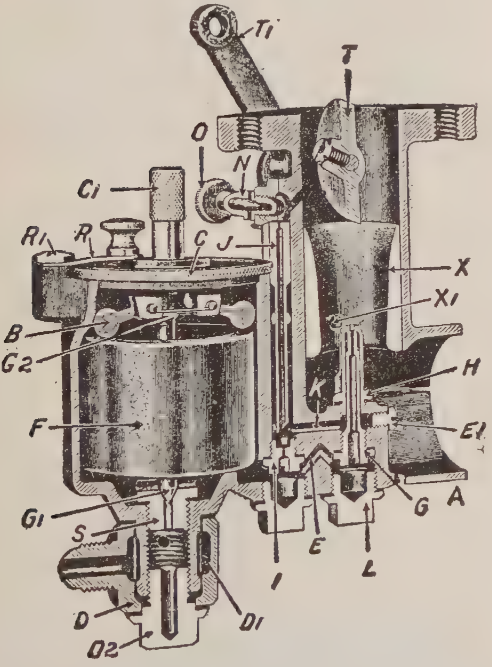

Fig. 21. Zenith model "O," a modified "L" type designed with shorter jets and simpler idling well. It is an Americanized Zenith, not intended for export, and sells for a less price than model "L". Not designed for high-pressure feeds.

A—Main air intake, connected by flexible tubing to take air from around the hot exhaust pipe.
C—Float cover.
C1—Needle-valve cap; by unscrewing this the float can be operated for priming if necessary.
D—Connects to gasoline supply.
D1—Filter screen.
D2—To drain.
E —High-speed gas opening.
E1 —Main jet set screw.
F —Float (metal).
G —Main jet.
G2—Needle-valve collar.
H —Cap jet.
I —Compensator.
J —Priming plug in idling well.
K —Low-speed gas opening.
L —Lower plug.
N —Seat of slow-speed adjustment screws.
O —Slow-speed adjustment screws.
R —Spring to hold float cover.
S —Needle-valve seat.
T —Butterfly throttle valve which is operated by T1, which is connected by throttle rod to accelerator or hand throttle lever on steering wheel; the opening of T, when closed for idling, is regulated by the stop and two set screws shown to the side of T1.
T1 —Lever operating throttle butterfly valve.
X —Choke tube.
X1 —Screw holding choke tube in place.

Zenith Model "HN" Carburetor

Another type of Zenith carburetor is the model "HN." It is similar to the models "O" and "L," except that it is designed for block-cast cylinder engines where the carburetor is fastened directly to the cylinder block without the use of a manifold.

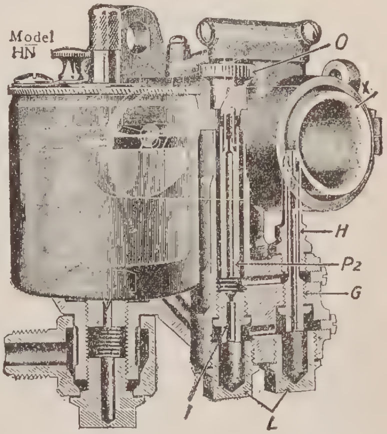

Fig. 22. Zenith model "HN" carburetor.

Zenith Duplex Carburetor

The Zenith duplex carburetor is so named, because there are two carburetors combined into one unit, both using the same float. This type of carburetor is used extensively on "V"-type engines and is a true **"compensating type,"** as is also the models shown in Figs. 20, 21 and 22.

The float is of metal and is a side-float type. The carburetor connection is vertical.

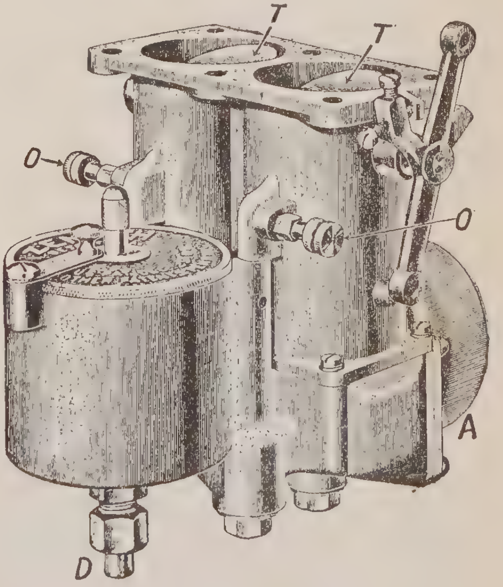

Fig. 23. Zenith Vertical "Duplex" model "OD" carburetor for eight and twelve-cylinder "V"-type engines.

Adjustments: There are but two adjustments on the Zenith and they apply to practically all models. These adjustments are provided to "idle" the engine properly. With the average carburetor, if maximum speed is desired, proper idling at slow speed is sacrificed, or vice versa. By means of admitting more or less air, however, through the small slow-speed adjusting screws (O), the Zenith carburetor will idle without "choking" and "loping," and yet the maximum speed can be obtained—providing, of course, the main jet, compensator, and choke tube are of the proper size.

By referring to the illustration (Fig. 21) it will be observed that a small amount of air is admitted over and above the mixture through the plug (J) that is fed from the idling well. After the engine is speeded up the mixture is drawn through the main jet.

There are three parts which must be of the correct size: the choke tube (X), main jet (G), compensator (I). The size is determined by the manufacturer, according to the type of engine: four, six, or eight-cylinder, bore and stroke. After once being fitted to the carburetor, there are no other adjustments except the slow-speed valve (O), as mentioned above.

If the choke tube is too large the pick-up will be defective and cannot be improved by the use of a larger compensator. Slow-speed running will not be very smooth.

If the choke tube is too small, the effect is to prevent the engine from taking a full charge with the throttle opened fully. The pick-up will be very good, but it will not be possible to get all the speed of which the car is capable.

If the main jet is too large, at high speed on a level road it will give the usual indications of a rich mixture: irregular running, characteristic smell from the exhaust, firing in the muffler, sooting up at the spark plugs, low mileage. The influence of the main jet is mostly felt at high speeds.

If the main jet is too small, the mixture will be too lean at high speed and the car will not attain its maximum. There may be back-firing at high speed, but this is not probable, especially if the choke and main jet are according to the factory setting. This back-firing is more often due to large air leaks in the intake or valves, or to defect in the gasoline line.

The compensator (I): From the explanation of the Zenith principle given on page 130, it will be readily noted that the influence of the compensator is most marked at low speeds. The compensator size is best tried out on a hill, as regular and as long as possible, and of such a slope that the engine will labor rather hard to make it on high gear. A long, even, hard pull of this sort taxes the efficiency of the compensator to the utmost, and will indicate readily the correctness of its adjustment.

If the compensator is too large, too rich a mixture will result on a hard pull. It will give the same indication as for rich mixture at high speed on the level.

If the compensator is too small, too lean a mixture will result. The engine is liable to miss and give a jerky action in the car, on a hard pull.

Note. When trying out or fitting new jets, etc., tests should be made systematically, first starting the main jet, then the compensator, then the choke. Bear in mind that when the choke is increased the main jet should be increased. Water in the gasoline will sometimes lodge in tube (J) and prevent proper idling. Remove and clean. This is a common trouble unless a strainer is used.

A temperature regulator as used on the Zenith carburetor is shown in Fig. 24. It is placed on the air opening of the carburetor. The air-control lever or air regulator operates the "air lever" or "choke" valve (Y), admitting more or less warm air.

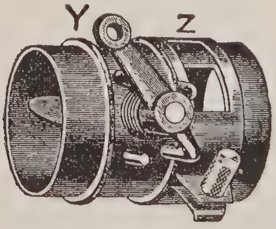

Fig. 24. Zenith temperature regulator.

The temperature of this warm air entering the carburetor can be regulated by a band (Z) placed around the opening. The opening permits cool air to be drawn in, and the use of this opening is governed more or less by the temperature. In summer, the opening (Z) is usually wide open, but closed more or less during cold weather.

Stromberg Carburetor Models "L" and "M"

The Stromberg models "L," "LB," "M," and "MB" are all called the **"plain-tube carburetor,"** the principle of which is explained on page 134.

The "L" and "M" models are the same carburetor, except that model "L" has an "economizer" action. The "L" and "M" are made for vertical connections to the intake manifold.

The "LB" and "MB" models are of the same principle as "L" and "M," except that they are made for horizontal connections to the intake manifold. The "LB" has the economizer action, the same as "L."

Instructions for Stromberg "L" and "LB" Carburetor

This carburetor differs from older styles in that it is a plain-tube type, having the air passages fixed in size, while the gasoline is automatically and accurately measured by the air flow itself, at all speeds and loads. The mixture proportion is maintained constant by the "air-bled nozzle" construction, in which a small amount of air is mixed with the gasoline before it reaches the jets.

There are three adjustments, the high speed, the extremely low speed or idle, and the "economizer."

The high speed is controlled by the knurled nut (A) (Fig. 25) which locates the position of the needle past whose point is taken all the gasoline at all speeds. Turning nut (A) to the right (clockwise) raises the needle and gives more gasoline; to the left, or counter-clockwise, less.

If an entirely new adjustment is necessary, put economizer pointer (L) in 5th notch (or nearest to float chamber) as an indicator; turn nut (A) to the left, counter-clockwise, till the needle reaches its seat, as shown by nut (A) not moving when the throttle is opened and closed. When the needle is in its seat it can be felt to stick slightly when nut (A) is lifted with the fingers. Find adjustment of (A) where it just begins to move with the throttle opening, then give 24 notches to the right or clockwise (the notches can be felt). Then move the economizer pointer (L) back to (O) notch (away from float chamber). This will give a rich adjustment. After starting and warming up the engine, thin out the mixture by turning (A) counter-clockwise, and find the point where the engine responds best to quick opening of the throttle, and shows the best power.

Low speed or idle adjustment: The gasoline for low speed is taken in above the throttle through a jet at (K), and is regulated by dilution with air as controlled by the low-speed adjusting screw (B). Screwing (B) in clockwise gives more gasoline; outward, less. The best adjustment is usually ½ to 3 turns outward from a seating position. Note that this is only an idling adjustment and does not affect the mixture above 8 miles per hour. When the engine is idling properly there should be a steady hiss in the carburetor; if there is a weak cylinder or a manifold leak, or if the idle adjustment is very much too rich, the hiss will be unsteady.

Economizer action and adjustment: The economizer device operates to lean out the mixture, by lowering the high-speed needle and nut (A) a slight but definitely regulated amount, at throttle positions corresponding to speeds from 5 to 40 miles per hour. The amount of drop and consequent leaning is regulated by the pointer (L).

After making the high-speed adjustment for best power, with pointer (L) in (O) notch, as above described, place the throttle lever on the steering wheel in a position giving about 20 miles per hour road speed. Then move pointer (L) clockwise (toward the float chamber), one notch at a time, till the motor begins to slow down; then come back one notch.

The amount of economizer action needed depends upon the grade of gasoline and upon the temperature. In the Mid-West, the best economizer adjustment will usually be the third or fourth notch. With Pennsylvania gasolines and in the South, the second notch; while on the Pacific Coast no economizer action is necessary unless Distillate (which should not be below 50° Baume) is used. Also fewer notches of economizer action will be necessary in summer than in winter.

Note. All Stromberg carburetors are supplied with hot-air attachments and a temperature regulator. When adjusting type "L," the dash control lever should be all the way down and the air-horn cam plunger (H) (Fig. 25), should clear the economizer lever so that this works freely as the throttle is opened and closed.

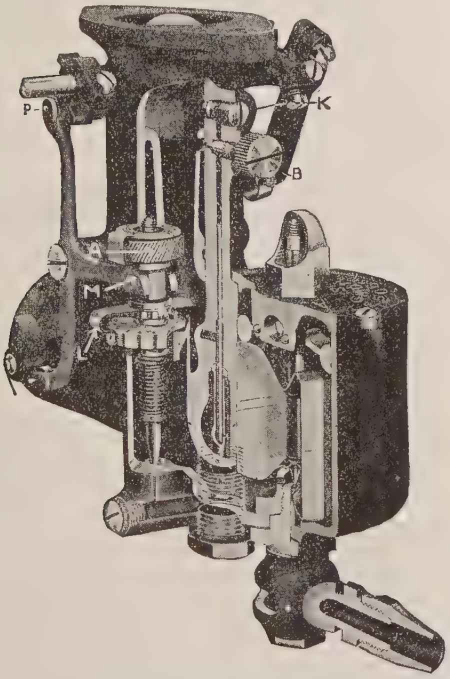

Fig. 25. Stromberg type "L." Note the vertical connection and economizer (the lever with roller P on it). This carburetor is adapted for high-speed multi-cylinder engines.

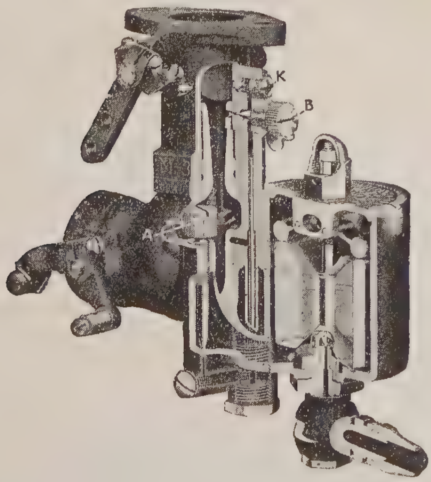

Fig. 26. Stromberg type "M," without economizer. Used on small 4-cylinder engines, trucks, tractors, etc.

Adjustment of "M" and "MB"

The only difference between the types "L" and "M," is in the "economizer" action, or the lifting of the high-speed needle valve (A) automatically. This needle valve (A) on type "M" is hand regulated.

(1) Open throttle about one-quarter of the way, which will give about 20 miles per hour on a pleasure car (or one-third governor speed on a motor truck).

(2) Open idling screw (B) from its seat two turns, so that this cannot affect the high-speed adjustment.

(3) Adjust high-speed needle (A) to the leanest adjustment which will give the best engine speed for this throttle position. Inward for less and out for more gasoline.

(4) Close the throttle gradually and screw the idling screw (B) in as far as necessary to give adjustment for low speed and idle. Screwing inward, right hand, gives more gasoline; outward gives less.

This "plain tube" and "Pitot" principle is further explained on page 102.

Note. Never adjust the carburetor to a cold engine. Start the engine and allow it to run a short time until it is warm. Not until then should the adjustment of the carburetor be attempted.

In starting the engine on a cold day it may begin "popping." Do not blame this on the carburetor and begin to adjust it. Wait until the engine has warmed up thoroughly, and then if the popping continues it is time to consider an adjustment.

Principle of Stromberg "Plain Tube" or "Pitot" Principle of Carburetor

This explanation also covers models "L," "LB," "M," and "MB," except that the economizer action, which is explained on page 132, is not used on the models "M" and "MB." The air passage and gasoline jet are of fixed sizes for all engine speeds.

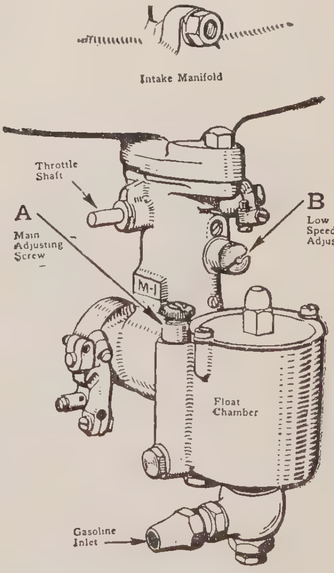

Fig. 27. Stromberg model "M," Vertical type, shown connected with the intake manifold.

This carburetor is termed a "plain tube" type, because the whole air supply is taken through a single unobstructed channel of fixed size through the jet. Air valves, metering pins, and dash pots have been dispensed with. The Pitot principle, explained on page 102, is used to provide air at sufficient pressure to force fuel from the well in the carburetor.

How the desired mixture can be maintained is answered in the principle of introducing a small amount of air into the gasoline jet at (G) before it sprays out into the main air passage, forming what is known as an "air-bled" jet or "Pitot" principle.

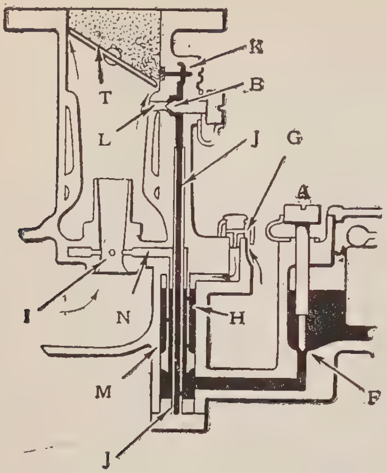

Fig. 28. Idling position. When idling, all the gasoline is drawn up the tube (J), through the idling jet (K) and sprayed above the throttle valve (T).

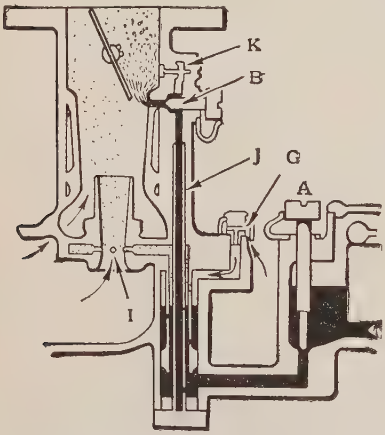

Fig. 29. Low and medium speed: At intermediate speeds the gasoline is drawn past the low-speed adjusting screw (B) from the tube (J). As the throttle is opened, more mixture is drawn through the small venturi tube (I) and augments that drawn from the opening (L) (Fig. 28).

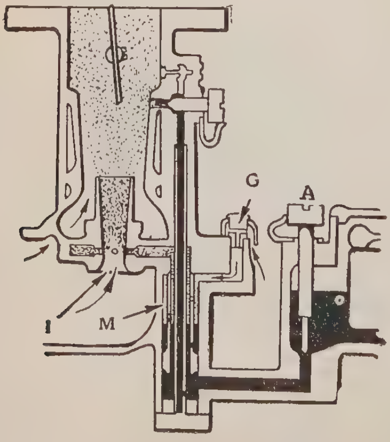

Fig. 30. High speed: At high speed practically all the gasoline is drawn through the small venturi tube (I) mixed with air, drawn through the opening (G) above the well (M).

Principle of operation: The level of the gasoline in the float chamber of the carburetor is maintained constant by the float and the valve which is operated by it. From the float chamber the gasoline flows to the accelerating well (M) through the needle valve (F) (Fig. 28) which is adjustable.

There are two tubes in the accelerating well, one a sort of standpipe (H), and the other a smaller one that is inside of the standpipe and which connects with the idling jet (K). The latter tube has a small opening in the bottom that connects with the bottom of the well (M), but otherwise has no connection with the well.

The top end of the standpipe (H) connects with a cross-passage (N) that feeds the gasoline to the eight discharge holes in the small venturi tube (I), which is located just below the main venturi tube (note that there are two venturi tubes). A rich mixture and not raw gasoline is fed through passage (N), because of the small air intake opening (G), which enters the top of the well (M), and supplies a certain amount of air with the gasoline that is drawn up the standpipe to the passage (N).

Holes in the side of the standpipe below the level of the fuel feed gasoline into the standpipe, while holes above the fuel level add air from the top of well (M), thus making a rich mixture to discharge into the small venturi passage.

At low and idling speeds, practically no fuel is drawn through the small venturi, because of the closed throttle. At this time the gasoline is through the hole in the bottom of the small tube (J), up to the idling needle valve (B), and through the passage (K), into the intake manifold above the throttle valve. This gives a rich mixture for idling and slow-speed running, but is cut out at about eight miles per hour when the throttle is opened more, and thus does not affect the running mixture at all.

Stromberg Model "OS" Carburetor

This carburetor used on the Marmon, Lincoln, Auburn, Jordan, Scripps Booth, Studebaker, and other cars, is of the **"plain tube"** type with a number of refinements which have been incorporated as follows: an improved form of accelerating well of greater capacity and of better adaptation to the great variety of fuels which must be handled today; a modified form of economizer device; a new mixture control, operating an auxiliary fuel needle. This control assists the choke valve control in starting, and gives a better control of the mixture after starting, before the engine reaches an efficient temperature.

The model "O" is suspended vertically and the "OC" and "OS," horizontally. Illustrations of the model "OS-1," are shown in Figs. 31 to 34.

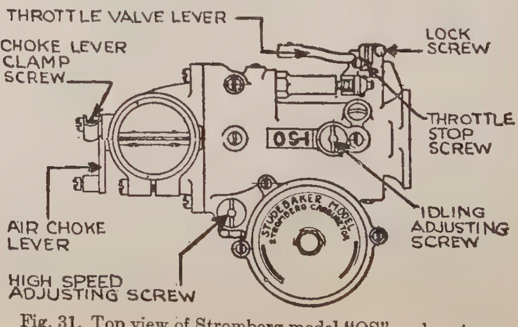

Fig. 31. Top view of Stromberg model "OS" carburetor.

Adjustment for idling mixture and closed throttle running up to about eight miles per hour is controlled by the idling adjusting screw (Fig. 31). This operates on the air, so that screwing it in gives a richer mixture and out a leaner one.

Turn the screw outward until the engine slows down, then turn in notch by notch until the proper idling mixture is reached. When the motor is idling properly there should be a steady hiss in the carburetor. If there is a weak cylinder or a manifold leak, the hiss may be unsteady. For a motor to idle steadily on present-day heavy fuel, the spark gaps must be set correctly.

If, after adjusting the low-speed needle as described above, the engine idles too fast, turn the small throttle stop screw (Fig. 31) to the left, or counter-clockwise, until the proper idling speed is reached. If the motor idles too slow and stops, turn the screw to right, or clockwise, until the proper speed is reached. Before adjusting with throttle stop screw, it will be necessary to loosen the lock screw.

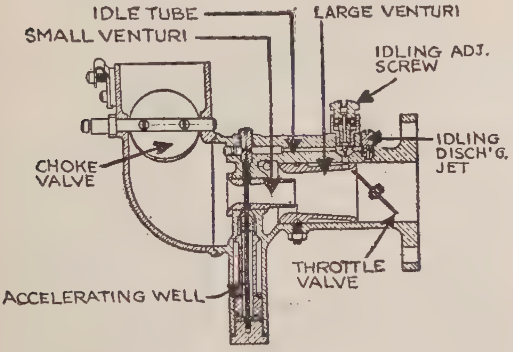

Fig. 32

Adjustment for high speed and main driving adjustment is regulated by high-speed needle (Figs. 31 and 33), which regulates the opening through which fuel flows to the jet. Turning to the left, counter-clockwise, gives more gasoline; to the right, or clockwise, less gasoline.

To make proper high-speed adjustments, advance the spark lever to normal driving position, set the throttle lever on the steering wheel at a position which will give a speed of engine corresponding to a car speed of about 15 miles an hour. Then adjust the high-speed needle to minimum opening that will give greatest engine speed for that throttle opening. This should give a good average adjustment. Two or three notches less may give best economy for continuous driving or touring, and two or three to the left may be best for short runs in cold weather when the motor does not reach normal heat.

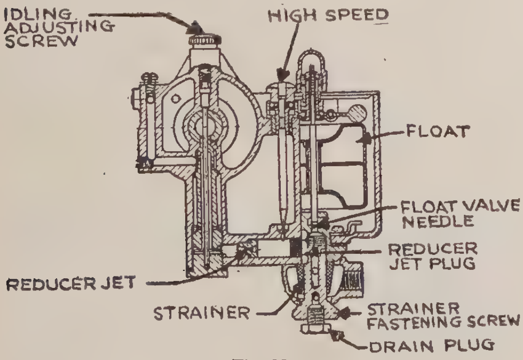

Fig. 33

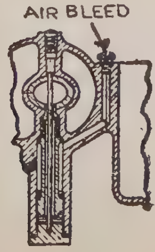

Fig 34

To prevent a wrong high-speed adjustment from giving a harmful rich mixture, a gasoline nozzle reducer is inserted beyond the high-speed needle opening, in a passage-way closed by a reducer jet plug (Fig. 33). The reducer placed in the carburetor at the factory will permit about 20 per cent more gas to pass through than is generally needed.

The economizer device operates to lean out the mixture automatically at speeds of from 10 to 45 miles per hour. The economizer needle is properly set at the time the carburetor is installed on the engine and no adjustment is needed.

When starting the engine, first open the carburetor butterfly valve slightly by means of the hand throttle lever on the steering-gear sector, then pull the choke button out all the way, turn the ignition switch to "on" position and depress the starter switch. As soon as the engine starts, push the choke button in about one-third of the way or to the point where the engine runs smoothly. Do not leave the choke button pulled out fully after the engine starts as this will flood the engine with gasoline and cause it to stop. As the engine warms up, the choke button should be pushed in gradually, the normal position for running being all the way in. It must always be remembered that the choke button should be out the shortest period of time possible, as running with an over-rich mixture tends to foul the engine, dilute lubricating oil, and use an excessive amount of fuel.

The engine should start after five or ten seconds of cranking. It it does not do so, it may be that the choke valve does not entirely close, in which case loosen the choke lever clamping screw (Fig. 31), and reset the lever on the shaft so that there is a clearance of 1/32″ between choke lever and stop on the choke-tube holder.

The normal position of the air temperature regulating sleeve is closed. Only in extremely hot weather is it desirable to have it open.

Schebler Plain Tube Carburetor

Adjustments: There are two gasoline adjustments, one for low speed, 4 to 5 m. p. h. up to the maximum without "loading" up or missing.

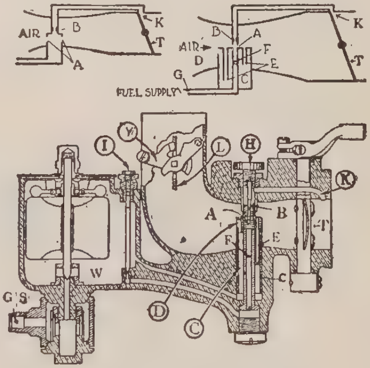

Fig. 35 (upper).
Fig. 36 (lower).

Figs. 35 and 36. (I), high-speed gasoline adjusting needle; (H), low-speed gasoline adjusting needle; (L), choker valve; (T), throttle valve; (K), idle and low-speed by-pass; (D), Pitot opening.

Operation or action: Air flows into and through the choke or venturi tube in the direction of the arrow (Fig. 35), but for idle speeds of the engine the velocity is too low to cause suction to draw gasoline through the main nozzle (A). An extension (K) is provided from the main nozzle to the space above or engine side of the throttle (T). The size of this extension or passage is controlled at (B) by screw (H).

In operation the high suction above the throttle (T) draws gasoline through the main nozzle and causes fuel to flow through the extension (K) with some air which is drawn in through the main nozzle holes (A) at (B) by (H). As the throttle is opened, the increasing suction at the main nozzle cuts down the air bleed through the holes (A) and causes more fuel to pass through the extension (K) until that suction caused by the flow of air at main nozzle (A) equals the decreasing suction above the throttle (T). Then fuel comes out of the main nozzle holes (A) into the main air stream. This also probably causes a slight reverse flow in the extension passage.

This combination produces a correct proportion of air and fuel through a very large range, if the throttle is not thrown wide open from its closed position suddenly. When this happens the engine would "lay down," or miss six or seven shots and sometimes die completely.

To overcome this trouble, an overflow well, or reserve chamber (C), is formed around the main fuel passage, whose top is integral with the main nozzle head and provided with a down-stream Pitot (D). From this head two acceleration tubes (E) extend to different depths into the overflow well (C) and discharge into the main air stream.

Pitot supplies air: With the engine idling or running slowly the well (C) will fill up by means of the hole (F) in the main nozzle passage.

On suddenly throwing the throttle wide open, the reserve supply of fuel is taken out from the acceleration tubes (E) as well as from the main jet (A). This practically makes a temporarily large jet or nozzle until one of the tubes (E) is uncovered by the lowering of the fuel level in the well. Air is then drawn out through this tube and acts in opposition to the supply of air from the Pitot (D). This opposition causes a gradually increasing suction in the well (C) and uniformly decreases the discharge of fuel from the longer tube (E). This operation fills in the time-element necessary for the main jet to resume its normal functions of delivering a thin mixture.

Tubes (E) are made of varying lengths to hold a reserve supply of fuel from some intermediate speed of, say, 15 m.p.h.

The Pitot function is simply to provide air at sufficient pressure to force fuel from well and to be inclosed in carburetor.

All the fuel passes through the main adjustment (G), which is located at the float bowl and is governed by screw (I), and therefore controls the whole range of the carburetor while still allowing the idle or low-speed adjustment to be changed with the condition of engine or variations in engines of same design.

The gasoline float level is 1" below the top of the bowl with the needle seated.

Tillotson Carburetor

This carburetor is illustrated as used on the Overland engine. It may be termed a "double-jet, compensating, variable venturi carburetor."

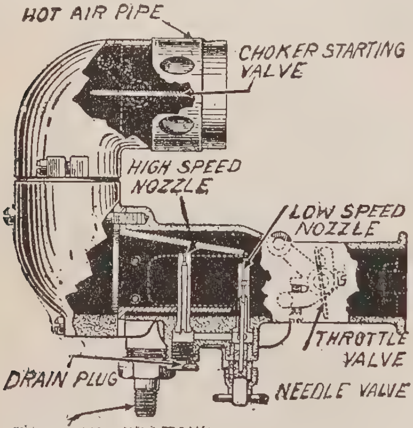

Fig. 37. The Tillotson carburetor.

A uniform partial vacuum is maintained at the fuel nozzle by two flexible reeds, which are mounted in a cage and so designed that maximum opening gives required volume for maximum speed.

When the reeds (Fig. 39) are closed, they cause the highest possible vacuum at slower engine speeds.

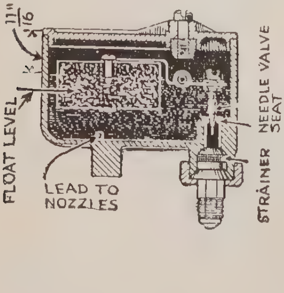

Fig. 38

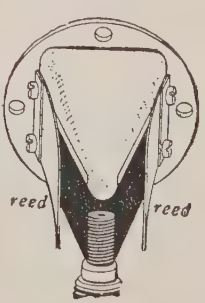

Fig. 39

Fig. 38. Float mechanism of the Tillotson carburetor, used on the Overland. Note the level of gasoline.

Fig. 39. The reeds. In Fig. 37 the reeds are placed above and on the sides of the nozzles.

The reeds open and close according to the speed of the engine. These reeds are so placed that as they move they form a virtual variable venturi. A secondary nozzle comes into operation at higher speeds and is not in use at the lower speeds.

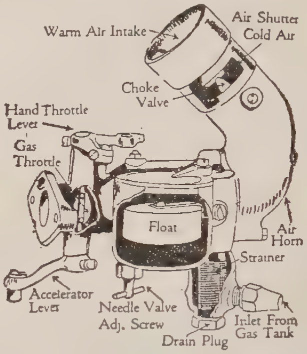

Fig. 40. Tillotson carburetor as used on Overland 4.

To adjust the carburetor, set the choke valve in full open position, after running the engine until it is warm. Push in the throttle-control button to its lowest operating point and pull out the spark lever about three notches. Slowly close the needle valve, by turning to the right, cutting down the amount of gasoline, until the engine starts to miss because of too lean a mixture. Then open the needle valve slightly, so that the engine begins to fire regularly. Push in the spark-control button and accelerate the engine either by hand or foot controls. If the engine backfires, or pops in the carburetor, increase the amount of gasoline by opening the valve slightly. Continue this until the engine fires regularly when suddenly accelerated. The engine should always be allowed to run for half a minute after it is slowed down before another attempt is made to accelerate it.

Another adjustment that is occasionally required is that of the sliding air shutter mounted on the air horn of the carburetor. In cold weather it will be found advisable to close this shutter, insuring warm air for the gas mixture. In the warm seasons this shutter should be opened.

The Hudson Carburetor

The Hudson carburetor operates upon the pneumatic principle and may also be termed the "metering-pin" type, and the "measuring-pin" type of carburetor. A glance at the sectional view of the carburetor (Fig. 41) will show clearly the operation. When the throttle is opened with the engine running, the suction is communicated to the air chamber by way of the pneumatic control passage (Fig. 42). This causes the piston to rise and with it the metering pin (A, Fig. 41).

The metering pin has a V-shaped slot cut in it, and as the pin rises or falls, according to the engine's requirements, it changes the area of the slot at the gasoline feed regulator, and consequently controls the amount of fuel passing through.

The proportioning of the mixture is automatic at all speeds, the piston giving instant response to the demands made on the engine.

Adjustments can be made entirely with the dash controls. The air-control adjustment is used only for starting the engine in cold weather, or after it has been standing for any length of time. Once the engine is running, it should be operated with the air-adjustment valve open.

The gasoline adjustment enables the driver to have the mixture as rich or lean as desired, by varying the amount of fuel allowed to pass the metering pin. This is done by raising or lowering the gasoline feed regulator which surrounds the metering pin. This regulator is actuated by the "Gas" button on the dash.

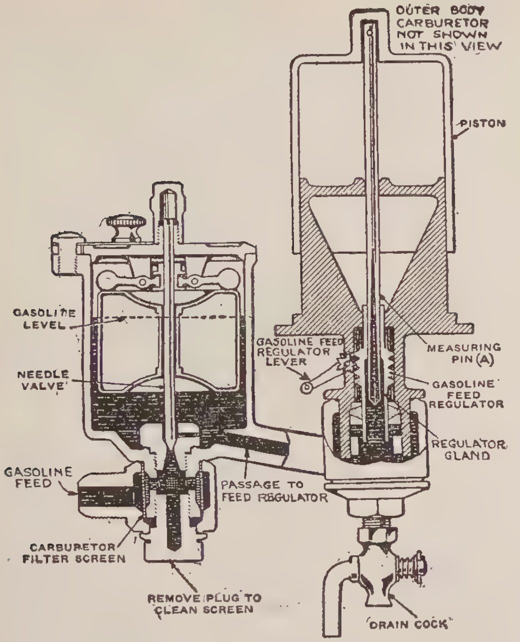

Fig. 41. View of the Hudson carburetor. Note the gasoline level.

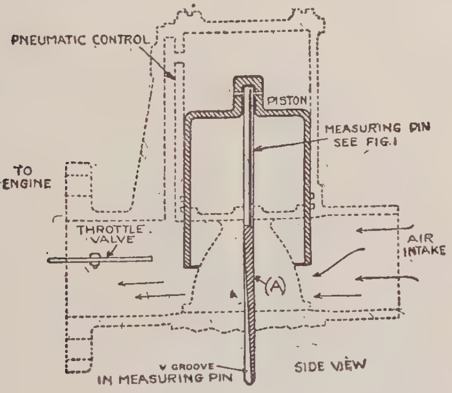

Fig. 42. Pneumatic control.

When the radiator shutter (see Index under "Radiator shutter") has been adjusted, so that the motor temperature maintains the red fluid in the motometer (see Index for meaning of "Motometer"), at the center of the circular opening, the engine will operate very economically on a lean mixture. Of course, heavier duty placed on the engine, such as hill climbing, pulling through sand, high speed, etc., places proportionate demands upon the amount of fuel, but in ordinary driving at speeds of 20 miles per hour upwards, the **carburetor should be adjusted as lean as possible.**

Too rich a mixture results in carbonization and misfiring; too lean a mixture gives less power and acceleration at low speeds. The entire range of adjustments is convenient to the driver.

Carburetor attention: Make sure, periodically, that the piston is clean and that the packing gland is tight. A sticking piston will seriously interfere with the action of the carburetor, and a loose packing gland will permit excessive gasoline consumption with its attendant troubles.

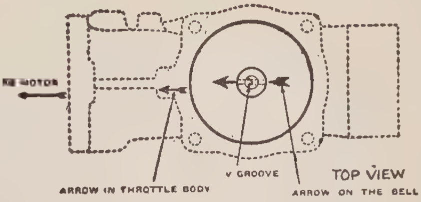

Fig. 43

Instructions for assembling measuring pin and piston: When assembling the metering pin and also the air bell to the throttle body (Fig. 43), be sure the arrow on the bell points in the same direction as the open end of the V-groove, and that the arrow on the bell also points in the same direction as the arrow in the throttle body.

Stewart Carburetor (on the Dodge)

On the Dodge the carburetor (Figs. 44, 45) is on left side of the engine, and is fed from a Stewart vacuum tank. The carburetor is supplied with a hot-air attachment which draws air from around the exhaust manifold to the air inlet.

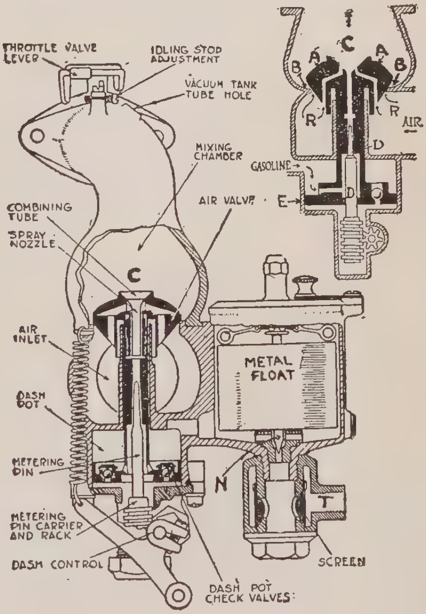

Fig. 44 (upper). How the metering pin **D** varies the mixture in the Stewart. Air passes through the passages **R** around the nozzle.

Fig 45 (lower). There is only one adjustment and that is the metering pin, which is interconnected with the dash control Ordinarily the metering pin should be two-thirds the way through.

Principle (Fig. 44): The automatic metering valve (**A**) rests on the valve seat (**B**) when the engine is not running. As the engine begins to rotate the suction of the pistons raises the valve (**A**) from the seat drawing in air (**R** to **B**) as indicated by arrows. The suction also draws gasoline up within the valve stem which mixes with incoming air in chamber (**C**).

The one adjustment of the Stewart is that of proportioning the volume of gasoline to the air admitted. The air being always a fixed factor, it is only necessary to adjust or regulate the volume of gasoline admitted which is controlled by means of the tapered metering pin (**D**).

This adjustment is made when the engine is running at idling speed. Turning the adjusting screw (on "dash control," see lower part of Fig. 45), either to the right or left, raises or lowers the position of the tapered metering pin, thereby allowing an increased or decreased supply of gasoline to be drawn up into the mixing chamber. When the proper proportion has been determined at slow speed, it will be seen that as the speed of the engine increases, the automatic metering valve (A) will rise higher from the seat (B) and away from the tapered metering pin (**D**), which will allow a greater supply of both gasoline and air, in exactly the same proportion, to be admitted to the cylinders.

On the Dodge (Fig. 45) the tapered metering pin is subject to control within fixed limits by means of the "dash control" ratchet (see lower part of Fig. 45 for connection), for the purpose of obtaining a rich mixture for starting. Should there be any reason for **changing the fixed adjustment** of the tapering metering pin (D), it can be done by turning the stop screw adjustment on the "dash control" (see lower part of Fig. 45). Turning it to the right lowers the position of the metering pin and allows more gasoline to be admitted to the spray nozzle, enriching the mixture. Turning it to the left raises the pin and decreases the supply. The **throttle valve** is in the top of the carburetor.

Ball & Ball Single Carburetor

The Ball & Ball single carburetor is used on the Studebaker "Big Six" and on many other cars (the Stromberg "LS" is also used on the Studebaker). In Fig. 47, the first and second-stage throats are plainly indicated.

Prior to making carburetor adjustment the following points should be thoroughly covered: (1) See that the spacing of the points in the spark plugs are set properly, or to .025". (2) See that the breaker points on the interrupter are set to .020". (3) See that the cylinders have good compression. It may be that some of the tappets are holding the valves partly open.

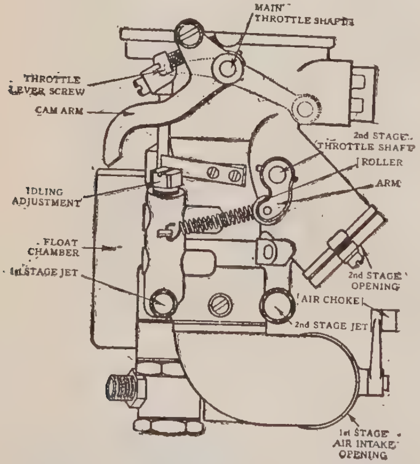

Fig. 46. Ball & Ball single carburetor designed for 4 and 6-cylinder engines.

Operation: Through a given range of throttle-opening all the gas is drawn through the **first stage** throat. The capacity of the first stage is sufficient to take care of all level road speeds up to approximately 40 or 45 miles per hour.

Fig. 46 shows clearly how the **second stage** is brought into action by opening the main throttle to its extreme position. The cam arm, integral with the main throttle shaft, coming into contact with the roller on the arm of the second stage throttle shaft causes the second stage throttle to open under additional pressure. The resultant action is to draw an additional or secondary supply of gas mixture through the second stage throat, as shown in Fig. 47.

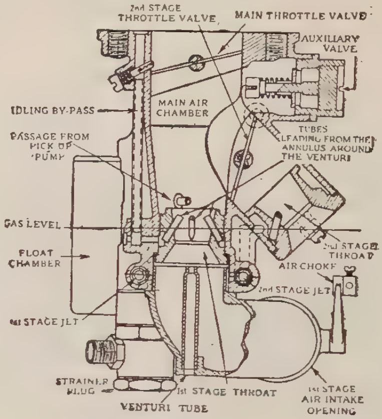

Fig. 47

Briefly speaking, the first stage furnishes all that is desired in what might be called the touring range, giving ideal economy and ample power for all ordinary purposes up to 40 or 45 miles per hour. The secondary stage supplies everything desired over and above the first stage in the form of added acceleration, power, and speed.

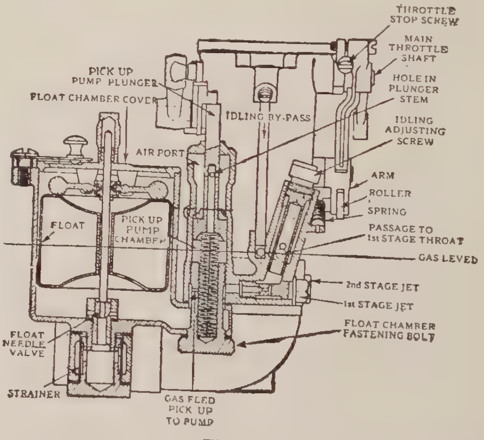

Fig. 48

In detail, the gasoline is fed into the float chamber through a removable cylindrical strainer (Fig. 48). From the float chamber the gasoline is fed separately to both first and second stage jets of the fixed orifice type (Fig. 47). In Fig. 48, the gasoline feeding to the first stage throat after leaving the first stage jet, passes through a tube, adjustable in height, known as the "idling adjustment screw." By raising this screw the idling mixture becomes leaner; by lowering the screw, the mixture is made richer. **This is the only adjustment on the carburetor,** aside from the throttle stop.

The pick-up device consists of a spring-operated plunger pump (Fig. 48) which receives a supply of gasoline directly from the float chamber through a small hole in the float-chamber fastening bolt. The gasoline fills the pump chamber to the level of that in the float chamber. In opening the main throttle, the "pick-up plunger" is depressed, which results in gasoline being forced out through holes in the plunger stem and carried into the main air chamber of the carburetor along with the air drawn through ports at the top and side wall of the pump chamber. The resultant action is to supply additional gasoline required for "quick get-away." This construction, on account of the time required to fill the pump, is such that the engine cannot be flooded by excessive repeated opening and closing of the throttle.

The idling by-pass consists of a tube through which a sufficient amount of gas mixture is taken in above the throttle valve to keep the motor running when the throttle is closed.

The choke valve is located below the first stage throat for the purpose of starting, and also may be used in a partially closed position to enrich the gas mixture until the motor warms up.

The only adjustment that can be made is the idling adjustment previously explained. This produces no effect whatever on the running of the car except when the throttle is closed to the idling position. The richness of mixture at all speeds above idling, is determined by calibrated orifices in the first and second stage jets respectively.

The possible troubles that might interfere with carburetion are insufficient gasoline supply or obstructions lodging in the carburetor passages.

To test for insufficient gasoline supply, remove the float chamber cover (see Fig. 48) and float, and note if gasoline flows freely. The gasoline strainer at the bottom of the float chamber may have become clogged.

In looking for obstructed passages in the carburetor, remove the first and second stage jets and carefully examine the jet orifices, keeping in mind that an almost imperceptible obstruction will reduce the jet capacity. Blowing through the orifice is generally effective, or, in addition, the opening may be cleaned out by means of a small wire.

For starting in cold weather, first, pull the choke button all the way out; second, open the throttle slightly and start the engine; third, as soon as the engine starts, push the choke button in part way; fourth, when the engine is warm, push the choke in all the way.

Ball & Ball Double Carburetor

The Ball & Ball double carburetor is used on 8 and 12-cylinder "V"-type engines.

First or primary stage, when starting and under usual running conditions: (1) is the hot-air passage of the primary carburetor containing the choke valve (2). (3) is the primary venturi throat connecting the hot-air passage with the mixing chamber (6), and containing the gasoline jet (4). (5) is another fixed air regulating orifice connecting the hot-air passage (1) with the mixing chamber (6) and provided with a spring-opposed idling valve (7) arranged to control the air when small quantities only are being used. (8) is a throttle valve of the usual type. The parts so far described constitute the first stage.

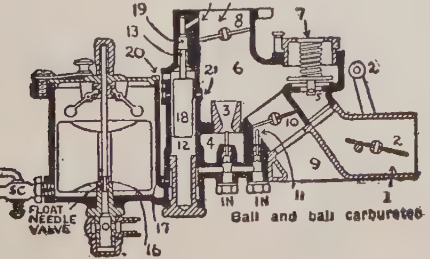

Fig. 49. Ball & Ball double carburetor, as used on the Peerless, King, Oldsmobile, and other "V"-type engines.

Second stage, or when throttle is wide open for full power: (9) is an air passage leading from the external air to the mixing chamber (6), and it contains the butterfly valve (10), arranged to control the flow of air through this passage. (11) is a gasoline jet arranged to discharge gasoline into the passage (9), when the valve (10) is opened, causing the gasoline jet (11) to be acted on by the suction of the mixing chamber (6). The air passage (9), with the gasoline jet (11), constitutes the second stage which is brought into action by opening the butterfly valve (10). A connection between the butterfly valve (10) and the throttle valve (8) (not shown) is so arranged that when the throttle valve (8) is nearly wide open, the further opening of this valve throws the valve (10) wide open. At all other times, the valve (10) is held closed by a spring (not shown).

From the foregoing description, it will be seen that under all the usual running conditions of the engine, the primary carburetor, or first stage only, is in service, and the second stage comes into service only when the throttle is thrown wide open for full power. The effect of this arrangement will be described farther on.

Pick-up device: Continuing the description (12) is a cylindrical chamber with an extension (13) of reduced diameter connected by the passage (14) with the chamber (15), above the throttle valve. The chamber (12) is connected with the float chamber (16) by means of the restricted passage (17), so that the gasoline at all times in this chamber (12) stands on a level with the level in the float chamber. (18) is a loosely fitting plunger with an extension (19) on its upper end, forming a piston in the chamber (13). An atmospheric opening (20) is located in the wall of chamber (12), and a passage (21) leads from chamber (12) to the mixing chamber (6) through which passage air is constantly drawn into the mixing chamber.

Operation of the pick-up device: It will be seen that in the operation of the engine, when the throttle is closed, the vacuum of the manifold acting on the piston (19) causes the plunger (18) to rise to its upper position, thus closing the passage to the chamber (15). The space below the plunger (18) is now filled with gasoline from the float chamber, and the mechanism is ready for action.

The opening of the throttle (8) breaks the vacuum in chamber (15) and releases the plunger (18), which falls and displaces the gasoline underneath the plunger, causing it to flow into the space above the plunger, where it is quickly discharged through the passage (21) to the mixing chamber, thus augmenting the normal supply of gasoline and causing a rich mixture to momentarily enter the cylinder. This develops a strong pick-up.

Adjustments: There are no adjustments after the size of jets is determined.

Air regulation: The amount of air is controlled by valve (2) which is operated by the choke-rod handle on the dash or steering post. For cold weather this valve (2) should be closed to draw in a rich mixture. Immediately the engine starts, push it down part of way until engine is warm, then close entirely. Don't open the throttle at all when (2) is closed, and don't run with (2) closed any more than possible.

Troubles: Dirt under the float valve will cause dripping; unscrew the cap over the float-needle valve and give it a few turns. Water or dirt may lodge in small openings and this is indicated by popping and missing. Close the valve on the gravity tank, remove four nuts at bottom, and clean jets.

Packard Carburetor

The primary air intake elbow (30, Fig. 50) is at the front end of the carburetor. The elbow contains a shutter (28) which is normally open and not in use when running. This shutter is operated by the "carburetor control" on the instrument board, which also operates the auxiliary air valve (34).

By pulling the control all the way out, the primary air intake is completely closed, allowing a very rich mixture to be drawn into the cylinders. The control should be pushed in, at least part way as soon as the engine has started firing.

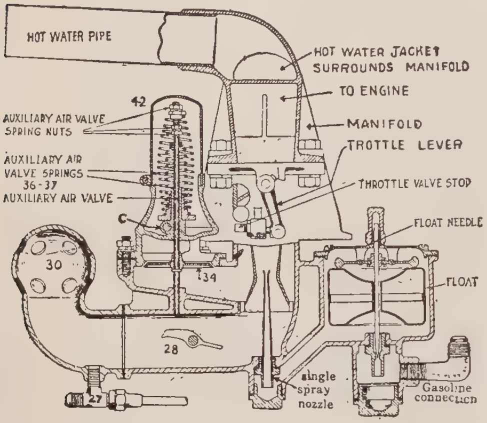

Fig. 50. Packard carburetor.

The auxiliary air valve (34) is in a housing (42) forward of the mixing chamber, and is controlled by the tension of two springs, one of which is within the other.

At low engine speed most of the air is admitted through the primary air intake (30) around the spray nozzle.

To prevent too rich a mixture at a greater throttle opening, the auxiliary air valve (34) is opened by the increase in the vacuum, admitting the right proportion of air to meet all conditions.

Carburetor adjustment: There is only one carburetor adjustment which directly affects the mixture, and this is the auxiliary air-valve adjustment. This adjustment is made by changing the tension of the air-valve springs (36, 37). This is changed by either of two methods, the first being through the operation of cams (C) at the lower ends of the springs. Raising the cams increases the pressure of the springs, and lowering the cam decreases the pressure. Increasing the pressure produces a richer mixture, and decreasing the pressure makes a leaner mixture.

These cams are controlled and operated by the air-valve control on the instrument board.

The large outer spring is at all times under tension, but the smaller inside spring is not normally under pressure until the valve opens up a little.

The other adjustment of the springs is made by changing the position of the nuts on the stem of the valve. There are two sets of nuts, one for each spring, and they allow individual adjustment of the springs.

Under ordinary conditions, and with the engine warm, the control on the instrument board should be set at the No. 4 notch. Pulling the rod out makes a richer mixture and pushing it in makes a leaner mixture.

Caution: In warm weather, or if the engine is warm, the mixture may be so rich, if the knob is pulled out, that the charge will not ignite and the surplus of unburned gasoline may interfere with the proper lubrication of the cylinder walls.

For idling, the throttle valve is held very slightly open to allow a very small amount of mixture to go to the cylinders. If the engine races or stalls when the throttle is closed all the way, the stop screw needs adjusting.

The float chamber vent tube (27) is for two purposes: (1) to give air to the float chamber to prevent a vacuum being formed; (2) to drain surplus gasoline from the chamber around the spray nozzle when the engine is suddenly throttled down.

The latest Packard carburetor is equipped with a fuelizer. With the present-day gasoline, which is heavy and slow to vaporize, when first starting and until the engine is thoroughly heated, raw gasoline often passes into the cylinders which not only produces carbon, but thins the lubricating oil on the cylinder walls and passes to the crank case and dilutes the oil. The engine also frequently misses when cold.

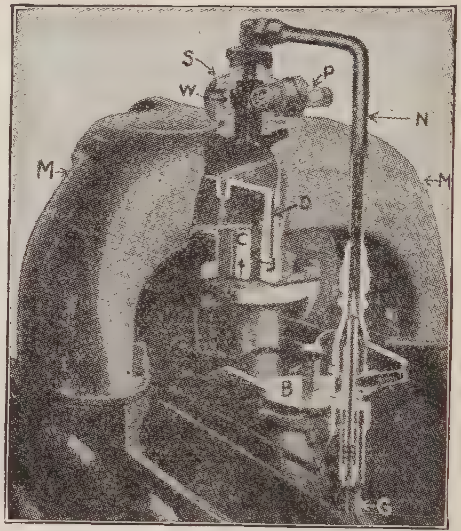

Fig. 51. The later Packard carburetor (**B**) is the same as in Fig. 50, except that the Fuelizer is attached to the intake manifold and a gasoline connection (**N**) is provided for the Fuelizer.

To heat the mixture and provide complete combustion within 20 seconds after starting on the coldest day, the Packard Co. has developed a device to heat the mixture, called a "Fuelizer."

The "Fuelizer" consists of a small supplementary carburetor (S) and a burning chamber where the gas from the little carburetor is burned. This chamber is situated in the intake manifold (**M**). When the gas enters, it is ignited by a regulation spark plug (**P**), and passes into the fresh charge going from the carburetor to the cylinders through wall (**D**) to (**C**). The heat of the burned gas changes the wet, poorly carbureted mixture to a dry vapor, which combusts with full efficiency when it is ignited by the spark in the cylinder.

The action of the Fuelizer is entirely automatic, without involving a single moving part. When the engine is starting, the Fuelizer is in full operation, and the heat supplied to the charge becomes less as the throttle is opened. This regulation is provided by an air valve similar in operation to the air valve of the main carburetor.

Through a small Pyrex glass window (**W**) the operation of the Fuelizer may be seen. A perfect mixture produces a purple flame, a fairly rich mixture produces a bluish-green flame, and an exceedingly rich mixture is indicated by yellow streaks in the flame.

(**B**) is the regular carburetor and (**G**) is the gasoline pipe connection to it from the gasoline tank, which feeds the carburetor in the usual manner. (**N**) is a pipe which is also connected with the gasoline pipe line at the gasoline connection on the carburetor and which feeds the Fuelizer. See page 108 for a detailed description of the Fuelizer.

Dave Buick Carburetor

Note. This carburetor is not the carburetor used on the Buick car. For the carburetor that is used, see the Marvel, page 126. The Buick carburetor is used on the Briscoe and some other makes of cars.

Construction: In the Buick carburetor, the float chamber surrounds the aspirator, which is in the form of a hollow tube with very small holes in the side toward the intake pipe of the motor.

The air coming into the carburetor strikes a hinged plane, which is raised or lowered as the amount of air is increased or decreased. This hinged plane is connected with the hollow aspirator tube, which rises and falls with it as the quantity of air changes. As the aspirator tube rises in its guide, more of the holes are uncovered, and more gasoline is drawn into the intake pipe. This construction assures the correct proportion of air and gasoline under all conditions.

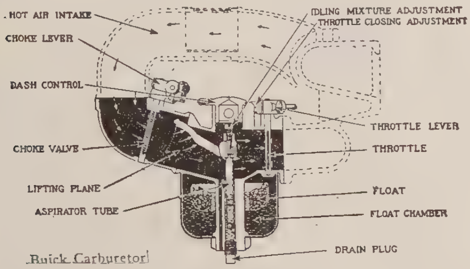

Fig. 52. Dave Buick carburetor.

At the top of the carburetor, the **auxiliary dash control** is fitted. This is simply a damper which admits additional air to the mixture. It can be used when coasting. By opening this control as far as possible, the leanest running mixture can always be secured.

The choke, which is also operated from the dash, reduces the air supply by closing a damper in the air intake, and at the same time raises the aspirator tube and allows additional gasoline to be taken into the motor. The choke may be used in starting when the engine is cold, and, if necessary, held partly out until warmed up.

The float chamber may be drained by removing the plug in the bottom. This can be done for flushing out dirt which may lodge in the float valve, causing dripping.

Adjustment: The idling mixture may be regulated by removing the auxiliary air cap from the top of the carburetor and slightly turning the screw directly below. Turning the screw to the left richens the idling mixture; turning to the right makes it leaner.

The Carter Model "N" Carburetor

This model is used on the Dort. The models "H" and "L" are similar. This carburetor is a "multiple-jet" type of carburetor.

A choker button is provided on the dash to enable the operator to obtain a correct mixture under all climatic conditions. To secure maximum economy run the car with the choker button pushed in as far as possible. When the engine is cold it will be found necessary to pull the button out as far as possible to aid in starting. It must be pushed in gradually as the engine warms up till, when thoroughly warm, it will be clear in or at regular running position.

An air-control band (Fig. 53) is provided on the hot-air sleeve for admitting additional cool air in hot weather. In cold weather the band should entirely cover the ports. It may be set at any point between full open and full closed positions at the option of the driver, according to temperature.

The throttle lever on the carburetor is provided with adjusting screws (Figs. 53 and 54). The purpose of these screws is to hold the throttle open far enough to keep the engine running when the throttle lever on the steering wheel is closed all the way and the engine is idling. If the engine runs too fast at idle speed the adjusting screw should be turned very slightly to the left, to bring the throttle nearer to closed position.

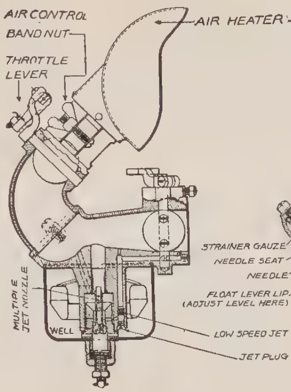

Fig. 53

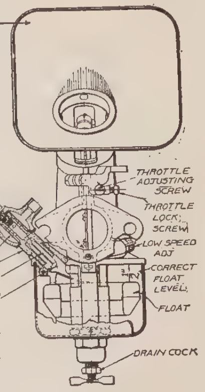

Fig. 54

A low-speed adjustment is provided to regulate the strength of the mixture at idle engine speed (Figs. 53 and 54). Turning the screw in makes the mixture richer; turning the screw out makes it poorer.

To properly adjust, close the throttle lever, retard the spark lever, turn this screw out till the motor misses on account of the mixture being too lean, then turn the screw in just enough to get the engine hitting properly. This will give the most economical setting at low speed and helps to secure proper acceleration. This adjustment should be made when the engine is thoroughly warm.

The float level: When the needle valve is closed, the top of the float should be exactly ½″ from the carburetor body. If the float has been moved from this position, it can be restored by bending the float lever lip where it touches the needle. Only a very slight bend is necessary. This is a delicate mechanism. Handle it with care.

The strainer will, as a rule, keep all dirt from getting into the needle seat, but some small particles may get through from time to time and cause the carburetor to leak or flood. When this occurs it is necessary to take out the needle and seat and to clean them thoroughly. To do this, first, take off the strainer, then unscrew the needle seat. Both needle and seat will then come out and may be wiped clean and tested. If the needle does not seat tight, it may be reseated by giving it one light tap. Never try to grind the needle to a seat.

Dirt may also cause a loss of power or uneven running by lodging in the jets, and it is often possible to clean these jets by choking the carburetor and in that way drawing the dirt on through. It is best to do this when the car is running in high gear at 25 miles per hour. Open the throttle wide and at the same time pull the carburetor choke-rod button out as far as possible, holding it in this way for two or three seconds and keeping the throttle open; then push the choke-rod button and gradually close the throttle as the engine commences firing again.

Miller Carburetor

The Miller "H" is a "multiple-jet expanding carburetor" of the rotary or barrel throttle type.

Four to six main jet tubes are used depending on the size of the carburetor, and these tubes, having

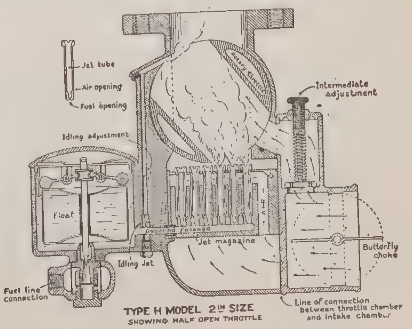

Fig. 55

each the fuel jet in the bottom and four small air holes a little above, are placed in a row in a removable magazine. This magazine has a fuel passage which supplies the jet in the bottom of the tubes and provides an air jacket which surrounds the main portion of each tube; these jacket spaces have a passageway near the top of the magazine above the float level that connects them with each other and with the outside air.

When not in action the tubes and surrounding air-jacket spaces are filled with fuel which provides a succession of puddles as the throttle is opened and the tubes brought into action one after another. Each tube, when the puddle has been drained, begins to function as a miniature carburetor with fuel entering at the jet in the bottom and air being supplied through the four small air holes just above.

By this design the fuel goes through a "two-stage" atomization process; the first in the bottom of the tubes, where a heavy spray is formed, and the second in the venturi of the carburetor, where the spray unites with the main air column. The main feature of this construction is the fact that the fuel flows through the jets by gravity from the float chamber and combines with the air of the first stage at a point below the float level. This brings the partially atomized fuel out of the tube and into the venturi for the second stage without the choke restriction necessary to create a depression at this point.

Two exterior adjustments are provided. The first is for **idling** and is a control of the idling speed air by means of a screw in the passage. The second adjustment is for **intermediate speeds** and has its principal effect on the first third of the throttle range. It amounts to a control of the spring tension on a poppet valve which admits a certain amount of air during the first part of the throttle opening when the vacuum is at a relatively high point. This adjustment has its greatest effect as a control for pick-up, and consequently is also an adjustment for economy.

The air intake is made in two sections, with an adjustable clamping ring at the joint. The second section can be supplied as a vertical elbow which can be set at any angle required for the hot-air tubing. At the intake connection a butterfly valve is provided as a choker or strangler for starting; this is operated by a flexible wire control from the dash.

The carburetor here described is the same in all respects except for the two exterior adjustments as the instrument which the Miller company has been making in large sizes only for marine and aeronautical engines in past years.

The Claudel Carburetor

The Claudel carburetor, widely used in Europe for a number of years, is now being manufactured in the United States by the Claudel Carburetor Co., Long Island City, New York.

This carburetor was used on the Sunbeam engines of the British dirigible R-34 which made the first round trip across the Atlantic. It was also used on the Rolls-Royce engines of the Vickers-Vimy aeroplane, which was the first plane to make a non-stop trip across the Atlantic. It was also used by Sadi Lecointe, the French aviator, who set a world's record of 232 miles per hour.

The design of the European model has been changed somewhat to meet the particular requirements of American cars, and such features as quick starting and rapid acceleration when cold have been provided for.

The carburetor itself is a "plain-tube" automatic compensating unit which has no moving point.

The principle used is that of breaking up the gasoline by a swift current of air which makes an emulsion inside the jet itself before delivering it to the carburetor proper.

The Claudel is really a combination of two types of jet, one, the main jet, of constant flow per unit of time; the other, shown as a series of nozzle holes, of suction-controlled flow.

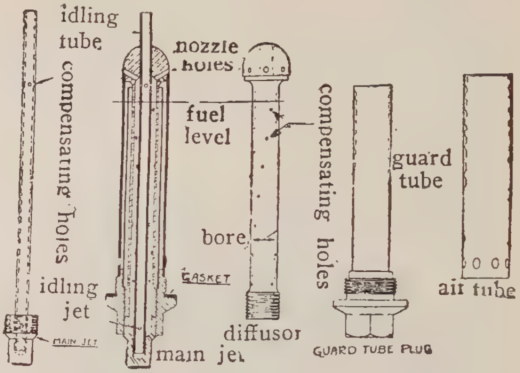

Fig. 56. Diffusor of the Claudel carburetor in section, and in its components.

Fuel from the float chamber flows through the main jet into the diffusor, then through the compensating holes into the reservoir of diffusor bore. It also flows through the idling jet into the idling tube, the level in the three tubes being the same as that in the float chamber.

Air at atmospheric pressure enters the outside base or air tube of the diffusor column, passes up this outer sleeve and over the top of the gasoline guard tube which prevents the fuel from overflowing.

As the throttle is opened gradually and the suction in the diffusor increases, thereby lowering the liquid level in the diffusor bore, a series of air-bleed or compensating holes are progressively uncovered. Through these holes the air rushes into the ascending column of gas vapor and out of the nozzle holes at the top of the diffusor in a finely broken-up gasoline emulsion. The higher the suction acting upon the diffusor, the lower will be the level of gasoline within it, and therefore, more of the compensating holes will be uncovered, permitting a greater dilution of the mixture.

At the higher speeds, the diffusor is practically emptied and twenty-one spirally arranged air-bleed holes are in action. As the gasoline globules are lifted by the suction, they must pass through a barrage of twenty-one air guns shooting at right angles into the ascending fuel. This turbulent mixing effect produces a finely divided fuel emulsion, ideal for rapid-flame propagation, extreme economy, and high power. The diffusor discharge is in approximately the ratio of fifteen parts of air to one part of gasoline by volume. This thorough intermixture of air and gasoline before it enters the carburetor barrel is the Claudel method of breaking up the heavy fuel of today for extreme economy.

The idling device is incorporated in a central tube projecting up into the depression of the barrel throttle where a strong pull is exerted on the idling jet for low-speed action. The barrel throttle is slotted to pass around the idling jet for low-speed action. The rotary or barrel throttle is slotted to pass around the idling jet, and **the only adjustment on the carburetor** is a screw extending into the air space to partially block off the area of this slot as desired. Screwing it in lessens the air area and enriches the idling mixture. Screwing it out makes the mixture leaner.

In the American type of Claudel shown in Fig. 57 a decided improvement has been incorporated for strangling the air by means of a sliding air cone (**A**), which, when in strangling position, fits snugly into the venturi entry (**V**). This cone is controlled from the dash. This device assures quick starting and warming up in cold weather. The streamline air cone, concentric with the diffusor, may be raised into contact with the venturi, shutting off the air supply and putting the full suction on the diffusor. In this position it is only necessary

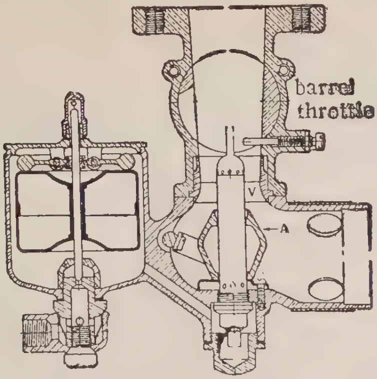

Fig. 57. Section through the standard American design of Claudel carburetor.

for the cylinders to exhaust the air in the top of the carburetor before the diffusor discharge must commence. This action is instantaneous, as the volume is small.

Master Carburetor

A sectional side view of this carburetor is shown in Fig. 58.

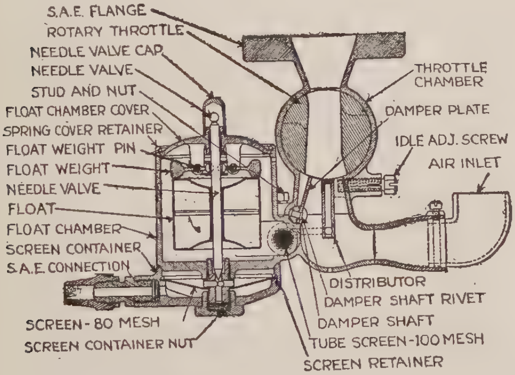

Fig. 58. Sectional view of the Master carburetor.

The fuel distributor (Fig. 59) is placed across the mixing chamber, the number of its jets varying from 11 to 19, according to its size. Each of these tiny jets occupies a different position in the path of the inrushing air, thus forming a perfectly atomized fuel that is instantly and thoroughly mixed with the air, the two elements being merged into one.

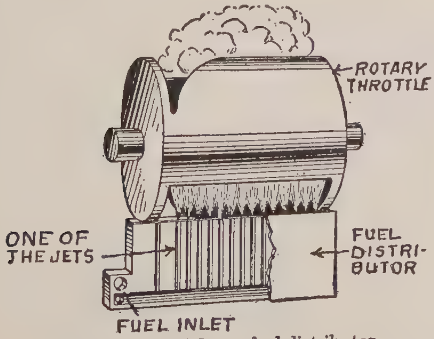

Fig. 59. The Master fuel distributor.

When the throttle is closed, a single hole remains uncovered to admit a supply of fuel that is ample for idling or for slow running. As the throttle is opened the additional holes are uncovered, one by one, and the fuel supply increased.

The rotary throttle eliminates the butterfly throttle which is extensively used in other makes.

As stated above, the fuel openings are fixed, but the air opening can be varied through the use of the positive control which operates the **damper** in the carburetor. The changing of the damper position, which increases or decreases the volume of air passing the distributor, increasing or decreasing suction on the jets, gives the widest possible mixture range.

The air supply is constricted by the damper at the outlet, like a variable venturi. When the lever on the steering-post control (which is connected to the damper), is pulled to "rich" position, the venturi (or opening) paralleling the row of 11 to 19 jets is very small and the pure gas rushes to the engine under tremendous suction, thus enriching the mixture so that quick starting, even with a cold engine, is easy and certain. As the engine picks up speed, the mixture may be modified by decrease to any mixture required.

Rapid acceleration. Do not open the throttle suddenly. A gradual opening will give quicker get-away and save wear and tear on the motor.

Idle adjust-screw. For perfect idling of the engine set the control lever in center position. If the engine rolls or gallops at idling speed, back out on idle adjust-screw. If the engine seems not to have sufficient gas at idling, screw the idle adjust-screw in. Turning it to the right enriches the mixture coming from the idle hole only.

Fuel distributors of various capacities are available for each size carburetor. Should the engine run and pull best with control in rich position at ordinary speeds, you should have a distributor of greater fuel capacity. Should the engine take all the air possible to give it at idle speeds, you should then have a distributor of less fuel capacity. The letter on the end of distributor designates its fuel capacity. See below for sizes.

Control centers are numbered at the base of the lever and care should be taken to see that the proper control center is used with the different sizes of carburetors.

Those stamped No. 1 are for 1" and 1¼" JR carburetors. Those stamped No. 2 are for 1¼" STD and 1½" JR carburetors. Those stamped No. 3 are for 1½" and all larger sizes. Manufacturers are the Master Carburetor Company, Box 444 Sta. C., Los Angeles, Cal.

Carburetor on the Maxwell

The Eagle carburetor used on the Maxwell engine is an "air-valve" type of carburetor.

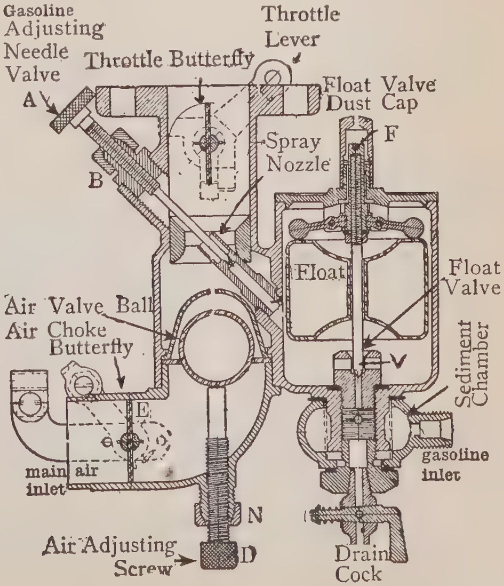

Fig. 60. Sectional view of the Eagle carburetor.

An air-ball valve is placed in the main air inlet, which thus controls all air passing the spray nozzle.

At low speeds the ball permits only a small quantity of air to pass. **At high speeds** the ball is raised by the greater suction of the piston, and thus more air is admitted.

Adjustment: Loosen lock nut (B) and turn the gasoline adjusting needle valve (A) to its seat and set the stop screw on the throttle valve to approximately the correct position for idling. Then open adjusting needle valve by turning to the left three-quarters of a turn. With this adjustment the engine can be started.

The engine should be run long enough to be warmed up to service condition. Be sure that the choker butterfly valve (E) is open when making adjustment.

Then retard the spark control, open the throttle until the engine is running at average driving speed. Next turn gasoline adjusting needle (A) to the right until the engine speed decreases from lean mixture. Then turn to left until the speed increases and again starts slowing up, which is as rich a mixture as engine can be run on. By turning again to the right to a point half-way between the two, when the engine speed is highest, the correct mixture for general driving will be obtained. Tighten lock nut (B), and the adjustment is complete.

The air-adjusting screw (D) is provided only for the purpose of controlling the air supply to the carburetor when running at low speeds. It may be possible that the adjustment on the gasoline adjusting needle is slightly too rich for idling purposes and will cause the carburetor to choke. By loosening lock nut (N) and turning the air adjusting screw (D) to the right, admitting more air, this condition will be eliminated. Tighten the lock nut, and the adjustment is complete.

Adjust the throttle-lever stop screw until the desired idling speed is secured. Adjustments should be made with spark and throttle fully retarded.

When starting with a cool engine, it is absolutely necessary to have choker butterfly (E) closed. This is operated from the dash and should be opened gradually as the engine warms up to conditions.

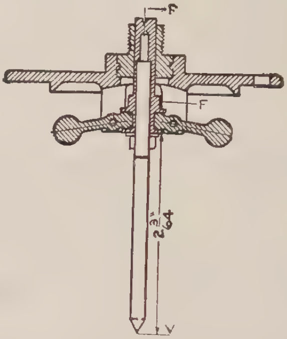

Fig. 61. If carburetor drips, it is usually due to dirt under the float needle valve (V). Remove the float dust cap, place a screw driver in the end of float collar (F) and turn gently back and forth, thus seating the float needle valve. Eagle Carburetor Co., Cleveland, Ohio.

INSTRUCTION No. 15

COOLING THE GASOLINE ENGINE: Cooling Methods; Water Circulating Pumps; Fans; Radiators; Water Thermostats; Water Temperature; Water Cooling Troubles; Overheating of Engine; Non-Freezing Solutions; Air-Cooling Methods; Heating a Car.

WATER COOLING

If no provision is made for **cooling the cylinder of a gasoline engine,** the intense heat of the explosions would heat it to a point that would cause the lubricating oil to burn and become useless. At the same time, the cylinder must not be kept too cool, for that would prevent development of full power; the cylinder must therefore be permitted to get as hot as is possible without burning the lubricating oil. About 170° Fahr. or below the boiling point, appears to give the best results.

The cylinder may be cooled either by water or air, and while the greater number of engines are water cooled, air cooling has been developed to a point where successful results are attained.

The water-cooling system consists of jackets around the part of the cylinder that is to be cooled, through which water may flow; a **radiator** for cooling the heated water; and some method of keeping the water in circulation, together with the necessary connections (see Fig. 4). **The cylinder water-jackets** are usually cast in one piece with the cylinder. When heated, the water passes to the radiator tank, thence through the radiator tubes, where the rush of air to which it is exposed absorbs the heat, cooling the water, which then passes back to the lower water connections on cylinders.

The radiator system is always fixed in the forward part of the car, to obtain the full benefit of the draught of air. The same water is used over and over again, so that it is only necessary to replace the loss caused by evaporation and leakage.

It is usual with **radiator systems** to **have a rotary fan** to assist in inducing a draught of cold air through the radiator tubes and in accelerating the cooling when the car is moving slowly, as in hill-climbing or slow running in traffic. The fan is driven from the engine shaft by a belt or gear and fixed back of the radiator. The alternative method, which avoids the use of a separate fan, is provided by fan-vaned arms in the fly wheel.

WATER—CIRCULATING METHODS

The two systems of circulation are the "thermo-syphon" system and the "force" system.

Thermo-Syphon Water Circulation System

The thermo-syphon system of water circulation is as follows: Upon becoming heated, the water rises to the top, entering the pipe and passing into the radiator at top where it is brought into contact with a large cooling surface, in the shape of the radiator. On being cooled and thereby becoming heavier, the water sinks again to the bottom of the cooling system, to enter the cylinders once more and to repeat its circulation. The cooling action is further increased by a belt-driven fan which draws air through the radiator spaces. The connections are the same as for the force system, except that there is no pump, and the connection from the water-jacket outlet to the top of the radiator slants upward. It is more necessary to have clear passages for the thermo-syphon system than for the force system, because the pump, in the latter, will force the water past an obstruction that would stop the flow of water that moves only because of its heat.

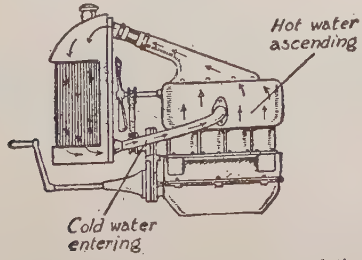

Fig. 1. Thermo-syphon principle of water circulation. See also page 155 for a typical example of a "thermo-syphon" system.

The height of the radiator with the thermo-syphon system must be higher and lower than the extreme top and bottom of the water jacket (see Fig. 1 and also, refer to page 155).

The height of water with the thermo-syphon system should be kept at level above top inlet of radiator to insure proper circulation. Below this point circulation ceases and water boils.

Keep the radiator full: When the cooling water is kept in motion by thermo-syphon action, it is quite important that the radiator be kept reasonably full in order that there be a back resistance to aid in forcing the water forward. It is good engine care to add frequently a little cold water, instead of waiting for the engine to knock, especially in summer.

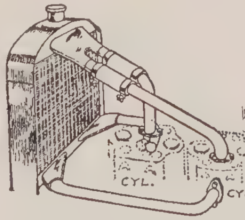

Fig. 2

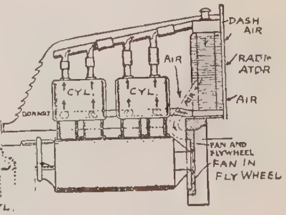

Fig. 3

Fig. 2. **A** thermo-syphon system in which independent pipes are taken from each pair of cylinders, the outlet pipes joining at the upper or tank part of the radiator. Cylinders in this instance are cast in pairs (obsolete). Where cylinders are cast in-block, one water inlet and one water outlet pipe will suffice, as in Fig. 1. See also, page 155.

Fig. 3. Simple thermo-syphon circulation without the use of a fan. The arms of the fly wheel are designed to act as fan blades; a separate fan is unnecessary, but the underpart of the engine must be carefully screened in (formerly used on Renault).

Force Water-Circulation System

In the force system, the engine drives a pump which keeps the water in constant circulation, as shown in Fig. 4. The pump forces the water from the bottom of the radiator to the inlet at the bottom of the water jacket, through which it flows to the outlet at the top, whence it goes to the top of the radiator, and flows through the radiator tubes to the bottom. As it passes through the radiator tubes it is cooled. After passing through in this manner, it is again drawn through the pump and forced again through the same path.

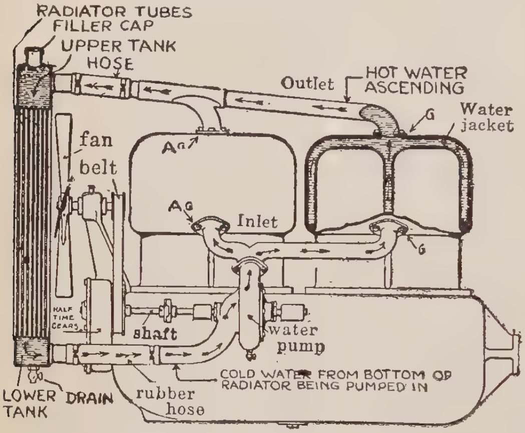

Fig. 4. This illustration shows how the pump shaft on the forced water-circulating system is usually driven, and also the fan. G are gasket connections which must be kept tight—usually made of copper asbestos-lined composition. The path of the water circulation is also shown.

Circulating Pumps

Practically **all water-circulating pumps are driven by a gear on the crank shaft or cam shaft,** so that motion is positive, and without slipping. All forced circulating systems must use a circulating pump.

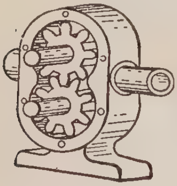

Fig. 5

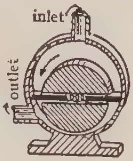

Fig. 6

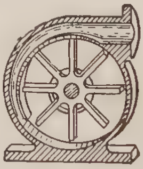

Fig. 7

Fig. 5. The gear type of circulating pump consists of two small gears with large teeth, the two being in mesh, and placed in a casing that fits as snugly as possible. The water enters at one side where the teeth separate and is carried around to the opposite side in the spaces between the teeth, where it escapes through an outlet.

Fig. 6. The rotary type of circulating pump consists of a ring-shaped casing, within which a disk revolves, the disk being "eccentric," or to one side of the center of the casing. Through a slot across the disk are two arms, their ends being pressed against the casing by a spring. As the disk revolves, the water is forced from the inlet to the outlet by the arms.

Fig. 7. The centrifugal pump acts on the principle of an air blower, and has blades projecting from a hub, which revolve at high speed inside of a casing. The water enters at the hub, and is thrown outward by the blades to the outlet in the casing. This is the type in general use.

There are three types of circulating pumps, in general use: the "gear" type, the "centrifugal" type, and the "rotary" type.

Cooling Fans

In order to cool the water sufficiently, **a fan is** driven by a belt attached to a special bracket on the engine. This is shown in Fig. 4.

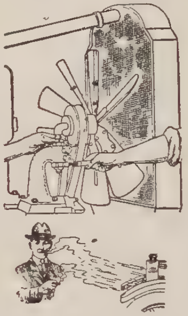

Fig. 9 (upper)
Fig. 8 (lower)

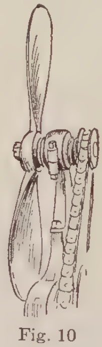

Fig. 10

Fig. 8 shows how the fan draws air in through the cores of the radiator to keep the water cooled. This demonstrates clearly the function of the fan, and shows how futile is its attempt to cool the radiator when a winter cover is placed over the radiator and is fully closed. There is no cooling action to the fan unless the front of the radiator is at least partially exposed. Often obstructions are placed in front of the radiator, as license tags, etc., which cut down the efficiency of the cooling system.

The fan draws a current of air through the passages in the radiator in addition to that driven through it by the forward motion of the car.

There are two types of fans in general use: the multiple blade (Fig. 9), and the two-blade (Fig. 10).

Fan adjustment: the belt can be tightened by raising the fan by an eccentric adjustment (Fig. 8A), or by bodily lifting the fan and its bearing and tightening a bolt holding it (Fig. 9).

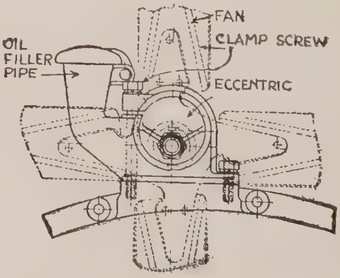

Fig. 8A

The belt should be kept tight. A slack fan belt often causes overheating. Ball bearings are usually provided and they should be kept well oiled. This is quite often overlooked.

RADIATORS

The purpose of a radiator is to keep the water, which circulates around the water jacket of the cylinders below the boiling point.

The early type of radiator (Fig. 11) consisted of a corrugated copper tank, with horizontal tubes running lengthwise of the tank. A tank was placed on each side of the body connected with the water jacket of the engine. A circulating pump was used to circulate the water. Modern constructions are shown farther on.

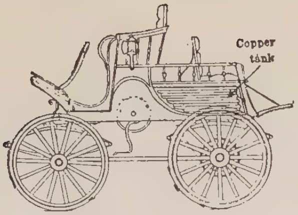

Fig. 11. One of the early methods employed for cooling the water.

The location of a modern radiator is usually in front of the engine, where it will come in contact with the air. The air passes between the tubes or fins on a tubular type of radiator and through the cells of a cellular type. A fan is usually placed directly behind the radiator, which is operated from a pulley on the crank shaft of the engine, for the purpose of drawing a large quantity of air through the radiator, thus increasing the cooling capacity.

Construction of a radiator: There is a reservoir or tank placed at the top and one at the bottom, as shown in Fig. 4. Between these two tanks, the tubes or cells are connected. A flexible hose pipe connection is made with the top and bottom tank from the engine, as shown. When the engine is running, the hot water passes to the top tank, thence downward through the radiator tubes (if a tubular type), or around the cells (if a cellular type), and is thus cooled. The cooled water then passes into the lower part of the engine from the lower tank of the radiator.

Radiators must be used with either the "forced-circulating" system, using a pump, or with the "thermo-syphon" system, which does not use a pump.

Types of radiators: There are two types in general use, the "tubular" and the "cellular," or "honey-comb."

The tubular type consists of vertical tubes placed between the upper and lower radiator tank. The **water passes** downward **through** all of the **tubes.** If one tube becomes clogged, then all of the water must pass through the other tubes. Each tube is a separate path through the radiator.

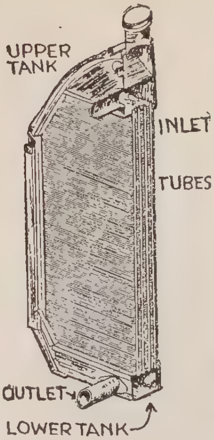
The cellular radiator consists of tubes or cells placed horizontally, through which the air passes and the **water flows** downward **around** these cells or **tubes.**

The honey-comb type of radiator was a term originally applied to a cellular type of radiator, due to its likeness to a honey-comb, but now that tubular type radiators can be constructed so as to have the appearance of a cellular radiator, the term could also be applied to the tubular type.

Tubular-Type Radiators

The tubular type of radiator used in 1900 and 1901 is shown in Fig. 13. The tubes were placed horizontally in heads (H). Crimped fins (F) were placed on the tubes. The radiator was suspended under the front of the car by studs (S). A pump circulated the water.

The vertical tubular type with "spiral" fins (F) (Fig. 14) was the next type introduced. These tubes were placed between an upper and lower tank (Fig. 4, page 146). This type is still in use, principally on trucks.



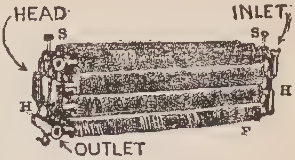


Fig. 13

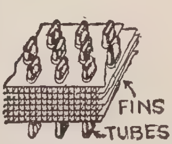

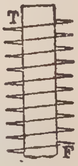

Fig. 12

Fig. 15

Fig. 14

The vertical tubular type with "flat" fins (Fig. 15) was the next type introduced, the idea being to have it resemble the cellular radiator which at that time was introduced on the Mercedes car. A tubular radiator made up with flat fins, is shown in Fig. 12.

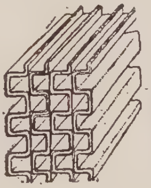

Fig. 16

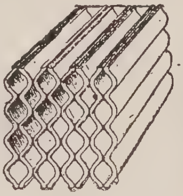

Fig. 17

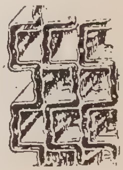

Fig. 18

Variations of construction of the tubular type radiator are shown in Figs. 16, 17, and 18. Note that the appearance is similar to the cellular type, but the water flows through the tubes, whereas, with a cellular radiator, the water flows around the tubes.

Cellular-Type Radiators

The original cellular type was the Mercedes (Fig. 19). It consisted of four or five thousand ¼″ square copper tubes 4″ long, nested horizontally together, being separated from each other by wires arranged to run between the rows of tubes in both directions. The blocks so made were clamped together, and dipped in a bath of solder, both front and back, by which means a space $\frac{1}{32}$″ thick was left on each side of every tube. The blocks (divided into sections similar to Fig. 20) were assembled with the top and bottom tank of the radiator, and water was forced to pass in between the tubes, the air being allowed to travel through the inside of the tubes. A very large radiating surface was thus obtained, and it would be hard to conceive of any arrangement offering a larger radiating capacity for any given size of radiator.

The cellular radiator is a very expensive type to construct. In this country, where large quantities are required, this construction was quickly modified to make the production cheaper.

Honeycomb Type of Radiator

The tubular type construction of radiator is often termed a "honeycomb" type. It is very much like a cellular honeycomb in appearance. See Fig. 18

The Fiat true cellular type of radiator (Fig. 20) is similar to the Mercedes. It is formed in four divisions indicated by horizontal lines. Where these lines cross there are open horizontal passages through which the water may flow from one side to the other. Thus a section can be removed and repaired separately.

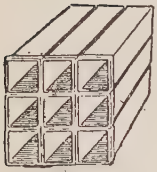

Fig. 19

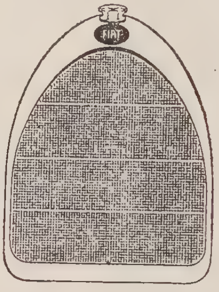

Fig. 20

Some of the modifications employed are shown in Figs. 21 and 22. Note in Fig. 21 that the tubes are expanded at the ends, thus eliminating the wires.

The Mayo is constructed in a similar manner with the water passage to the sides of tubes. In the Fedders (Fig. 22) the hexagon tubes can be removed and replaced. The Harrison hexagon cellular is shown in Fig. 23. Between every other row of cells there is a water passage .08″ thick.

Fig. 26. Extension or syphon tank (S), used on many thermo-syphon systems to give greater body of water and to absorb steam and to maintain a constant level—a desirable feature on all radiators.

WATER TEMPERATURE

The temperature of the water circulating around the water jackets should be about 170° to 180°, at which temperature gasoline engines operate at maximum efficiency. If over this temperature, or as high as 212°, the water will boil and steam. If the temperature of the water is low, then the cold engine condenses a portion of the gasoline, which leaks past the piston rings, dilutes and thins the lubricating oil, with the result that the engine is not properly lubricated, and furthermore, the raw, unvaporized gasoline produces carbon deposit in the cylinders.

Water boils at a lower temperature in a high altitude, because the pressure of the atmosphere, which water must overcome before it can boil or change into steam, is lower in a high altitude. At an elevation of one mile water will boil at a temperature 10° lower than at sea level. In crossing the Rocky Mountains the road is frequently much more than one mile above sea level, and water boils away very rapidly.

Temperature Indicator

A device which is placed on the filler cap of the radiator (Fig. 27), serves to indicate the temperature of the water vapor. This device is known as the "Boyce Motometer." It is a very useful device for warning the driver when his engine is overheating. This device is placed on the radiator cap. The fluid in the tube reaches different levels according to the temperature. These figures can be seen from the driver's seat. (Note: At high altitudes, say 10,000 ft. above sea level, the boiling point of water is reached about ⅛″ below the point indicated at the top of the instrument.) If the level of the fluid reaches too high a point, the driver is warned to stop and locate the trouble before serious trouble develops.

In this case, first determine the different causes of overheating and try first one, then the other, until the trouble is found. If you think the trouble is in the lack of lubrication, lack of water, or too much

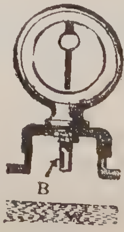
Fig. 27. Boyce motometer; a water temperature indicator. Note that 170° is the point where the engine operates best.



The thermometer bulb (B) does not extend to the water (W). The temperature of the vapor above the water is indicated.

Fig. 27A

asoline feeding at the carburetor, examine each; emedy the trouble and watch the results.

A distance or extension type of motometer is also nade, which can be placed separate from the radia- or and is adapted for use on aeroplanes, motor oats, tractors, etc. (Made by Boyce Moto-Meter o., Long Island City, N. Y.)

Extension type of temperature indicator: This levice (Fig. 28) will indicate the temperature of vater or oil circulating through the engine. The nstrument is placed on the dash and the tube (E) s placed in the top of the radiator.

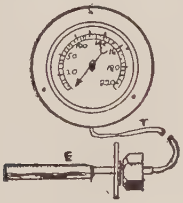


Fig. 28. Extension type of water temperature indicator Boyce motometer with an extension tube).

Principle: The hollow spring in the head of the nstrument and the copper tube (T) and bulb (E) are illed with treated alcohol under pressure. When he bulb (E) is subjected to changing temperatures, he alcohol expands or contracts, thus moving the minute column of alcohol forward or backward in he entire length of the tube, and causing expansion r contraction in the spring which moves the needle.

Temperature Regulation

There are three methods employed to **heat a cold engine** more rapidly than if these methods were not employed, as follows: (1) by the use of a radiator hutter; (2) by restricting the water circulation by means of a water thermostat or sylphon; (3) by heating the inlet manifold.

Radiator Damper

A radiator damper or shutter is shown in Fig. 29. It is a very efficient heat-conserving device. Engineers saw the futility of putting gasoline into an engine to get heat and at the same time permitting great drafts of cold air to be drawn through the radiator to drive away the heat. Therefore the shutter was devised to retain the heat, especially on starting during cold weather.

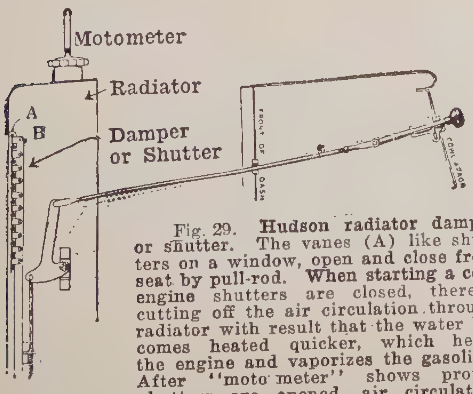

Fig. 29. **Hudson radiator damper or shutter.** The vanes (A) like shutters on a window, open and close from seat by pull-rod. **When starting a cold engine** shutters are closed, thereby cutting off the air circulation through radiator with result that the water becomes heated quicker, which heats the engine and vaporizes the gasoline. After "moto meter" shows proper temperature, shutters are opened, air circulation begins and temperature remains normal.

Thermostat Control of Water Circulation

The thermostat as used on the Studebaker (Fig. 30), is located at the cylinder-block water outlet and serves to make the engine more efficient in respect to power and gasoline consumption by regulating the flow of water through the cooling system. When the temperature of the water in the cylinder-block water jacket is below 150° Fahr., the thermostat valve is closed, allowing the engine rapidly to reach normal driving temperature. As soon as the water reaches this temperature, the valve automatically starts opening and allows water to flow through the usual circulation channels. The small hole in the valve is an air vent, necessary when filling the cooling system with water while the valve is closed.

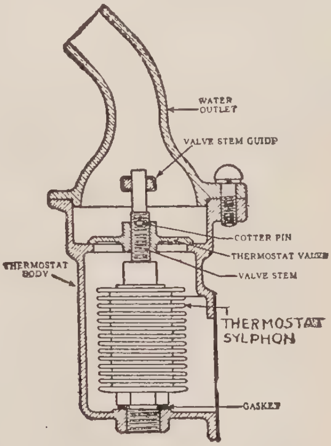

Fig. 30. Thermostat control.

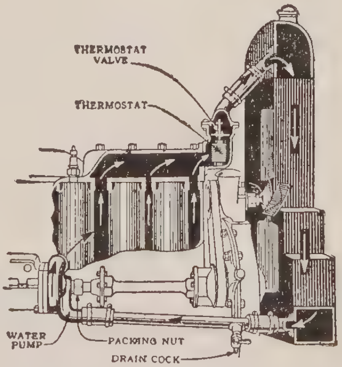

Fig. 31. View showing where the thermostat is placed in the water circulation system (Studebaker as an example).

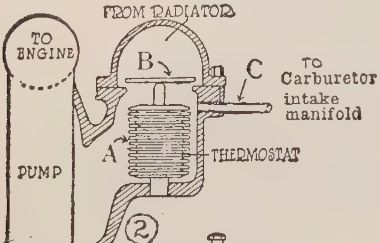
If the sylphon becomes inoperative, the valve will remain open and circulation will continue the same as if no thermostat were used. This necessitates installation of a new sylphon.

To install a new sylphon, remove the thermostat assembly from the engine and disassemble the cover by removing three screws which hold it to the body. Unscrew the sylphon from the body by the use of a wrench on the hexagonal base of the sylphon, and remove the valve from the stem. In replacing with a new sylphon, make sure that it is drawn tight against the copper gasket in the bottom of the body. Then screw the valve on the stem until it just rests on the seat and place the cotter pin through the stem and valve to make secure. If the hole in stem and the notch in valve do not line up at this point, back off slightly to obtain alignment.

Cadillac Water Thermostat

A housing containing a sylphon thermostat and a valve controlled by the thermostat, are located on the cover of each water pump.

The sylphon thermostat (A) (Fig. 32) is accordion shaped. It contains a liquid which is driven into gas when heated. The resulting pressure elongates or expands the thermostat, forcing the valve (B) from its seat.



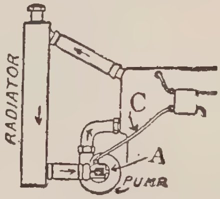


Fig. 32

Fig. 32A

A drop in temperature changes the gas back to a liquid, reducing the pressure in the thermostat and allowing it to contract, thereby bringing the valve (B) back to its seat.

This valve on thermostat is placed in the line of circulation of water, to the side of pump (Fig. 32A). When cold, the thermostat valve (B) is closed, thereby stopping circulation. When warm it expands and opens the valve (B), which permits the pump to draw water from the radiator.

A hand control, connected with a shaft extending from the cover of the pump, is also provided from the seat, which can raise this valve, in order to drain the radiator.

On the Cadillac models 55 and 57, the water-circulation pipe (C) is through the jacket of the inlet manifold. **On the Packard** this thermostat is placed directly at top of the radiator (rear), similar to the Studebaker (Fig. 31).

Radiator and Hood Cover

The use of a **radiator cover** over the cooling surface of the radiator during cold weather is advisable. The roll in front on the radiator cover can be lowered or raised during cold weather, until the engine warms up. Some merely tie a piece of card board over the lower front of the radiator during extreme cold weather.

The radiator cover should be left over the front of the radiator until the engine is heated up, as shown by the motometer. This prevents the fan from drawing cold air through the radiator.

Another point relative to a radiator cover is that the cover should be designed so that the lower part of the radiator remains covered, more so than the upper part, especially with thermo-syphon systems, even though a non-freezing mixture is in the solution, because the solution does not start to circulate until hot and in many instances the water freezes in the lower rubber tubing connecting the radiator with the engine, thus preventing circulation and causing steaming.

To tell whether the radiator is frozen, feel the water inlet pipe at the bottom of the radiator. If it is cold, and the upper connection is hot, then you may know it is frozen at the bottom. See also page 154.

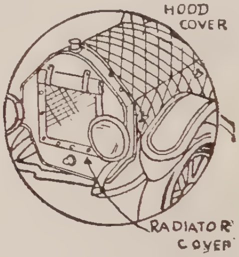

Fig. 33

Hood cover: During cold weather the hood cover is advisable, as it tends to retain the heat under the hood.

WATER-COOLING TROUBLES

Water

In localities where pure water is not easily obtained, it is well to strain the water through muslin. Soft water is better than hard water, because the latter is likely to deposit a scale on the walls of the radiator. The best water to use is rain water.

It is very hard **to tell whether water is hard or soft,** but the following may be used with success: Take a quantity of water in the hands and go through the motion of washing. If it is difficult to rub the hands together, the water is hard. Ordinary city water is generally hard to some extent, but is not as bad as that which is found in streams. Rain water is very soft, and for that reason is desirable for automobile use.

Many automobilists have a rain catcher on the roofs of their garages, while others depend on the old-fashioned rain-barrel. The water should be filtered first, however, if it is taken from the roof, as it is likely to contain impurities. But even with fairly soft water the monthly use of a soda solution will prevent harm (this applies only in districts where the water is unusually hard).

Water-Circulating Pump

The pump requires no attention, other than to see that it does not become choked by using dirty water. There is a "packing nut" on the shaft, which, if the pump should ever leak around the shaft entrance, should be repacked. This can very easily be done by turning off the packing nut (see Fig. 31), removing the old packing, and rewinding the shaft with a few inches of "well-graphited or wick packing" and tightening up the packing nut. The packing should be wound on in the same direction as that in which you turn the nut to tighten it.

Sometimes the pin which connects the pump with its shaft becomes loose or sheared. See page 153, for a discussion of "Broken Pump Shaft."

Where a pump is used to circulate the cooling water, it is wise to fill the radiator to the top and then turn the engine over several times, so as to insure the water reaching and filling all parts of the system. If the engine is not turned, the pump is an obstruction to the passage of the water into the jackets, which remain partly empty, or fill so slowly as to leave the impression that there is more water in the system than there actually is.

Fan

The fan requires no particular attention, except oiling. Sometimes the belt gets loose and causes the fan to slip and not to turn as rapidly as it should, causing overheating of the engine. If this happens, loosen the nut which holds the eccentric arm of the fan, raise the arm slightly, and retighten the nut. This will tighten the belt. Note that this nut frequently has a left-hand thread. Do not tighten too tight, as you are liable to crack the fan support. See also Figs. 8A., 9, and 36.

Cleaning Radiator

The circulating system should be carefully washed out, early in the spring, because the anti-freezing solutions, used in the winter, are likely to leave the tube clogged up. In summer, it is advisable to flush out the circulating system about once a month.

To do this properly, the radiator inlet and outlet hose should be disconnected, and the radiator flushed out by allowing the water to enter the filler neck at ordinary pressure, whence it will flow down through the tubes and out at the drain cock and hose. The water jackets can be flushed out in the same manner.

To remove scale from the inner surface of the radiator: One method is by using hot water, in which a small amount of ordinary washing or baking soda (about one teacupful to each two gallons) has been dissolved. Fill the radiator with this solution, and then start the engine and run it with the spark retarded for about 15 or 20 minutes until the solution becomes hot and has thoroughly circulated through the entire water system. Drain off the solution and thoroughly flush the system with clean water, using a hose for the purpose. Do not permit the soda solution to remain in the radiator for more than an hour. Be careful not to spill any of the soda solution on any painted or varnished surface.

For very hard deposits a solution of one quart of commercially pure muriatic acid to five gallons of water circulated through the cooling system slowly for five minutes is advised by one manufacturer.

Another good method is, to one pint of glycerine add enough boiling water to fill the system, then run the engine slowly and drain out after running, and flush with fresh water. Reversing the flow of water in flushing also helps.

Cleaning a muddy radiator: If the air spaces of the radiator become clogged with mud, after driving over dirty roads, do not attempt to remove the mud with a screwdriver, wire, or other metal instrument. Instead, soften the mud with water. The best way is to wash the radiator by flushing a stream of water from a hose through it from the rear. In doing this, take care not to let water get into the magneto or electrical system, which is likely to be short-circuited in that way.

Hose Leaks

The rubber hose (H, Fig. 34) **and its connections** (C) are often a source of leaking. When the hose is worn it will become ragged-looking on the outside. The rubber which surrounds the fabric will commence to have a torn appearance and the water will seep through the fabric. There are two ways of remedying this; one is to renew the hose, and the other is to repair old hose. The first is the better and more permanent repair. In doing this a piece of hose of the same thickness and length as that now in place is secured. The clamps which hold the hose in place are removed. The new hose is slipped in place and the clamps put over it and screwed up tightly. Paint all threads of water pipes with white or red lead.

A good plan is to use shellac or rubber cement on the ends of pipes before placing on the hose.

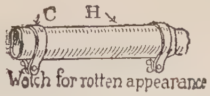

Fig. 34

On airplane engines, where hose connection is made to a pipe, it is connected with a "connector" and then taped and shellacked.

Where gaskets are used on water manifolds, it is not necessary to use shellac. Usually copper gaskets are best, or sheet packing such as "rainbow" or "mobolene," is often used. Do not use leather.

On cylinder heads copper gaskets interlined with asbestos are used extensively. Use heavy oil on both sides when replacing. Be sure the surface is clean.

If gaskets are old, they usually have a rough surface. Clean thoroughly and use shellac on both sides. Do not permit shellac to get into the cylinders, which will happen if put on too thick. See Index under "Gaskets."

Cylinder Leaks

Cylinder leaks: A slight leakage of water from the jacket into the cylinder may be caused by a crack, but more usually will be found to be simply a defect in the seating of the pipe plug fitted in the heads of many engines.

A crack in the cylinder, when on the inside, is difficult to locate. Its action may be of such a nature as to be only operative when the engine is at full working heat (due of course to the expansion). It is generally accompanied by misfiring and boiling, the former owing to leakage of water into the cylinder, and the latter owing to the exploding gases (at a very high temperature) being forced into the water-jacket.

The best means of detection is to fill the radiator entirely to top of cap, run the engine till hot, then stop it and turn it over by hand against the compression in each cylinder. If there is a crack, bubbles will appear at the cap. Thus, by noting the compression of each cylinder, the defective one can be located.

Slight leaks inside of the cylinder have been remedied by rusting, if the hole is very small. See Index under "Rusting a hole in cylinder."

Leaky Radiators

Leaks in the radiator are often hard to reach. They are detected by the steam arising from the water that flows through the leak and down the outside of the radiator. The great facility with which the cooling water will boil after the radiator has been refilled is another clue which, although it is common to all leaks in the system, will lead the operator to the point at which it occurs. On the subject of testing for radiator leaks, see Index.

Scouring out the circulation system with a strong alkali, such as soda, will sometimes tend to seal up any small leaks, and it might also be effective for a slight crack in a water jacket, as the soda, coming in contact with the iron, would form an insoluble filling and prove even better than rusting up the crack.

The standard honeycomb radiator is somewhat prone to these leaks; the metal is so thin and the joints so numerous. It is not always possible to have a leak soldered up at the required time. In this case recourse can be had to a small, useful accessory known as a "leak preventer." It consists of a couple of small plates or washers with a piece of sheet rubber fixed on; these plates have hooks, so that a spiral spring can be fixed on to draw them together. The spring is threaded through the aperture at the leaky cell, the plates hooked on, and thus held firmly up against it. Most accessory houses keep them, and if the car has a honeycomb radiator it pays to carry several of these devices. The construction of this type of radiator lends itself to a repair of this kind, but leaks in other forms of radiators, when they occur on the road, are rather troublesome. Even soldering them is by no means an easy job. There being such a large mass of metal, the solder cools as soon as it touches it.

A temporary repair can be made with white lead, especially if a piece of tape can by any means be bound over the repair. It is often possible to hammer up or plug a leakage in a tank or radiator.

Leak Preventives

There are many so called leak preventives, for instance, a cement called **cold solder.** The manufacturers claim that by pasting externally on the leak (Fig. 35), it will harden and stop a leak temporarily until the radiator can be repaired. (Stone Solder Co., Cleveland, Ohio.) Another leak preventive is a **chemical mixture of cement** which is placed internally in the radiator when the water is hot. The solution is supposed to pass out of the leak in the radiator and as it is exposed to the air it hardens and closes the leak. It is claimed that this preparation will also close cracks in water manifolds, etc.

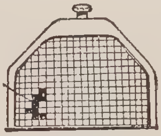

Fig. 35

One radiator manufacturer states that ordinary bran mixed with water will stop a slight leak. The writer has never tried this. Another manufacturer advises against the use of bran, meal, or patented preparations. The best plan is to have the radiator soldered. See Index under "Radiator repairs."

Some of the manufacturers of radiator cements are Woodworth Mfg. Corpn., Niagara Falls, N. Y.; X-Laboratories, 630 Washington St., Boston, Mass.; N. W. Chemical Co., Marietta, O.

Paint for radiator fins can be made from drop black ground in Japan and gold size, thinned with turpentine. See Index under "Painting radiator."

Water Boiling

Water boils at 212° Fahr. at atmospheric pressure. For this reason the cooling system of an automobile is so designed that the water is at a temperature of about 170° to 200° under average running conditions. This leaves quite a margin before the boiling point is reached.

When climbing a hill with a retarded spark, the engine naturally becomes warmer and for this reason the margin is left, although as a matter of fact the engine would run at a higher efficiency if the temperature of the cooling water could run higher. If the cylinders are kept too cool, it means that too much heat is being withdrawn from the explosions. On the other hand, if permitted to become too hot, power is lost through: (a) the entering gases being unduly rarified or prematurely expanded, and thereby containing less combustible material per volume; (b) friction due to the thinning of the oil, and probable binding or seizing of the piston or bearings.

Therefore **the best water temperature** to maintain is about 170° to 178°.

To determine if the boiling is due to stoppage of circulation, feel the radiator. It should be slightly hotter at the top than at the bottom, but if clogged, there will be a pronounced difference in temperature.

Do not get alarmed if the water boils occasionally, especially in driving through mud and deep sand or up long hills in extremely warm weather. Remember that the engine develops the greatest efficiency when the water is heated nearly to the boiling point. But if there is persistent overheating when the engine is working under ordinary conditions, find the cause of the trouble and remedy it. The chances are that the difficulty lies in improper driving or in carbonized cylinders.

No trouble can result from the filling of a heated radiator with cold water, providing the water system is not entirely empty, in which case the engine should be allowed to cool before the cold water is introduced.

OVERHEATING OF ENGINE

In some engines an inclination to overheat gradually develops as the car gets older, and appears to defy all efforts to remedy by attention to carburetion or ignition.

This may be due to the clogging of the cooling system with incrustation or to deposit in the walls of the cylinder jackets and the water system generally.

Assuming that the design and the construction of the engine, including all features of the cooling system, are correct, then, except for leaks, insufficient water, and bursting of the water jackets from freezing, **overheating is the final result of all troubles from the cooling system,** and overheating is generally due to one or more of the following causes:

1. **Insufficient water supply** in the radiator.
2. **Constricted holes in the gasket** where the pipe connects to the cylinders and pump.
3. **Frayed hose connections** clogging the water passage.
4. **Incrustations or lime deposits** on the wall of cylinder or radiator tubes.
5. **Carbon in the cylinders.** In such a case, remove the cylinder head and scrape out the carbon.
6. **Driving on low gear.** The engine should not be raced when driving on low gear, and the spark should be well advanced, because the engine speed is comparatively high. Do not use low, when high speed can be used without straining the engine.
7. **Spark retarded too far.** Keep the spark advanced as far as possible, without causing the engine to knock. As the throttle is opened and the engine slows down, it is necessary to retard the spark.
8. **Poor ignition.** If the engine is misfiring, it is necessary to open the throttle much wider and to retard the spark; this tends to cause overheating.
9. **Valves.** The exhaust valve may not open early enough to discharge all of the burned gas.
10. **Carburetion.** Too rich a mixture, or driving with the throttle open too far and the spark retarded too much.
11. **Insufficient or poor quality of oil.** Lack of oil will cause such friction between the pistons and the cylinder walls that the engine will overheat and the pistons may stick. Poor oil burns up, or becomes thin and runs away so quickly that the parts are left practically without oil. Use good oil—it costs less in the long run.

12. **Racing the engine.** Close the throttle when the clutch is disengaged, and so save gasoline and prevent overheating.

13. **Clogged muffler.** Too rich a mixture or too much oil will deposit soot in the muffler and by preventing the escape of the exhaust, will cause overheating. Clean the muffler by disassembling it.

14. **Water frozen—steams.** To thaw out, open drain cock. Water usually freezes at bottom of the radiator, therefore pour hot water on the bottom until circulation starts. This will be indicated by water running out of the drain cock. Then close the drain cock and fill the radiator with water and keep the engine running. Sometimes when the engine steams, if a blanket is thrown over the engine and radiator, the heat will thaw out the bottom of the radiator. See page 150 under "Radiator and hood cover," on how to tell when the water is frozen at the bottom of the radiator.

15. **Fan not working properly.** A broken or a loose and slipping belt will not rotate the fan fast enough to draw a cooling current of air through the radiator. This will tend to cause overheating when the engine is idling or running on low gear. Tighten or replace the belt. Perhaps it may be necessary to bend the fan blades at a slightly sharper angle, in order to draw more air through the radiator (see Fig. 36).

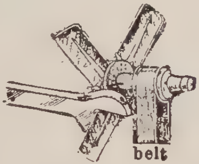

Fig. 36

16. **Poor water circulation** due to low water. Where the thermo-syphon system is used, the water will cease to circulate as soon as the level falls below the inlet to the radiator. Keep the radiator well filled. Leaks may lower the water level. The rubber hose connections may have rotted and a flap of rubber on the inside of one of these hose connections may seriously impede the flow of the water.

17. **Broken pump shaft.** It is difficult to tell whether or not a circulating pump is working. Remove the radiator cap and see if water is circulating while running the engine. The pin holding the pump shaft may be sheared off, yet the pump shaft would continue to revolve.

18. **Brakes dragging.** This would call for an increase of power from the engine. Examine the brakes with rear wheels jacked up.

19. **Bearings.** If the engine is new or just overhauled, the bearings may be too tight. Put in plenty of oil and run until loosened up.

20. **Radiator clogged with mud or dirt,** or an obstruction in front of the radiator, thus preventing passage of air.

Fire Truck Engine—How Cooled

Q.: How does the engine on an automobile fire truck cool itself when the engine is running continuously for long periods with the car standing, which is often the case at a fire?

Ans.: There is a cooling line from the discharge side of the main pump directly into the water manifold. This is a ⅜″ line, and is controlled by a gate valve which enables the operator to keep the engine at any desired temperature. An overflow on the radiator allows this cooling water, which amounts to 8 to 10 gallons per minute, to pass off.

NON-FREEZING SOLUTIONS FOR COOLING SYSTEM

In winter, a water-cooled **engine must be carefully guarded against freezing,** for if the water freezes in any part of the system it will cause the breakage of piping or radiator, or crack a water jacket. When the engine is running, the water is kept warm, therefore the danger is not as great. It is advisable, however, to take no chances, as freezing has been known to occur, even with the engine running.

When leaving the car for several days, during cold weather, the safest plan is to drain the water out of all parts of the system, cocks being provided for the purpose at the lowest point of the system, usually at the bottom of the radiator. The engine should be run for a few minutes to make sure all the water has been removed.

Non-Freezing Solutions

Note. Be sure that there are no water leaks. Tighten up hose connections and drain the water system and wash it out thoroughly before putting in non-freezing solutions.

To prevent the water from freezing when it is not desirable to drain it out, there are a number of chemicals which can be mixed with the cooling water, such as calcium chloride, wood alcohol, denatured alcohol, glycerin, and alcohol.

Calcium chloride (common salt of calcium) or any acid or alkaline solution is injurious to metal parts, and if there are leaks it will corrode the parts. The amount of calcium chloride to mix with water is given in the table below. Calcium chloride is simply mixed with water in the proper proportion. It is best to make a saturated solution of the salt, and then add this to water in desired proportion. It dissolves quickly in hot water.

In using calcium chloride it is the acid in it which attacks the metal. This can be neutralized by adding ammonia or soda ash until blue litmus paper no longer turns red when dipped into the solution.

There are three grades of alcohol: denatured alcohol, which is a disguised grain alcohol of first still (not suitable as a beverage). It sells for about $1.05 per gallon and has a higher boiling point than wood alcohol. Wood or methyl alcohol sells for about $1.60 per gallon, and has a lower boiling point. The high-proof or double-still grain alcohol used as a beverage is too expensive. Therefore, denatured alcohol is cheaper, has a higher boiling point, and is the proper thing to use.

Wood alcohol boils at 153° Fahr. and denatured alcohol boils at 171° Fahr. Therefore alcohol, while it is not injurious in any way, lowers the boiling point of the water. Consequently on warm days, with the car standing and the engine running, the solution will tend to boil easily and to evaporate. However, denatured alcohol and water is the least expensive and is probably used more than any other solution. The proportions of denatured alcohol, or of wood alcohol and water are given in the table below.

For losses by evaporation, use 75 per cent alcohol to 25 per cent water, as the alcohol evaporates quicker. This does not apply to loss by leaks or boiling over. It is best however, to check the solution with a hydrometer before filling, and to add alcohol and water until the specific gravity as shown in the table is reached. It will be observed that as the specific gravity is given in the table, a hydrometer may be used for mixing and maintaining a correct solution, by first testing the original and keeping it up to a standard.

The use of glycerin raises the boiling point of the solution. It is more expensive than alcohol (a pound of glycerin costs about 50c.; there are 10 lbs. to a gallon) and is slightly injurious to rubber.

Glycerin and alcohol mixed with water can be used. The proportions are given in table below.

Where glycerin, alcohol and water are used, only the alcohol need be replaced for evaporation, which should be added occasionally. The glycerin does not evaporate with the water. If there are leaks, however, the glycerin and alcohol should be replaced.

Glycerin and water alone is not advisable, as this solution would form crystals at temperatures slightly lower than zero. Hence the necessity of adding alcohol due to evaporation.

Where engines are equipped with thermostat temperature controls, the glycerine mixture is the best to use.

For a second filling of any of the solutions, the best plan is to take a hydrometer reading of the specific gravity of solutions when mixed, and to keep the solution up to standard.

Non-Freezing Solution Table

The table below prepared by Mr. P. J. McCullough, gives the freezing temperature of four different anti-freezing solutions in various proportions of mixture with water for ten gallons of solution. The number of pints of each liquid required for 10 gallons (80 pints) of solution is given as designated. If a mixture of 5 gallons is required, then use one-half the quantity of each. If a mixture of 15 gallons is required, use the amount shown in the table plus one-half additional.

What to Do if the Water Freezes

If the cooling water should freeze, the usual indication of a frozen radiator is steaming excessively. It would appear that the steam or heat would thaw it out and start the circulation again, but such is not the case. When the water freezes, do not run the engine to try and start circulation as the fan draws in cold air and only assists in keeping it frozen. Find the nearest warm garage and, if possible, turn hot water on the bottom of the radiator until steaming ceases, as a radiator in this instance usually freezes at the bottom first.

When the engine overheats by steaming, due to frozen water, feel the radiator and inlet hose connection between the engine and radiator at bottom. If cold at the bottom and hot at the top, the bottom is frozen; if warm, then circulation is all right, and the trouble is due to lack of water or something else.

In addition to using a non-freezing solution, it is always well, when making a stop, to **cover hood and radiator.** See Fig. 33, page 150.

Also **draw in a full charge of gas** by speeding up the engine slightly and opening the throttle, before stopping.

In carbide-gas lighting generators, using the water drip, a suitable non-freezing solution is alcohol and water in equal proportion (no glycerin).

Kerosene for Cooling

Objections to kerosene are the odor of heated kerosene. When heated, kerosene evaporates and is liable to cause a fire if near a flame; on warm days in winter there is a tendency for the engine to heat on account of difference in the coefficient of heat of kerosene and water or alcohol; kerosene rots radiator tubing and will also deposit a greasy mist over the car. Gas is also liable to form and cause expansion and bulging of the radiator. The boiling point of kerosene is much higher than alcohol. See Index.

Kerosene is used in extremely cold climates where engines are equipped with water-circulating pumps. It could not be used at all with the thermo-syphon system.

Cadillac Condenser

The Cadillac patented condensing device is shown in Fig. 37. With this device it is possible to use with safety the expensive alcohol solution as an anti-freezing cooling medium. A condenser of simple construction is attached to the frame, and is connected by a tube to the overflow which runs from the upper tank of the radiator.

Alcohol vapor driven out of the solution by heat, as well as any water vapor, is restored to liquid form in the condenser.

When the radiator gets cold, the vacuum produced by the contraction of its contents automatically causes the surplus liquid in the condenser to return under atmospheric pressure to the radiator.

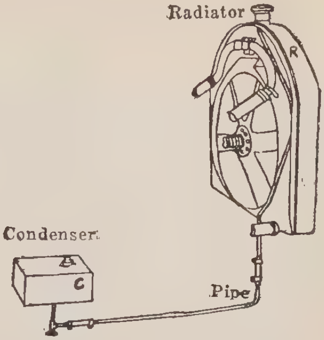

Fig. 37

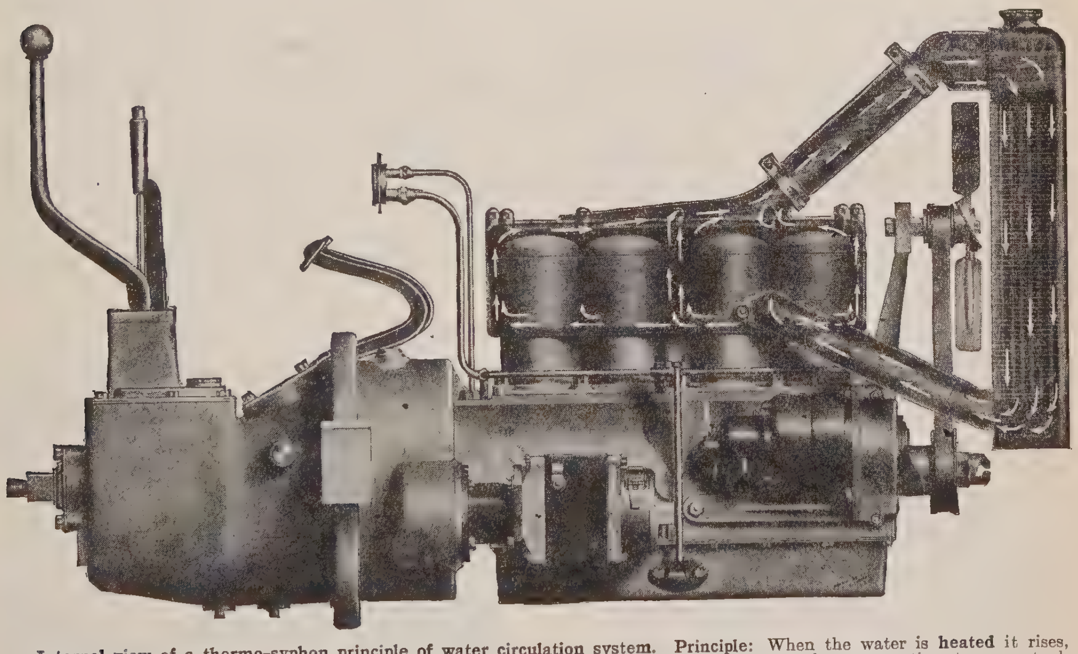
TYPICAL EXAMPLE OF A THERMO-SYPHON WATER-CIRCULATING SYSTEM

The illustration below is that of the Golden-Belknap and Swartz 4-cylinder engine showing the outer water jacket of the cylinder removed to show the **direction of flow of the water.**

The reader will also gain an idea from this illustration as to the location of a **starting motor** (to the left) and the **generator** (front). The generator is operated by a silent chain (encased). Note that the **fan** is operated from a pulley on the end of the crank shaft. The **pressure oil gauge** is shown to the left, above the foot pedals, and is attached to the dash.



Internal view of a thermo-syphon principle of water circulation system. Principle: When the water is **heated** it rises, and passes from the top of the water jacket at the top of cylinders, through the upper rubber hose connection, to upper tank of radiator, through radiator cores, whence it is **cooled** by air drawn through the radiator openings by the fan. The cooled water then passes to the lower radiator tank, up through lower hose connection, to lower part of cylinder water jackets.

The word **"thermo"** pertains to heat and the word **"syphon"** refers to drawing off a liquid from a higher to a lower level. Thus the water rises from a high level due to the heat in it, or to being lighter, or less dense.

By referring to page 146, Fig. 4, this thermo-syphon principle of water circulation can be compared with that of the "forced water-circulation" system.

AIR COOLING

The object of cooling is to remove the excess heat from the cylinders. There are only a few cars on the market in which this is accomplished by the air direct, without the use of water.

Air-cooled engines usually have small-bore cylinders.

The different methods of air cooling are summed up as follows:

(1) By having a large radiating surface by means of cast flanges or gills, inserted pins, or tubes.

(2) By using extra large exhaust valves, so as to cool the combustion space between power strokes.

(3) By combining large radiating surfaces with low speeds in multiple-cylinder engine.

(4) By the use of auxiliary exhaust ports, combined with surface radiation.

(5) By forced draught of air circulating through an air jacket around the cylinder.

A cylinder with radiating flanges is shown in Fig. 38. When in motion, the current of air blowing against the flanges drives the heat away. This principle is used extensively on motorcycle engines.

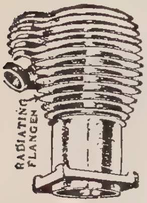


Fig. 38

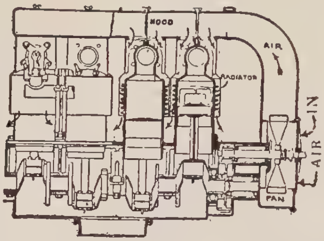

Fig. 39

A forced draught air-cooling system is shown in Fig. 39, formerly used years ago on a prominent make of car. With this system the circulation of air was forced through jackets placed around each cylinder, open at the bottom and top, being connected to a pipe from a centrifugal air blower or fan. The forced air passed the radiator flanges, and out at the bottom. In some respects, this principle is similar to that in use on the Franklin.

The Franklin air-cooled engine is a very successful engine for automobile pleasure cars employing the air-cooled method. The six cylinders are 3¼″ bore and 4″ stroke, giving a formula horsepower of 25.3.

By referring to the illustration (Fig. 40), the path of the air is shown, first through the hood, thence over and down through the air jackets. The air is then deflected downwards and out through the flywheel blades.

Vertical steel fins are made integral with the individual cylinder casting, by having the iron poured around the strips of steel. Very light aluminum jackets guide the air draught downward from the heads of the cylinders.

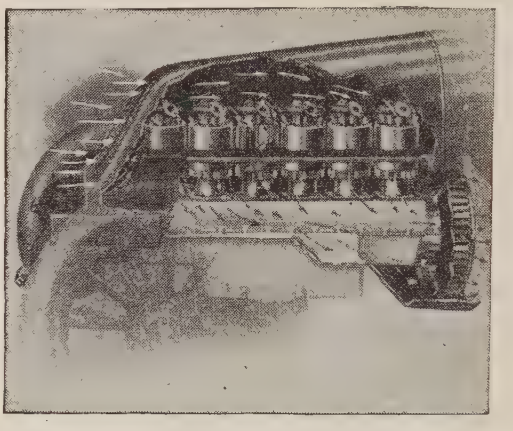

Fig. 40. Direct air cooling of the Franklin. The fly wheel is the only moving part of the cooling system.

Note the vanes in the fly wheel, which create a suction equal to 2,200 cubic feet every 60 seconds; a continuous flow of air literally wiping the heat away. It is stated that the heat on a Franklin engine is about 350° Fahr. (see Fig. 12, page 107, for Franklin exhaust-heated inlet manifold). This heat is shut off after the engine is warmed up.

The Franklin at one time employed **auxiliary exhaust valves** to assist in dispelling the heat of explosion from the cylinder as rapidly as possible. This method, however, has been discontinued.

Another popular make of air-cooled car is the Holmes, manufactured by The Holmes Automobile Co., Canton, Ohio.

HEATING A CAR

There are three methods of heating a car as explained below:

(1) hot water; (2) exhaust gas; (3) hot air.

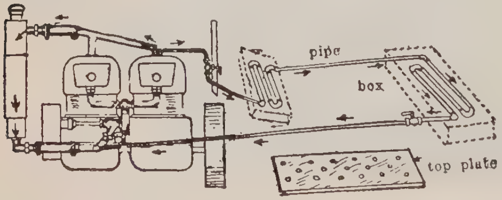

Fig. 41. Hot-water method of heating a car.

The hot-water method is shown in Fig. 41. This method can be used only where there is a forced or pump-circulation system. Connections are made with the circulating system at the top of the rear cylinder. The water circulates through the heater, whence it returns to the bottom of the radiator.

The heater is made of regular water pipe, and the housing of aluminum or light cast iron. The floor is cut away, allowing the surface of the heater to be flush with the floor. The top plate, made of aluminum, is then placed over the heater box.

The exhaust method for heating is to utilize the exhaust gases instead of water. In this instance the pipes would be connected with the exhaust pipe instead of with the water pipe. Only one side, the inlet, would be connected and an outlet is provided for the emission of the gas.

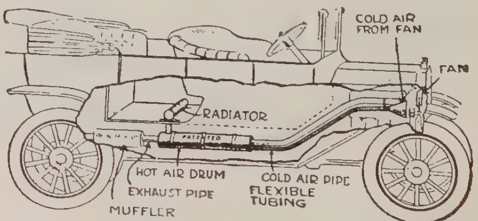

Fig. 42. Hot-air method of heating a car.

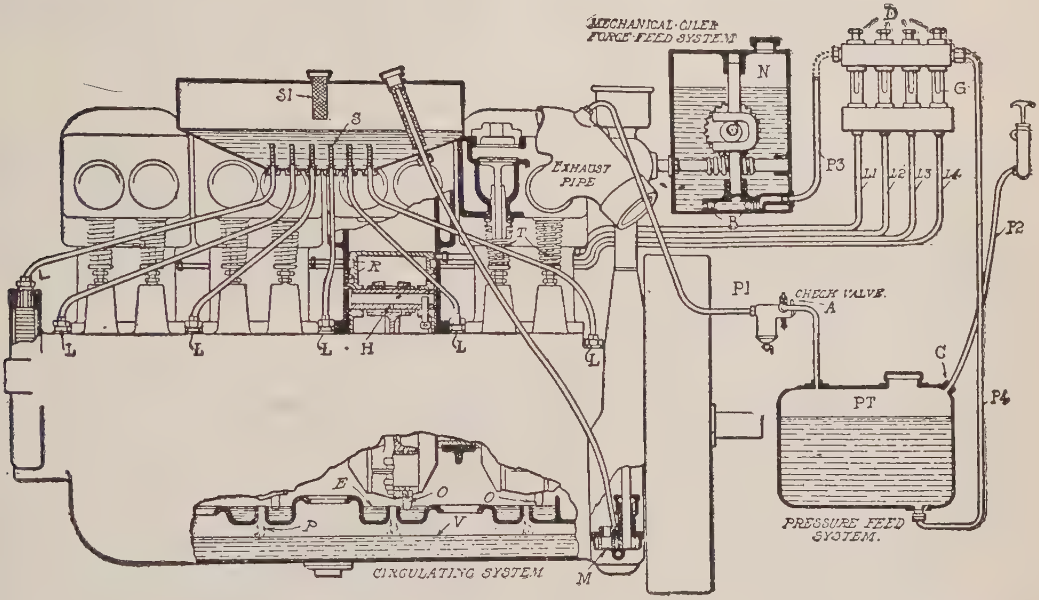
The hot-air method is shown in Fig. 42. This example illustrates the Brickly (patented) method. The air is taken from the fan through a funnel opening, and a flexible metal hose drives it through a metal jacket 24 to 30 inches long, which covers the "piping hot" exhaust pipe, and warms it thoroughly. It then drives it through a 1½-inch opening in the floor of the car, into a tubular register, along the back edge of the front seat, sending a continuous stream of heated air into the car. (Exhaust gases are not used.)

INSTRUCTION No. 16

LUBRICATION: Engine Lubrication Methods; Purpose of Lubrication; Oil Gauges; Kind of Engine Oil to Use; Engine Lubrication Troubles; Relation of Carbon to Lubricating Oil; Pointers on the General Lubrication of a Car



Some of the early methods of engine lubrication: There are four different systems shown on this engine in order to clearly explain each system. The systems are enumerated and described below.

EXAMPLES OF SOME OF THE EARLY ENGINE LUBRICATION SYSTEMS

Splash system: We will assume that oil is placed in the crank case through the breather pipe. The scoops (O) on the end of the connecting rods pick up the oil from troughs (E), and splash it to the various parts. This would be termed a "non-circulating" system.

Splash, force, and gravity: We will assume that the splash system just described is a part of this system. The overflow passes to reservoir (V); it is then forced by pump (M) to a gravity feed reservoir placed on top of the engine. The passage is then through the different pipes (S to L) to the bearings, thence back to the troughs (E) and reservoir (V). This system would also be termed a circulating system, as the oil is in continual circulation.

Force feed and splash: The mechanically operated pumps (B) are driven by belt, chain, or gears. There are several small pumps in the oil reservoir box (N), in fact a pump for each feed; the delivery pipe is from (B) to (D) through pipe (P3) and each separate feed (L1, L2, L3, L4) are piped to the different parts to be lubricated. The oil passes through a sight glass (G). The oil then passes to the bearings and falls to the bottom of the crank case. The oil reaches such a level or height in the crank case so that the connecting rods give an additional lubrication by splash. The amount of oil fed is regulated by drops, through the sight glasses, by the regulation of the screws (D), and depends upon the size of the engine and on the speed. (Note that pipe (P4) is not connected with this system.) This would be termed a "non-circulating system."

Exhaust pressure feed and splash: This system consists of an air-tight oil tank or reservoir (PT). A small pipe (P1) connects the tank with the exhaust pipe. A check valve (A) permits the gas pressure to pass into the tank but not to flow back.

The initial pressure is given to the tank by a small hand pump through pipe (P2). After the engine is started, the pressure from the exhaust is sufficient to force the oil through pipe (P4) to the sight-feed glasses, thence to the various parts to be lubricated —thence to the crank case.

This system, like the third system, requires oil to be fed by drops, as it is not pumped over and used again, and would be termed a "non-circulating system."

With the exception of the "splash system," the systems mentioned above are now seldom used.

Note. The illustrations above are not intended to exemplify the latest approved engine lubrication methods. In order that the reader may clearly understand the advantages of the modern engine lubrication systems, it is necessary that he understand the early systems. Furthermore, he may have occasion at times to work on engines equipped with some of the early systems. Moreover, some of the systems shown above are now used on marine and stationary engines.

PURPOSE OF LUBRICATION

When two parts of a mechanism rub together, it is necessary to use some means of preventing excessive friction, and this is usually done by applying a **film of lubricating oil** between them. Without a lubricant the friction would cause heating, and the result would be cuts or scratches on the surfaces of the two parts.

Two parts intended to rub together, like a shaft in its bearing, should be made as smooth as possible, for roughness would cause friction that lubrication could not prevent. The more rapid the movement of the parts against each other and the greater the pressure, the more they must be lubricated.

A bearing in which a shaft is turning at a constant speed requires a constant supply of oil which must be fed to it regularly as required. Too much oil would be wasteful, and too little would permit the bearing to become heated. All the moving parts of an automobile must be lubricated, but as some parts move much more than others and are subjected to greater strain and pressure, the kind of lubrication must be varied to suit these conditions.

ENGINE LUBRICATION SYSTEMS

The principal parts of an engine to be lubricated are: main shaft, cam shaft, crank pin and wrist pin bearings; cylinder walls, piston and piston rings, valves, push rods, and all moving parts.

Methods of engine lubrication may be divided into two general classifications: the "circulating" and the "non-circulating" systems.

The circulating systems would be represented by systems having a continuous circulation of oil and these are frequently termed the "pump over" systems. For instance, a system using a force pump for pumping the oil from the lower part of the crank case to the upper part, with a drain back to the lower part again, would be termed a "circulating system."

A non-circulating system, such as a drip or gravity system, or a mechanical feed, so many drops per minute, depending upon the speed and size of the engine, with no provision for circulating the oil again, would be termed a "non-circulating system."

These systems may be combined, which is frequently done. For instance, the combination of a "forced feed" and "splash" system is often met with.

But, speaking generally, the systems can be grouped under: (1) splash, and (2) forced-feed lubrication.

Drip (or Gravity Feed) and Splash

This non-circulating system consists of a drip or gravity-feed oil cup (Fig. 1) placed over the bearings and also on the side of the cylinder. Special oil cups are required for the cylinder which will prevent the compression interfering with oil entering the side of the cylinder wall.

The oil drips by gravity, and the surplus flows to the oil trough from where it is picked up by the connecting rod and splashed to parts above. (C) is the cylinder and (B) the bearings; (S) is the crank pin. The oil in the lower part of the crank case is kept at a sufficient level for the connecting rod to pick it up and splash. The filling is done once in a while as required, by pouring the oil in by hand.

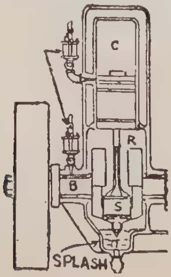


Fig. 1 Gravity or drip feed (oil cup).

The oil cups feed by drops, and usually the manufacturer determines how many drops per minute are required.

The oil flow is not controlled by the engine, and each cup is therefore provided with an adjustment, whereby the feed may be regulated when the engine is running, and turned off when it is stopped. This would be classed as a "non-circulating system."

This system is used extensively on two-cycle marine engines, and stationary engines. Two-cycle engines are also lubricated by mixing the oil with the gasoline through the mixing valve, the mixture being about one pint of oil to five gallons of gasoline.

The Splash System—Non-Circulating

The true splash system alone is non-circulating. The crank case is made oil-tight, and oil is placed in it to such a depth that the bottom end of the connecting rod dips into the oil, and splatters it to all parts of the crank case, the bearings, and the lower part of the piston. An oil groove is sometimes cut around the lower part of the piston, and the oil splashing into this is carried upward and distributed on the cylinder wall and rings. There are no oil troughs in this system.

As the oil is used, more must be added to the crank case to keep the necessary level. This is done either by means of (1) a hand pump connecting the crank case to an oil tank, or (2) by an oil cup that drips a certain amount of oil into the crank case every minute, or (3) by filling through a breather pipe.[1]

With the hand pump, the driver gives it a stroke or two every few miles, experience being his guide as to how often and how much. This latter system, however, is not much used on automobiles, but is extensively used on motorcycles. This system would be termed a non-circulating system.

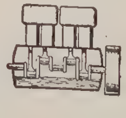

Fig. 2

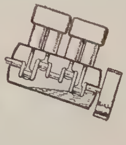

Fig. 3

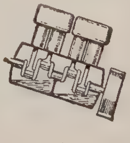

Fig. 4

The objections to the splash system are as follows: a reference to Fig. 2 will show that the engine is in a level position. As long as the engine remains level the splash system gives fairly good satisfaction; that is to say, so long as the level of the oil is kept up to the lowest point of the connecting rod where it can be picked up and thrown to the upper part. If, however, the car is in such a position as that the engine will be tilted, as shown in Fig. 3, then the oil goes to the rear cylinder. The rear cylinder is over-lubricated and the others are under-lubricated. Even though a "baffle" plate is placed as shown in Fig. 4, still there are two cylinders minus oil. Therefore some other means must be employed so that all cylinders will receive their proper share of oil.

---

[1] **A "breather"** for an engine is a pipe opening connected with the crank case, and extending slightly above it, where oil is poured into the crank case. The opening is closed by a cap which does not fit tight, but allows the air to enter, and at the same time prevents oil from working out. (See Fig. 19, page 39, for location of breather or oil filler).

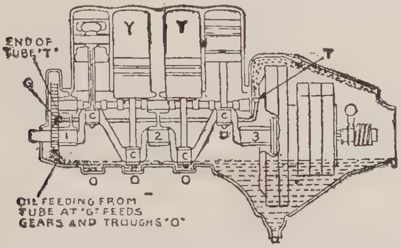

Fig. 5. The Ford semi-circulating system.

Splash System—Semi-Circulating

One method of overcoming the objection just mentioned is to provide troughs (O) under each connecting rod, which is shown in the cut of Ford engine (Figs. 5 and 5A). The troughs retain the oil, even though the engine is at an incline. The next method is to keep the oil at a **constant level** in the troughs. This is accomplished by some means of **circulating the oil.** In this instance the constant level of oil is maintained by the action of the fly wheel.

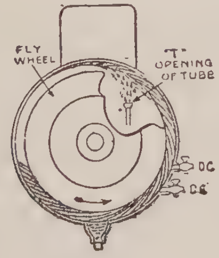

Fig. 5A. Showing how the flywheel circulates the oil.

The fly wheel throws the oil to the top of the transmission case where part of the oil is caught by tube (T) and fed by gravity to the cam gears. The overflow coming back tends to keep the troughs (O) filled with oil. This system would be termed a "semi-circulating system" (used on the Ford engine).

Splash System—Circulating[1]

This system could be termed a "circulating-splash system," also a "pump over" system, and is the true constant level, circulating-splash system because the oil troughs are kept at a constant level by a pump. It could also be termed a "force-feed and splash" system.

The operation of a "circulating" or "pump over" oiling system is shown in Fig. 6; the main oil supply is contained in the reservoir (**R**), from which it is drawn by the pump (**M**) and forced through the pipes or leads (**L**) to the main crank-shaft bearings (**G**).

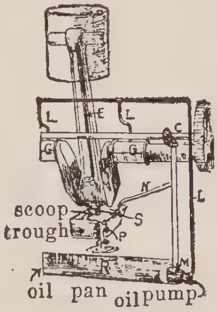

Fig. 6. Circulating system.

The overflow from these bearings is thrown by centrifugal force against the walls of the crank case and cylinders, and, as it runs down, is collected by inclined channels (**N**) which conduct it to troughs.

For lubrication of the connecting rod bearings, scoops (**S**) are fitted to the lower ends of the connecting rods, which dip into the oil contained in the troughs and scoop it up into the crank-pin bearings at the lower ends and through tubes (**E**) running up the rods to the piston-pin bearings.

Overflow pipes (**P**) are provided in the trough, so that the excess oil can return to the reservoir (**R**).

The pump (**M**) is usually a gear type of pump, operated by bevel or spiral gears and vertical shaft from the cam shaft (**C**). On many engines the pump is a plunger type, operated by a cam from the cam shaft.

Force-Feed System

In this system, oil is forced by pressure from the oil-pan by a pump to the crank-shaft bearings, then through drilled holes in the crank-pins, as shown in Fig. 10, page 160. Oil is not forced to the piston-pin, piston and cylinder, but these and other parts are supplied by oil thrown from the crank-pin bearings. The connecting rods do not dip.

Full Force-Feed System

In this system, oil is forced by pressure from the oil-pan by a pump to the crank-shaft bearings, then through drilled holes in the crank-pins, as in Fig. 7. Oil is also forced to the connecting rod, upper part, or piston-pin, through channels or pipes, thence out

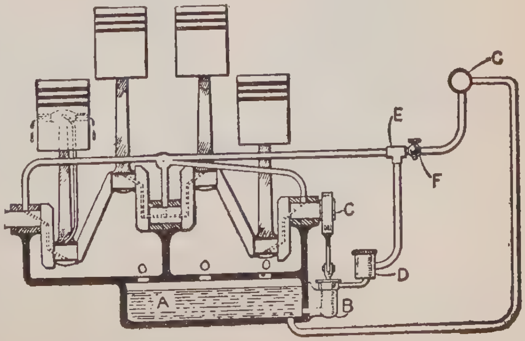

Fig. 7. Diagram of a "full-force-feed" system.

---

[1] The depth of oil in the oil-pan of an engine using the splash system should be just enough so that the splash will distribute the oil.

of the piston-pin to the wall of the cylinder. Thus the difference between the "force" and "full force" system will be apparent. The connecting rods do not dip.

Note the dotted lines showing the path of the oil. **(A)** is the oil reservoir; **(B)** the piston or gear type of pump; **(C)** eccentric or gear for operating pump; **(G)** gauge placed on the dash to indicate the pressure; **(F)** check valve; **(D)** a strainer. This would be termed a true "full-force-feed" engine lubrication system.

Where a "full-force-feed" system is used the pistons must fit accurately as to clearance. If there is too great a clearance there will be an excess of oil in the combustion chamber and smoke will come from the exhaust.

OIL PUMPS

There are two types of oil-circulating pumps in general use: the "gear" type (Fig. 8) and the "plunger" or "piston" type (Fig. 9).

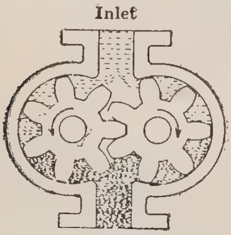

Fig. 8

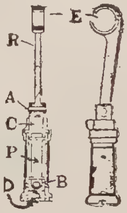

Fig. 9

The gear pump (Fig. 8) is generally used with a "force-feed" system and sometimes with the "circulating splash system."

Gear Pump

The gear pump is usually driven from the cam shaft. The oil is drawn into the spaces between the teeth and then forced out to the distributing pipe.

There are **two methods of mounting a gear pump:** One, by having it **submerged** in the oil as shown in Fig. 10, and another, by having it **elevated** (Fig. 11) above the oil level. In the latter case it is necessary that oil be drawn up to the pump before it will circulate, and quite often, if the oil level reaches a point where the pump loses its suction-effect, it will be necessary to prime it.

The submerged gear-type of oil pump is self-priming. The submerged pump with a large screen will lend itself to the circulation of heavier-bodied lubricants with greater ease than the system with the elevated pump and small screen.

Plunger or Piston Pump

The plunger or piston pump (Fig. 9), quite often used with circulating-splash oiling systems, consists of a plunger **(P)** which draws the oil into the pump at **(D)** on the suction stroke, through a ball valve **(B)**. On the return stroke, the ball valve is closed and oil is forced into the oiling system. The rod **(R)** of the piston pump (Fig. 9) is connected by an eccentric strap **(E)** to an eccentric on the cam shaft, which moves the piston **(P)**.

The adjustment of the piston pump (Fig. 9) is made by screwing the plunger rod **(C)** in, which shortens the stroke, or out, which lengthens the stroke. This shortening or lengthening of the stroke has the effect of regulating the flow of oil. The longer the stroke, the more oil flows, and vice versa.

Rotary Pump

Another type of pump, as used on the Dodge car, is a rotary pump (similar to that in Fig. 6, page 146), which is not submerged. See Index under "Dodge oil pressure."

EXAMPLE OF A FORCE-FEED ENGINE-LUBRICATION SYSTEM USING A SUBMERGED GEAR-TYPE PUMP

A true force-feed engine-lubrication system as used on the King eight-cylinder engine is shown in Fig. 10. There are no troughs and no splash with this system.

Fig. 10. Force-feed lubrication system. (CRB) refers to connecting rod bearings.

Path of Oil Circulation

Oil poured into the filter tube flows down into the oil pan, filling it up to a height indicated by the oil-level gauge on the right-hand side in the center of the engine. Note the float at the bottom of this gauge. From the pan or reservoir the oil is drawn up through the oil pump, which is driven by a vertical shaft from spiral gears on the cam shaft.

The oil pump is a submerged gear-type surrounded by a fine screen, so that all oil entering the system is thoroughly strained to remove the dirt or lint that might stop up the oil ducts and cause damage. The illustration shows the principle of the system, and by following the arrows the oil can be traced from the oil pan.

The gear pump at the extreme bottom of oil pan or reservoir draws the oil through the screen which surrounds it and forces it into a distributing pipe running the entire length of the crank case. From this pipe the oil is forced to each of the three crankshaft main bearings.

From the main bearings the oil is forced through holes in the crank shaft to the connecting-rod bearings. Since, at every revolution of the crank shaft, these holes register with the leads from the distributing pipe, an excess of oil is forced to the connecting rods, where it is drawn off in fine drops or mist on to the cylinder walls. A part of this spray is also utilized for lubricating the cam shaft, valves, and tappets.

Principle of the "spring and ball" valve which regulates the oil pressure. The ball is placed in the path of the oil line with a spring tension behind it. When the pressure of the oil circulation is reached, to which the spring tension is adjusted, the ball is forced open and oil overflows past the hole—in this instance, to the chain sprocket. In other words, it is merely a "relief-valve."

The ball and spring perform the same function as a safety valve on a steam boiler. It can be placed anywhere on the system (preferably farthest point away from oil pump). There are certain positions of the crank shaft when no oil channels register and pressure would build up excessively high, were it not provided with some means of release. When the pressure exceeds that at which the regulating screw is set, it forces the ball off its seat and the oil passes through the channel to lubricate the chains. If this regulating screw were set at too low a pressure, then all the oil would pass out under the ball and the crank pins would go dry. If set too high, the oil feed would be too great and smoke, carbon, and fouled plugs would be the result.

Adjustment

To increase pressure: The pressure-regulating screw (Fig. 10) can be screwed down after releasing the lock nut, which increases the tension of the spring against the ball. Thus more oil pressure is required to force the ball against the spring tension so that it will open the overflow opening.

To decrease pressure, the regulating screw is turned counter-clockwise, which lessens the spring tension on the ball.

It is best **to make adjustment** when the engine is running at a speed equivalent to about 25 miles car speed. At this speed, the pressure should be between 10 and 15 lbs. at maximum car speed, and should not be below 5 to 8 lbs. at minimum car speed. Be sure and **tighten the lock nut.** Always adjust oil pressure when the engine is warm.

Over-lubrication: If the oil pan at any time contains more that seven quarts of oil (King 8), the connecting rods will dip and thus create a splash which will over-oil the pistons and cylinders, more on the right-hand block than on the left, causing smoke to issue from the muffler pipe.

EXAMPLE OF A FORCE-FEED AND SPLASH ENGINE LUBRICATING SYSTEM USING AN ELEVATED GEAR-TYPE PUMP

As an example, the Studebaker Light-six engine is used. Lubrication of the engine is of the circulating-splash force-feed type (Figs. 11 to 11D).

Path of Oil Circulation

Oil is drawn from the oil pan by means of an elevated gear pump, driven by accessory shaft. From the oil pump, oil passes through a pipe to a distributor pipe fastened to the underside of the crank case. By means of four drilled holes in the crank case registering with the distributor pipe holes, oil is conducted to the cam-shaft bearings. Through the bearings of the cam shaft are holes through which oil passes twice every revolution of the cam shaft. When this hole in the cam shaft registers with the hole in the crank case, oil is forced through, allowing gravity feed to the crank-shaft bearings. Besides these holes in the distributor pipe, there is another series of small holes drilled in the under

Fig. 11B

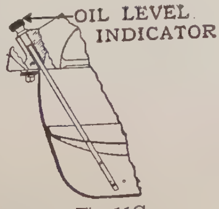

Fig. 11C

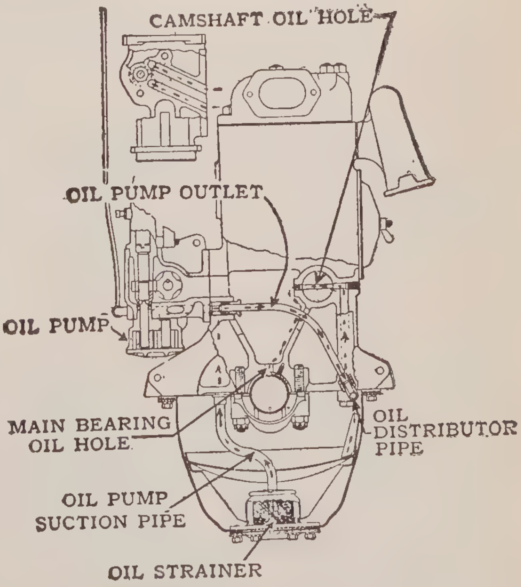

Fig. 11. Force-feed and splash lubrication of Studebaker "Light six" engine.

side of this pipe to keep the troughs in the dip pan filled to a constant level. At each revolution, splashers (Fig. 11B), which are a part of the connecting-rod bearing caps, dip into these troughs, splashing oil which lubricates the connecting-rod bearings, piston, and cylinder walls and piston pins.

From the passage in the case through which oil is forced to the front cam-shaft bearing, is an outlet through the front of the case into which is screwed a plug having four cross-drilled holes near the end. Oil is by this means forced to the silent chain and sprockets, finally returning to the reservoir through a return opening under the front crank-shaft bearing.

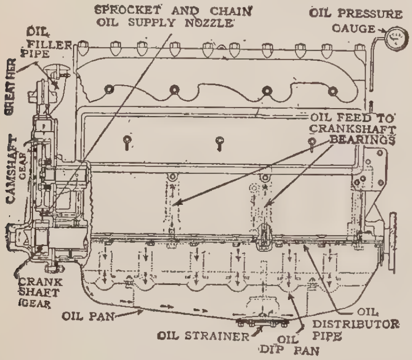

Fig. 11D

An oil-pressure gauge is located on the dash (Fig. 11D), which indicates back pressure on the oil pump. This gauge should normally indicate "one" to "three" when oil has become warm. If the gauge continues to show higher than "three" it is an indication of an obstruction in the distributor pipe, and it is necessary to remove the oil pan in order to clean the pipe. If the gauge does not indicate, the pressure system is inoperative. First make sure that there is oil in the reservoir.

Priming the Oil Pump

If the gauge fails to operate, after finding that the reservoir contains oil, then all joints and gaskets should be checked for tightness and the pump primed by disconnecting the oil-gauge pipe from the distributor base and squirting in oil.

The oil reservoir is filled through a filler tube at front of the engine on the right-hand side.

Oil-Level Indicator; Bayonet Type

Inserted in the right-hand side of the crank case is an oil-level indicator, "bayonet type" (Fig. 11C). In order to determine the quantity of oil in the reservoir, pull the rod out, wipe free from oil, and insert into the case again. Pull the rod out a second time, and the amount of oil in the base can easily be determined by noting the height at which the oil shows on the rod. Empty, half and full positions are shown by grooves in the rod. When the indicator shows that the reservoir is only half full, more oil should be added, but do not continue to add after the indicator registers full.

The quantity of oil required to fill the reservoir is one and one-half gallons.

An oil strainer is located at the lower end of the oil-suction pipe near the middle of the oil pan, as shown in Fig. 11, so that all oil is strained before entering the oil-circulating system. Should this screen become stopped up with foreign substances, it can easily be removed by taking out six cap screws which hold it to the bottom of the oil pan.

After the first 500 miles that a car is driven, and every 1,000 miles thereafter, all oil should be drained from the engine and replaced by new. When draining oil, remove the screen and clean thoroughly.

EXAMPLE OF A CIRCULATING-SPLASH ENGINE LUBRICATING SYSTEM USING A PISTON OR PLUNGER TYPE OF PUMP

As an example, the Hudson Super-Six system is used.

Path of Oil Circulation

The oil is taken from the pressed steel reservoir at **(A)**, straining all of it through a filter or metal screen of fine mesh (Fig. 12).

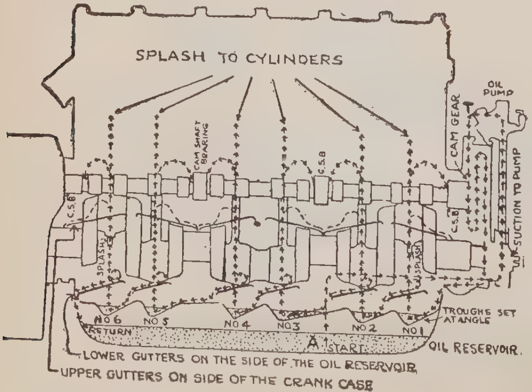

Fig. 12

The oil is fed directly into the front compartment containing the timing gears at (T) and their bearings, and flows from this into the first oil trough immediately under No. 1 cylinder. The large splasher or dipper (Fig. 12A) on the end of the connecting rod practically empties the oil trough at every revolution, throwing the oil into suitable channels or gutters on the side of the reservoir and crank case.

The upper gutters feed the main bearings in a continuous stream. The **lower gutter** feeds the oil directly into No. 2 oil trough (Fig. 12).

The splash from No. 2 oil trough feeds No. 3, and so on until No. 6 oil trough is reached, at which time the oil flows back into the reservoir.

The connecting-rod dipper is sufficiently effective to permit a very high level being maintained, thus insuring lubrication on all grades without excessive oil consumption. The two center bearings are fed by two troughs each.

The front bearing is fed from the timing gears and one trough, and the rear bearings are fed by two large troughs. It is apparent that all oil which enters at the front end must circulate through the various troughs to the reservoir again.

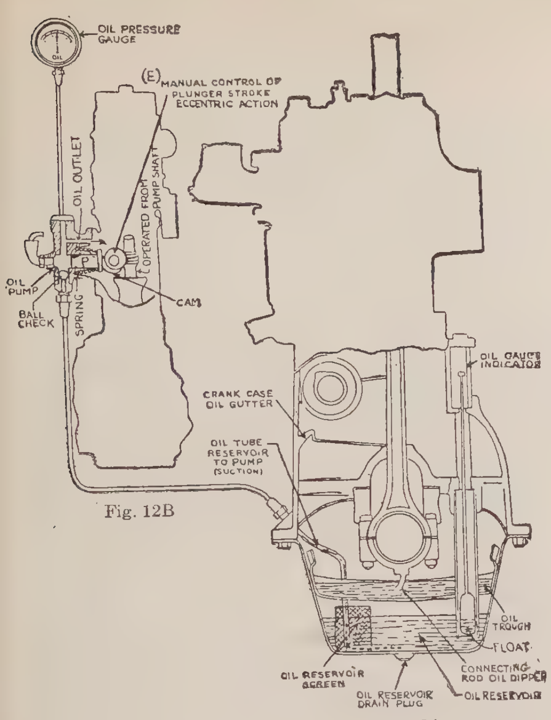

Fig. 12B

Fig. 12A

The Oil Pump

The piston or plunger-type of oil pump (Fig. 12B) is operated by a cam with an eccentric movement. The cam is driven by a vertical shaft from the crank shaft. The pump is elevated.

The cam forces the plunger in and a spring forces it out again, thus creating a suction effect which draws oil from the lower oil-reservoir or oil pan.

The plunger (P, Fig. 12B) is also under the control of another eccentric (E) which is connected with the foot accelerator and throttle control. Thus the quantity of oil pumped to the engine varies with the demand made upon the engine.

At slow engine speed the plunger is held in by the eccentric. Thus a shorter stroke is the result when the cam comes around (Fig. 12 B).

At a car speed of 18 to 20 m. p. h. the gauge should register 1° to 1½° of oil pressure. As the throttle is opened for **higher engine speeds,** the eccentric **(E, Fig. 12B)** is turned away from the plunger, thus permitting a longer stroke of the plunger **(P),** and the gauge should register 3° to 4° at about 30 m.p.h. Thus it will be observed that the pressure is governed by the speed of the engine.

If the gauge does not register the amount in the manner described above, the pump mechanism should be investigated. On indication of a pump being inoperative, or if the gauge needle shows no movement, make sure that there is plenty of oil in the reservoir and that the engine is getting lubrication by splash, and run irrespective of the pump. Then you can drive in carefully and have the system examined.

The oil reservoir on the Hudson contains over 3 gallons of oil in the troughs and in the reservoir itself. It is fitted with a **float indicator** which shows the level of the oil by means of a red button working in a glass tube. This is on the left-hand side of the engine. See Fig. 12A.

If the gauge does not show pressure at all, make sure that the oil pan contains plenty of oil, as shown by the oil-level indicator. Should this show "full," remove the priming plug on top of the pump and start the engine. If oil flows from this, the pump is working and the trouble is with the gauge.

Priming the pump: In case you think that the pump is clogged, it is a good plan before taking it down to try priming it with the same kind of oil that you put in the crank case. To prime the pump, remove the plug, pour in oil until it fills, replace the plug, and start the engine. If priming does no good, then it will be necessary to clean the pipes in order to find the obstruction. It is also advisable to clean the oil strainer occasionally. When the pump is taken down it must be primed with oil, after replacing.

Evidence of Poor Adjustment (Hudson)

1. **Excessive and continued smoking at slow speeds.** Sooty plugs. This indicates that the central eccentric does not shorten the stroke of the pump sufficiently. Adjustment of control eccentric is necessitated.
2. **Oil-pressure gauge readings** other than from ¾° to 1° when idling or 2° to 2½° at high speed. Eccentric adjustment necessary, or there is possibly a leak in the oil pipe lines.
3. **Engine hot.** Dirty oiling system, necessitating cleaning and change of oil, with possible readjustment.
4. **A pressure reading at slow speeds—none at high speeds.** Caused by the control cam permitting the plunger to work at slow speeds, but stopping it at high speeds. Adjustment of cam necessary. It is usually advisable to remove the oil pan, and to clean and refill with new oil in case of any oiling troubles before making any adjustments. A draining and replenishing of the oil supply is advisable every 1,000 miles; or after the first 500 miles with a new car.

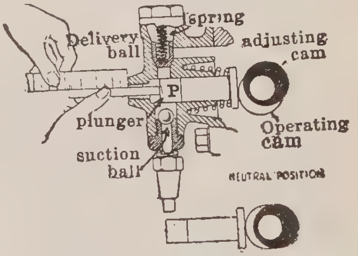

Fig. 13. Sectional view of oil pump, showing adjustment.

5. **If oil pressure is more than** 2½°, stop the engine, remove the spring, as shown in Fig. 13, and stretch it slightly in order that there may be more spring tension on the delivery ball, thus reducing the pressure. Replace spring and again test.
6. **Should the gauge read less than** 2½°, squeeze the spring shorter and test; couple up the throttle lever, as shown in Fig. 14.; start the engine and let it run with closed throttle; turn the adjusting screw (Fig. 14) in a counter-clockwise direction until the oil gauge registers ¾° to 1°; lock the throttle lever in place.

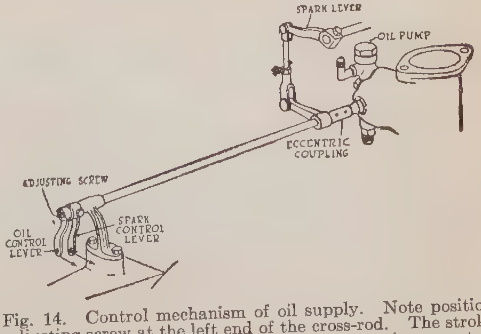

Fig. 14. Control mechanism of oil supply. Note position of adjusting screw at the left end of the cross-rod. The stroke of the oil pump is decreased by turning this screw in a counter-clockwise direction.

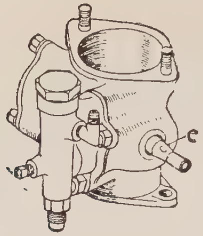

Fig. 15. The letter (C) of the eccentric cross shaft should be just forward of the vertical, when the engine is speeding, in most cases of proper adjustment.

To Check Up Adjustment

1. Remove the plug (Fig. 13) and insert a match or nail in the hole, bringing it into contact with the plunger head. The pump can be felt going through its stroke. (Care must be taken in doing this, as the fan runs very close to the plug and offers opportunity for injury.)
2. When the engine is idling, with the throttle closed, the stroke of the plunger should be about ⅛″ to 3/16″.
3. When racing, plunger should have a stroke of about 3/16″.
4. With the throttle open, the mark (C) on the control eccentric arm at the coupling should be just forward of the vertical (see Fig. 15). (In making any adjustment on the oil pump, always start with the control eccentric in the inoperative position and follow the steps through as outlined, otherwise the cam may be set in the wrong position.)

To Adjust Oil Pump

1. Loosen the throttle arm on the pump-control eccentric at the right side of the engine.
2. Turn the control eccentric arm with a screwdriver until it is entirely free from the plunger. This point can be determined when the engine is idling by turning the adjusting screw (Fig. 14) until a point is reached where the screw turns freely.
3. It is then in the position shown in Fig. 13, permitting the plunger to take a full stroke under all conditions.
4. Speed the engine up; note oil pressure. It should be as stated above.

The Dodge Oil Adjustment (Engine)

The oil gauge on the dash should show a pressure of 2 to 4 lbs. at 20 m.p.h. If the pressure is too low or too high and investigation shows that adjustment is required, remove the springs in the by-pass located directly in front of the water pump, stretching it for more pressure or cutting it off for less pressure.

To determine whether oil is flowing through the feed pipe inside the crank case when the gauge does not work, it is best first to remove the oil inspection plug just beyond the lower rear corner of the rear valve cover plate. If oil spurts out with the engine running, it shows that trouble is in the gauge.

OIL GAUGES

Two types are in general use: (1) "sight-feed"; (2) "pressure."

The sight-feed gauge is generally used with a "splash-circulating" oil system, where oil is only forced to the timing gears and to the oil troughs. The gauge mounted on the dash has two pipes connected to it, and the oil can be seen circulating (not illustrated).

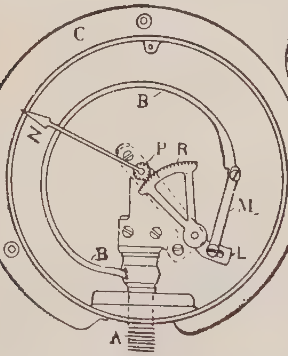

Fig. 16

Fig. 16A

Fig. 16. Internal view of oil gauge.
Fig. 16A. External view of oil gauge.

The pressure gauge differs, in that but one pipe is connected to it, and oil is not supposed to reach the gauge.

At low speeds of the pump the oil will probably go one-quarter the height of the pipe leading to the gauge, and at high speeds about three-quarters.

The oil as it rises compresses the air in this pipe up into the thin metal expanding tube (B) (Fig. 16). The greater the speed of oil pump, the greater the air pressure in (B), which causes it to tend to straighten out, thus operating (R), (P) and (N).

Pressure gauges are of low pressure when operated with a "splash circulating" system (see Figs. 11 and 12, pages 161, 162), and of high pressure when with a "force" system (Fig. 10, page 160), or "full-force" (page 159).

The oil gauge is usually placed in the dash or cowl board, and indicates the pressure of the oil being circulated.

The amount of pressure varies with the speed, temperature, and viscosity or thickness of the oil.

When the engine is cold, the pressure will be higher until the oil thins down. An excessive pressure on the gauge may also indicate the clogging of the system. If after the engine is warmed up the pressure is excessive and the regulation does not vary it, then it can be attributed to clogged pipes.

In other words, **maximum pressures** will be indicated at given speeds when the engine is cold and the oil is fresh; **minimum pressures,** when the engine is hot and the oil becomes thin.

Practically all engine lubricating oils become less viscous from use, even under normal conditions. Running the engine too long with the "choker" control lever pulled back will cause the oil to be thinned more rapidly, owing to the condensation of gasoline from the rich mixture.

Too high a pressure will cause abnormal oil consumption. This should be adjusted according to the pressure recommended by the manufacturers. Always adjust when the engine is hot.

If the indicator needle on the gauge drops to zero, it indicates that the oil level is low, or that for some reason oil is not circulating. In cold weather it may be an indication that the cold test of the oil you are using is not sufficiently low, and that the oil has congealed to a point where the pump cannot draw it from the oil pan. Do not under any consideration continue to run the engine if the hand on the cowl board vibrates or returns to zero, or if it remains at zero after starting the engine.

Oil-Gauge Indications

If the needle fails to indicate: (1) See if there is oil in the oil pan. The "oil-level indicator" (see Fig. 10, page 160), may be stuck. (2) If there is oil, then disconnect the union leading to the oil pump; run the engine. If oil flows, then look for air leaks, in piping, or in tube (B), Fig. 16. If oil does not flow, then look for the clogged strainer, pump, or pipes.

If the needle reads lower than usual: (1) Look for air leaks. (2) Loose bearings permit oil to pass freely, reducing the pressure. (3) Thin oil or oil diluted with gasoline, due to excessive priming may be the cause. (4) Pressure adjustment at pump, or at "ball and spring" relief valve (see page 160) not properly adjusted, or weak, or broken spring, may account for the trouble.

If the needle reads higher than usual: (1) Heavy or cold, congealed oil, which produces back-pressure, due to slow circulation; (2) obstruction in oil pipes; (3) new and tight bearings after overhauling engine, will all produce higher pressure, as the oil will not circulate as freely as when loose. If the oil gauge shows full pressure when running at a slow speed, foreign matter has become lodged in the distributor pipe.

Sometimes, when tube (B), Fig. 16, is expanded out of normal shape by too high a pressure, the needle fails to return to zero. In some instances, this tube can be pressed back into shape with the fingers. It is usually made of light spring copper.

Oil-Level Indicators

The oil-level indicators are for the purpose of indicating the amount of oil in the oil reservoir. There are three types in general use: the "float" type as shown in Fig. 10, page 160, the "bayonet" type as shown in Fig. 11C, page 161, and the pet cocks in the oil pan, as on the Ford and many truck engines.

To Test Oil Pipes or Tubes

If an air leak is suspected, remove the oil pipe at the couplings and test them carefully with air pressure, submerging them in water to make the test.

If the pipe is clogged, remove it, and use air pressure.

THE KIND OF ENGINE LUBRICATING OIL TO USE[1]

At the present time most lubricating oils are straight mineral oils made from different distillates of petroleum.

A good high-grade gas-engine oil is necessary, because the heat inside of an internal-combustion type of engine will burn the oil, leaving nothing for lubrication—hence wear. Therefore nothing but a high-grade oil will answer—one which will stand up under high temperature of the cylinders without thinning down.

Another point to consider is that if the rings are tight and compression is good, then it is possible to use a light-weight oil so that it will splash readily. A light-weight oil, under heat, can hold its body and will lubricate better than a good heavy oil, if of proper quality. Where clearance of pistons is greater than normal, then a good heavy-bodied oil is advisable, if the oil will maintain its viscosity.

If the piston rings leak, which naturally lowers compression, or if the piston clearance is greater than normal, then too light an oil will pass into the combustion chamber where the fire and flame will rapidly turn it to carbon, causing the carbon to stick to the valves, combustion chamber, and spark plug. The result is loss of oil, fouled spark plugs, and carbon deposit.

Some heavy-bodied oils may appear to hold their body or consistency, but under heat it will thin down considerably, whereas a light-bodied oil will hold its consistency equally as well. Any oil however, no matter how thick or heavy, will thin down to a certain extent when heated.

Light-bodied oils will flow freely through small passages. Heavy-bodied oils are less fluid and require large passages.

The viscosity, or the fluidity or the body of oil depends upon many factors:

The operating temperature of the engine[2] is the first factor.

The next factor is the **type of the lubricating system.** Where the "splash" system is used, the oil is splashed and atomized by action of the connecting rods, and light and medium-bodied oils are generally used. Where "pressure" systems are used, the heavier-bodied oil is favored.

Other factors governing the grade of oil, are such as the kind of oil pump used. If a submerged type of oil pump is used, it will probably circulate heavier-bodied oils more readily in chilly weather than the elevated pump. The oil screen, if of a fine mesh, will restrict the use of too heavy a bodied oil. If the oil pump and oil pipes are on the oustide of the engine[3], the oil will readily chill during cold weather, and such a condition demands an oil which will freely circulate. In fact, free circulation of good oil is the correct lubrication.

The proper oil to use is generally recommended by the maker of a car. The object has been to secure an oil that leaves no carbon deposit and that at the same time gives uniform complete lubrication. It must hold its body and form a lasting film on the wearing surfaces. If it thins down too much, it will leave the bearing without lubrication (see also, page 169).

Flash and Burning Points of Oil

A difference in oils is shown by their "flash points" and "burning points" explained as follows:

Oil when heated generates gas, just as gasoline does when not heated.

---

[1] A chart of automobile recommendations, also a very instructive booklet, *Correct Lubrication*, is issued by the Vacuum Oil Co., 61 Broadway, New York City. It will be sent free to readers of this book on request. It specifies the correct grade of oil for each car and model for the last five years.

[2] The maximum temperature in the cylinders, at the top of the explosion stroke is approximately 2700° F.; the minimum temperature during the suction stroke, about 250° F.; average temperature during the four strokes, about 950° F. These are temperatures in the cylinders to which the outer side of the oil film is exposed.

The oil which is in contact with the cylinder walls and pistons is kept below the flash point (about 500° F.) by being in contact with the metal which conducts the heat away.

[3] **Cooling the lubricating oil.** On some racing cars and high-speed marine and aeronautical engines of high compression and speed, where heat is excessive, due to operating under full power for long periods of time, the oil is cooled by leading the oil out of the engine base, where the temperature can be lowered, before pumping it back into the engine.

The reason for cooling the oil is the fact that an airplane engine usually runs at full power for long periods of time and considerable heat is generated. The oil also loses its heavy lubricating film that is so very necessary between the bearing surfaces, and thins down to a point where the lubricating film is lost. Hence the advantages of keeping oil at a low temperature.

The best gasoline engine oils generate little or no gas at ordinary temperatures, but at high temperatures of, say, 500° F. it would generate a sufficient amount of gas so that it could be ignited with a match and would thus produce a flash and go out instantly. This is termed the "flash point."

If the heat is increased to, say, 550° F., and the match applied, the generation of gas would be so rapid that it would continue to burn until the oil was all consumed, unless extinguished. This is termed the "burning point."

A low grade of oil would perhaps flash at 300° F. and burn at 350° F., and should not be used because it would burn up at the working temperature inside of a gasoline engine. The flash and burning points are much higher in some oils than in others.

If oil with a low burning point is used in the cylinder of a gasoline engine, the intense heat will burn it before it can lubricate the cylinder walls and piston. If oil of a sufficiently high burning point is used, the temperature of the cylinder will not be high enough to burn it, and the cylinder walls and piston will be properly lubricated.

Simple Method of Testing an Oil

This method is not intended to be regarded as an approved method, but will give an idea as to the quality of the oil.

Drain oil which has been used in the engine, into a long narrow tube. Let it stand 24 hours. If good oil, it will show a small amount of black sediment at the bottom; but floating above it, the sediment is red in color (by transmitted light).

Let a poor oil be tested, which is used under the same conditions. At the end of a few minutes it will turn to a dense black. After standing 24 hours it will show a voluminous black sediment several times greater than that of good oil.

Black sediment indicates sulphur compounds in the oil. Sulphur is injurious to bearings, owing to lack of lubricating qualities; it also pits the valves, causing leakage of compression.

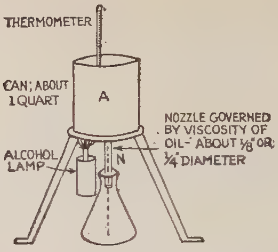
Cold Test of an Engine Lubricating Oil

Another test is the "cold" test which determines the temperature at which the oil congeals. Place some of the oil in a long narrow tube and insert a low-reading thermometer. Pack the tube in a freezing mixture of salt and ice. After the oil has frozen, remove the tube and incline it at an angle of 60°. When the oil starts to run down the tube, read the thermometer. This reading is known as the "chilled point." It should not be above 5° F.

Viscosity of Engine Lubricating Oils

Viscosity refers to the "body" or fluidity of an oil, or any other liquid. The viscosity of oils and liquids varies when heated. The viscosity of an oil does not indicate its lubricating quality, but only determines its fluidity.

To make a viscosity test, a viscosimeter is used. One type generally used is known as the Saybolt Standard Universal Viscometer. In order to give an idea as to the principle involved in the test, a simplified illustration is shown in Fig. 17.



THERMOMETER
CAN; ABOUT 1 QUART
A
NOZZLE GOVERNED BY VISCOSITY OF OIL - ABOUT 1/8" OR 1/4" DIAMETER
ALCOHOL LAMP
N

Fig. 17

The test is made by filling the can (**A**) with oil to be tested and heating it to 70° F. A stop-watch is then used to determine the number of seconds required for the oil to run through the nipple (**N**). The same process is repeated with the oil at a temperature of 212° F.

A good gasoline-engine oil at 70° F. would run through the nipple (**N**) in approximately 140 seconds, and at 212° F., it would require about 62 seconds.

A poor grade of oil would probably pass through in about the same time as the good oil, or in 140 seconds when heated to only 70° F., but when heated to 212° F., its body would thin down and pass through in 50 seconds instead of 62 seconds required for good oil.

A good grade of oil would come nearer maintaining its viscosity or body when heated to a higher temperature, while a lower grade of oil with a heavy body at ordinary temperature would become very thin and useless as a lubricant at high temperature.

Castor Oil for Engine Lubrication

Castor oil is considered an ideal lubricant for airplane engines of both the revolving and stationary cylinder type, for the following reasons as stated by the Baker Castor Oil Co., New York: higher viscosity, lower heat conductivity, no carbon, higher fire test, higher flash test, lower cold test, and that it will not mix with mineral oil.

The Use of Graphite in the Automobile Engine[1]

The Jos. Dixon Crucible Co., Jersey City, N.J., states that the use of flake motor graphite mixed with cylinder lubricating oil, when properly used, will improve compression, decrease the amount of oil required, fill up scores in the cylinder walls, prevent valves and rings sticking, and thereby cure smoky exhaust.

However, assuming that graphite is an ideal lubricant, certain requirements are necessary; for instance:

For the splash-oiling system, the Dixon Co. recommends adding a scant teaspoonful of motor graphite to each quart of oil in the crank case, and then adding another teaspoonful at the end of each one thousand miles. The graphite may be mixed with a little oil and poured down the breather. This is a very small amount of graphite, but it is all that is required.

For the force-feed system it is not advisable to mix the graphite with the oil on account of the possibility of clogging some of the small passages.

A small amount of dry graphite may be placed on the hand and permitted to be inhaled through the air intake of the carburetor directly to the cylinders. This should be done about once a week when the car is in ordinary service.

More graphite can be used when it is introduced in the dry form, because part of it is immediately blown out through the exhaust.

On account of the location of the magneto on **Ford cars** and the possibility of short-circuiting the use of graphite in the crank case or transmission case of these cars is not recommended.

---

[1] A free booklet, advising just where graphite as a lubricant can be used on a motor car, and the kind to use, can be obtained by writing the Joseph Dixon Crucible Co., Jersey City, N. J.

Using Oil over again, Adding Fresh Oil, Cleaning Crank Case, etc.

Using cylinder oil over again. The cylinder oil which is drained from the crank case of an engine is usually about one-half or two-thirds gasoline. Therefore it is not advisable to use it again. It may be used for the gear set if it is strained through a filter, and is good oil to begin with. It is then mixed with grease. The oil should be drained in a pan, mixed with grease until the mass assumes the consistency of the regular transmission lubricant, being neither liquid nor solid.

Adding Fresh Oil

It is important to note that **fresh oil of another make should not be added to the oil pan** before thoroughly washing out the old oil. Clean, good oil put into a dirty engine with gummed-up bearings has simply no chance of asserting its superiority under the unfavorable circumstances. It has first of all to get rid of the gumming round the bearings before its lubricating qualities will be manifested.

The engine should be drained and fresh oil added every 500 miles in winter, from the fact that the engine is primed more in winter than in summer, thus more gasoline mixes with the oil. In the summer, every 1,000 miles is sufficient. Oil can be drained by removing a drain plug in the bottom of the oil pan.

Cleaning Oil Pan

It is best to **remove the oil pan** and clean thoroughly with gasoline or kerosene, and at the same time to clean the oil strainer, making sure that **no trace of gasoline or kerosene is left in the oil pan,** otherwise the lubricating oil will be thinned.

If the oil pan is not removed, then the drain plug should be removed and the oil drained off. The plug should be replaced and about one quart of **light fresh oil** poured into the oil pan through the filler tube. With the ignition switch "off," so that the engine will not start, press in on the starter button and allow the starting motor to crank the engine for about 30 seconds.

Also step on the running board and rock the car back and forth. This will allow the fresh oil to wash the interior of the engine thoroughly. Remove the drain plug again, drain off, and refill with the proper grade of oil.

It is very important that kerosene be not used, as it will collect in the pockets inside of the crank case which are often provided to retain oil for the lubrication of the timing gears. Kerosene may be held in these and if left in engine will thin the fresh oil and cause it to lose its lubricating qualities.

The spark plug should be cleaned and properly set after refilling.

ENGINE LUBRICATION TROUBLES

Cause—too much oil: Oil pan too full; oil pressure adjustment too high; piston pumping oil or rings leak oil.

Effect—too much oil: Smoking at exhaust; carbon in cylinders; pre-ignition and knocking; carbon on valves necessitating grinding; spark plugs become fouled.

Cause—not enough oil: Oil level in oil pan too low; oil pressure improperly adjusted; oil pipes clogged; pump not operating.

Effect—not enough oil: Overheating; seized bearings or pistons; scored or cut cylinders; knocking.

Scored Cylinders, Piston, and Burned Bearings

Burned bearings on a crank shaft or elsewhere mean that the bearing surface is cut, caused by friction from lack of oil.

A **"scored cylinder"** means that there are scratches or cuts in the cylinder, caused by lack of oil, which permits the compression and also oil to leak through the cuts. A "scored piston" and rings is due to the same cause as well as to other causes.

If the engine is not getting enough oil, the cylinder will become so hot that any oil that may have splashed on its outside will be burned—the smell being an indication of the condition. Further running without oil will produce a hard metallic knock, and the heat will finally cause the piston to stick or "seize" in the cylinder.

An engine that is run without oil will be ruined, for the piston rings and the walls will be cut and scratched lengthwise (termed "scored"), so that the compression will not hold.

Another common cause of a scored piston and cylinder wall is the **dilution of the lubricating oil by gasoline.** The heavy-grade fuel is difficult to vaporize, especially in cold weather. To get an explosion, priming is resorted to—and right here is where much damage is done to an engine. If ignition is good, the engine probably will start because a little of the fuel has become vaporized at that particular engine temperature. But most of the gasoline remains unvaporized and washes the oil from the cylinder walls. It does not take long for a piston or cylinder to score under these conditions.

Then there enters again the human element. Many drivers forget to "unchoke" the engine, and a vast amount of unnecessary fuel is drawn into the cylinders for a long period. This raw fuel mixes with the oil on the cylinder walls and gradually finds its way into the crank-case sump, with the result that the oil is reduced to the consistency of a thin liquid and has no lubricating value whatever.

It is well to bear in mind, too, that a cylinder which "misses" allows fuel to get into the oil in even greater volume than when the cylinder fires, because none of the fuel is burned.

Another cause of scores is that the piston pin sometimes works loose and cuts the walls of the cylinder.

If the **piston sticks or "seizes"** and pounds from lack of oil, stop—wait until it cools, and then fill the crank case to correct level; also fill the radiator with water after the engine has cooled sufficiently.

The engine should then be thoroughly inspected before driving, to see if any damage has been done. If no obvious damage has been done, a thorough examination should be carried on to determine whether or not the running without oil has burned the bearings or caused other trouble. This can be ascertained by starting the engine, and if it pounds or knocks, it is a certain indication of bearings burned or cylinders scored. See, also, Index under "Seized piston."

A new bearing, or any other new part that has not worn smooth, requires more oil than one that has been run. It is always better to give a bearing too much oil than too little, but the exact amount of oil required for each part of the car should be learned as quickly as possible, in order to prevent waste.

When an engine is permitted to run excessively hot, partial oxidation of the engine oil takes place, which forms a certain percentage of water. For instance, if petroleum oils are treated with air at 300° F., water and carbon dioxide are readily formed. This accounts for the presence of water in the lubricating oil in the crank case, in some instances.

Smoky Exhaust

If the engine smokes excessively, drain the oil pan and measure its contents, as the oil-level gauge may be stuck. If the oil pan does not contain more than the right amount, the oil is probably pumping past the pistons, owing to worn or stuck piston rings or to too great a piston clearance. If this is the cause, new rings should be fitted at once.

Smoke Indications and Cause

If the vapor is black and foul smelling, it is caused by too "rich a mixture" (too much gasoline); this can be remedied in the carburetor adjustment.

If the smoke is white or blue, the engine is supplied with an excess of oil.

If the smoke is grey, there is too much fuel as well as lubricating oil.

The reason an engine excessively supplied with oil smokes is that there is too much in the crank case; the entire lower portion of the connecting rod will dip into it and the lubricant will be forced into the cylinder to work by the rings on the piston, then into the combustion chamber, thence out through the exhaust. The same applies to a pressure feed or force system where the pressure is too high.

Depending upon smoke issuing from the exhaust pipe of a car as a means of testing whether or not the cylinder lubrication is sufficient or over-sufficient is by no means always conclusive. The fact that the exhaust is smoky does not indicate that lubrication is complete, or excessive in all cylinders. If it issues in a steady and continuous stream, there is probably sufficient oil in the engine, and probably too much, but if it comes in intermittent puffs, it may be inferred that one compartment only of the crank case is flooded, or, maybe, one cylinder is getting too much oil. If there is a black gummy deposit on the spark plug it will indicate which cylinder is getting an excess of oil.

Leaky piston rings are quite frequently the cause of excessive smoke. See Repair subject, "Leaky piston rings."

A method formerly used, and still used on some marine and stationary engines, for preventing trouble caused by excessive oil, was a baffle plate as shown at (**BP**) in Fig. 18. This is a simple plate of sheet metal in which a slot is cut, through which the connecting rod works, thus preventing an excess amount of oil finding its way into the mount of the cylinder. This method has also been used in some automobiles.

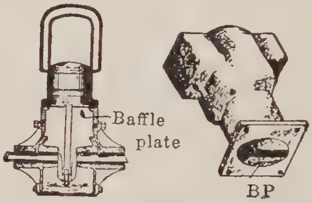


Fig. 18

If the spark plugs are constantly oil-soaked, this indicates leaky piston rings. The oil passes the rings, hence the trouble. It can also be caused by the "piston pumping" oil. An oil-soaked spark plug usually has a black gummy deposit on the spark plug.

Oil Drips from Engine

The average oil drips come from **the cap screws being loose on the crank case.** Other drips come from worn bearings out of the side of the crank shaft and quite frequently from the plungers or tappets above the cam shaft.

On some cars **the fan often picks up the oil** oozing from bearings and throws it over the inside of the hood.

RELATION OF PISTON AND RINGS TO SMOKE AND EXCESS OIL

Piston Pumping Oil

Quite often the combustion chamber will be constantly oil-soaked, thereby keeping the plug fouled and causing "missing." The front or rear cylinders are prone to this, and it appears that it is due to the fact that a necessary amount of oil must be carried in the crank case. When the car is going up or down hill the rear or front cylinders get an excessive amount of oil and the piston assists by pumping it past the rings. This is common where there is excessive piston clearance, especially in old engines and quite often in new ones, where there is excessive clearance to begin with and poor fitting rings in addition.

Another common cause—is **too high an oil pressure.** It is by no means unusual to see pressures of 30 lbs. employed.

Very few people are aware of the fact that the piston and cylinder walls in a well-designed engine should not be placed in the actual path of the big-end splash.

At ordinary engine speeds, the inside of the crank case is in a condition of what can aptly be described as "oil fog," and although all the crank-shaft bearings are fed directly with liquid oil, the cylinder itself should be supplied by "fog" only, which is much denser than one might imagine, and quite equal to its work in this respect.

Any actual splash which gets on the walls simply leads to waste and carbonization through the oil getting past the rings into the combustion head and being burnt.

A method of avoiding this, adopted by many, is to taper off the top of the piston so that the oil, instead of gathering on the head, will gather in the space around the outside diameter between the piston and the cylinder walls, where it does the most good.

A third cause of oil waste is to be found in the piston rings. If worn slightly oval, they will cause leakage if their position is not rigidly maintained.

Under racing conditions, where the piston is a very slack fit and a minimum of friction is essential, a slight advantage in engine speed is obtained by using a surplus of oil, for it is well to explain that in describing these various methods of reducing oil consumption the ideas aimed at are: (1) economy, and (2) prevention of rapid carbonization. It is not intended to convey the impression that any actual mechanical harm is done to the engine by over-oiling.

See page 167, relative to the **dilution of lubricating oil with gasoline** by too much priming, which causes cylinder walls and piston to become scored, thus permitting too much oil to pass to the combustion chamber.

Vacuum Cause of Piston Pumping Oil

When you see blue smoke issuing from the exhaust, it indicates that too much lubricating oil is being consumed. If this occurs regularly at all speeds, it is generally due to piston rings. If it occurs only when the engine is run at low speeds for long periods, or idling at the curb, it is due to either cause as follows:

When the engine is run fast a vacuum is not produced in the cylinder, because so much gasoline and air is drawn into cylinder.

When the engine is throttled down, only a little air is allowed to enter, therefore more of a vacuum is produced, the tendency being for the vacuum to suck up oil from the crank case past the piston rings.

No doubt you have seen many a car start off from a standstill after the engine has been running slowly for a time, and have watched clouds of smoke coming from the muffler. Gradually, as the car gets under way, the smoke gets less, and finally no smoke is evident unless the mixture should be too rich, in which case the smoke is black. See Index for meaning of the word "Vacuum."

Prevention of Excessive Oil in Combustion Chamber

Carbonization, sooty spark plugs, and a smoky exhaust are due to the fact that the oil works up past the piston into the combustion chamber. The usual cause is attributable to the piston pumping oil or leaky piston rings. This is common where there is excessive piston clearance, especially in old engines and quite often in new ones, where there is excessive clearance and poor fitting rings in addition.

If the piston rings leak, the oil passes around the rings, out through the exhaust, causing considerable smoke. Another indication of leaking rings is the constantly oil-soaked spark plugs which cause missing of ignition. Therefore, if the rings are not in the best condition, it would be wise to use heavier oil or to fit new rings.

Another common cause is too high an oil pressure.

Some of the **methods employed to prevent an excess of oil** in the combustion chamber are suggested in Fig. 19. For convenience, the drawing has been divided into quarters, designated 1, 2, 3, and 4.

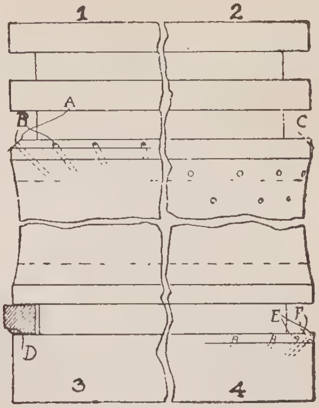

Fig. 19. In 1 at (A) is shown a popular method for overcoming some of the troubles due to an excess of oil. Note the chamfered lower edge of the second ring groove (B); 1/32" holes are drilled from the chamfered edge to the inside of the piston. This is for the return flow of the excess oil. An extra large hole in each side over the piston-pin bearing and running into it will improve its lubrication and insure long life. The number of small holes around the chamfered edge should be determined by the extent of the fouling.

At 2, is shown the chamfered lower edge of the second ring groove and the small holes drilled through the piston in the recessed space about the middle. Here, as at 1, the number of holes should be determined by the extent of the fouling.

At 3 is shown the chamfered lower edge of the bottom or oil ring. This very simple method is highly successful, a great deal easier to perform, and is the one employed in the repair shops of the various Ford branches, and is usually all that is necessary. This should be tried before fitting a patent ring or drilling a piston.

Fig. 20

Fig. 20. Showing a method of chamfering the lower part of the lower ring. To "chamfer" means to bevel the part (as shown in Fig. 20) with a file or emery wheel. The illustration gives an idea of the amount and angle of the chamfer. This will permit cylinders to get oil, but will prevent oil working past the rings into the combustion chamber, providing, of course, that the cylinder walls are not "scored." The treatment applies only to those cylinders in which the spark plugs are constantly oil-soaked, usually No. 1 (front), and often No. 4 (rear).

A repairman who had done considerable Ford repair work states that he changes the pistons in Ford engines which pump oil and allows about .002" to .0025" clearance instead of the usual .003" clearance and this usually remedies the trouble.

RELATION OF CARBON TO LUBRICATING OIL

The oil film which protects the friction surfaces in the engine is hardly thicker than the page you are now reading. It makes no difference how much oil you pour into your crank case. The only oil that protects your engine is this thin film between the moving metal parts.

And this thin film is not the cool oil you pour into your crank case. In use, the oil heats quickly. Then the test comes.

Only oil of the highest quality will retain full lubricating efficiency under the heat of service. Many oils break down under this heat. Part of the oil goes off in vapor, just as hot water gives off steam. With an oil film only .003" thick, this vaporization must be reckoned with.

To get full protection, you must have a constant, full, even oil film. You must have an oil which will stand the heat of service, and oil which is not diluted with gasoline. Hence the reason for changing the oil in the crank case often.

The Cause of Carbon Deposit

Carbon deposit is due mostly to the use of a poor grade of lubricating oil or to too much oil, and quite often to an improper mixture of gas or to too much gasoline being fed.

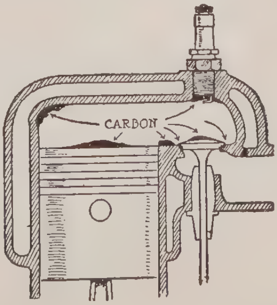

Fig. 21. Showing points in the cylinder where carbon deposits are most likely to gather.

Carbon has many lodging places. It fouls spark plugs and kills the spark. It pits the valve seats and thus weakens compression. By accumulating on the piston heads and in the combustion chambers, it causes knocking and racks the engine with pre-ignition.

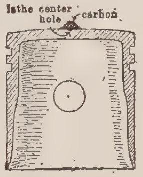

Fig. 22. The collection of carbon on the top of the piston head is often greatly accelerated by the lathe center mark in the head, and where possible this hole should be avoided or filled up. It is the starting point at which the carbon begins to collect, and soon there is a mound at this point. The rapidity with which carbon collects can be greatly reduced by smoothing the walls of the combustion chamber, especially the top of the piston. The surfaces should be polished with emery and crocus cloth.

The amount of carbon deposited in the engine depends upon the carburetion, upon gasoline combustion, and on the character of the gasoline as well as on the quality of the lubricating oil itself and the correctness of its body.

As both gasoline and petroleum lubricating oils are chemical combinations of hydrogen and carbon, carbon is an essential element of each.

Only the free (suspended) carbon can be taken out. To remove the carbon which is in combination with other chemical elements, constituting gasoline and oil, would result in the destruction of the product itself.

Carbon deposit is also likely to occur through incomplete combustion of the gasoline, or through the destruction of the excess lubricating oil which will work into the combustion chamber if the oil is of incorrect body. "No-carbon" oils do not exist.

To reduce carbon to a minimum, the lubricating oil must be of high quality and of correct body for the piston design and lubricating system of the engine.

Lubricating oil adds materially to the carbon deposit in an engine if the following conditions exist:

1. **Poorly fitting piston rings** or scored piston rings and cylinders.

2. **Carrying too high an oil level;** using an oil that is not suited to the engine, both as regards body and quality, or carrying the pressure in a force-feed system at too high a point.

3. **Allowing the oil** in the crank case or oiling system **to deteriorate** to the point that it becomes so thin that even a well-fitting piston ring will not prevent a surplus of oil from passing into the combustion chamber.

Relation of Carbon to Combustion

An important consideration is **the incomplete combustion of gasoline,** for from this source a large proportion of carbon deposit comes. When the charge of gasoline and air (the proportions of which are determined by the carburetor adjustment) is taken into the cylinder of a gasoline engine, it consists of hydrocarbon vapor and air. The oxygen in the air combines with the carbon and hydrogen of the gasoline and forms an explosive mixture. This mixture is fired, and after expansion, the products of the combustion are expelled from the cylinder through the exhaust valve.

If the amount of air entering the carburetor is not sufficient to insure complete combustion, we have what is known as a rich mixture. This is a slow-burning mixture, rather than an explosive one, and will cause excessive carbon deposit. For example, if the wick of an oil-burning lamp is turned too high, too much oil will be drawn through the wick for the amount of air entering the lamp to form complete combustion. The lamp will smoke, and soot (which is carbon) will be deposited on the chimney.

This is exactly what happens in the cylinder of a gas engine. The products of incomplete combustion, together with a portion of lubricating oil passing by the piston rings, deposit a certain amount of carbon in the combustion chamber. That portion of this carbon which does not pass out with the exhaust is baked on the cylinder heads, pistons, and valves by the heat of explosion. This carbon deposit will build up very much more quickly if it has a bed to build up on, such as would be produced by a lubricating oil, which, when exposed to the heat of explosion, would leave a gummy deposit.

Cause of Carbon Deposit

Carbon deposit is therefore due to: (1) the amount and grade of oil; (2) the carburetion mixture. If too much gasoline is used it will cause carbon deposit, just the same as a poor grade of oil.

Excessive heat will also cause carbon, as oil vaporizes. Because oil becomes more fluid when it is heated, the oil feeds should be adjusted after the engine has been running, for if adjustments are made for cold oil, the flow will be much more rapid when it is warmed, and the bearings will be flooded, and the excess oil will pass by the rings, causing carbon deposits.

Bad Effect of Carbon Deposit

Carbon deposit will cause the valves to leak by the carbon gumming under the seat of the valve, thereby decreasing the power.

Carbon deposit cakes on the end of the piston and on the walls of the combustion chamber, which, when the engine is hot, will cause the small particles of carbon to become red hot and cause premature ignition (or pre-ignition), which results in pounding.

Carbon deposit will also cause the spark plugs to become fouled, for if the oil that is being used will cause carbon in one place, it will accumulate on the spark plugs also. In other words, carbon is a bad thing for an engine, and ought to be removed, and, better still, guarded against.

Indications of Carbon

Carbonization of engine—general indications: If you should note that the engine, when fully supplied with water and oil and with the spark lever in proper position, is overheating easily, has weak compression, and develops a "knock" or "clank" when on a hard pull, there is probably a large deposit of carbon in the cylinder compression chambers. This may be due to the use of poor lubricating oil or to incorrect adjustment of the carburetor. Even though it is not affected by these two conditions, a small residue of carbon will adhere to the interior of the compression chamber, and if left for a great length of time, will develop the trouble mentioned above. The carbon sticking to the inside of a cylinder becomes red hot and pre-ignites the charge.

Methods of Removing and Preventing Carbon

This subject is fully treated under the "Repair section" of this book. See also Index.

OIL GROOVES IN BEARINGS

The old-fashioned arrangement of two simple holes on the upper side leading into the oil-way, either straight, starred, or spiral, appears to be as good as any. But, be it noted, the oil-ways should not be cut to the extreme edge of the bush, or their action as reservoirs is apt to be interfered with.

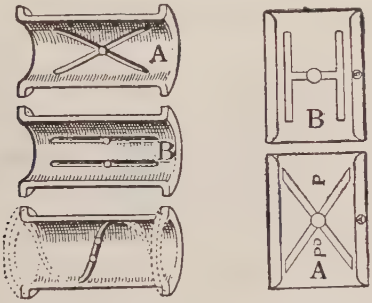

Fig. 23. Oil grooves in bearings.

Similarly, the beveling of the edges of the bush should likewise be discontinued before reaching the outside. The arrangements of oil-ways is shown in Fig. 23.

The usual practice is to make the grooves as shown in the figure at (**A**) like a letter X. The result of using this style of groove is that the areas of the bearing at **p, p,** run dry. A careful series of tests has shown that the type of oil-groove shown at (**B**) and made in the form of the letter H gives results far superior to the other. Some very bad cases of poor lubrication and heating of bearings have been cured entirely by the simple expedient of changing the type of oil groove from that shown at (**A**) to that shown at (**B**). (E. W. Roberts in "The Gas Engine.")

Keep oil grooves out of the pressure side of your bearing, whenever the pressure is one sided, as in the crank-pin bearing.

"Running-in" a New Engine

Fine grooves (not visible to the eye) are left on the piston by the cutting point of the lathe tool when originally made. Also pear-shaped pits are left by the grinding machine on the cylinder walls. When the engine is new the projections are in the fine-line stage.

With an ordinary temperature, at say, .003″ piston clearance, the projections will pass one another. When the temperature of the engine is raised, the projections will touch from expansion, and if the speed is excessive, the temperature is raised which, in turn, increases expansion, and friction takes place. The projections then imbed themselves in the recesses opposite them, which will cause a stuck or "seized" piston, with the attendant condition of a "scored" or cut cylinder wall.

Care is necessary to use plenty of oil and to run at normal rates of speed until the projections gradually change shape, and are bent over in such a way that the high points fill the recesses.

After the engine has been run 1,000 miles with care, the piston and cylinder surfaces become very smooth and polished.

When the engine stands over night, don't immediately race the engine to warm it up, because the oil has drained from bearings, cylinder walls, etc. Consequently it is going to take a few minutes to lubricate these parts properly. Therefore at first let it run slowly for a minute or so.

POINTERS ON GENERAL LUBRICATION OF A CAR

It is a difficult matter to advise just what lubricants to use on all cars, as different manufacturers advise what to use and their advice ought to be followed. However, a few pointers in general are given below:

Lubricated disk clutch: There is much misinformation about the caring for and lubrication of a disk clutch. Heavy oil is often put into such a mechanism with rather disastrous results. At the end of a reasonable distance, say 1,000 miles, the old oil in a disk clutch should be removed. There is usually a drain plug fitted to the clutch housing, and this should be removed to let the oil out, after which the clutch should be rinsed with kerosene, and again allowed to drain completely. Thus cleaned, a supply of a light clutch oil should be put in until the level is about even with the bottom of the clutch shaft. This allows the plates to pass through a bath of oil, and is the desirable condition. Some recommend a mixture of a light oil with kerosene, but as the proportion varies, it is best to purchase a regular light clutch oil.

Where multiple disk clutches are used which run in oil, it is very important that a light-bodied oil be used, else the plates will have a tendency to drag by sticking together. See Index under "Hudson clutch."

On the subject of **dry disk clutches,** see description on page 22 and the Borg & Beck clutch, page 24; if oil gets into the clutch it will cause slipping.

The transmission: On some transmissions, where dry disk clutches are used, there is an oil hole in the main transmission shaft which permits oil to pass to the clutch yoke. With this type, oil of a fairly heavy body is used, such as steam cylinder oil. On other transmissions, a special grease called "transmission compound" is used.

When grease is used, it should really be a heavy oil, or a grease of such consistency that it will flow. Thus, when the gears and shafts pass through it, it does not adhere to them, and there is not the tendency to throw it out of contact with the bearing surfaces. There are many special forms of gear-set and differential semi-fluid greases and heavy oils on the market, and the makers have studied these facts, so that the products perform their function of being just light enough to prevent sticking to the revolving parts. It is obviously wrong, therefore, to put any common grease into a gear-set, for it not only acts as described, but has not the ability to get into bearings like a fluid material.

In filling the gear-set, put in the lubricant to a depth about half the height of the gearbox, that is, have it come about even with the center of the main shaft. This will completely submerge the countershaft in the average gear-set design, and will bring the under face of the main shaft gears into the lubricant. It is important in this connection to see that the packing rings are tight and prevent leakage where the drive shaft emerges from the gear-case and where the shaft from the clutch enters it. If there is leakage here, it not only will act as a collector of dirt and dust, but the gears will be robbed of their proper lubrication.

The differential housing should hold the lubricant in the rear axle gears, so that attention is needed only as stated above. But sometimes a disagreeable-looking rear axle is noticed where the oil or grease oozes out through cracks or leaks in the rear cover plate or through the axle tubes or brakes on to the wheels. This is not so common a fault as it used to be, when axles were not designed so well to trap the oil and keep it where it belongs. However, an occasional careless driver will let his axle get in this condition by not having a proper gasket or felt packing between the differential housing cover plate and the housing itself, or by putting too much oil in the rear axle differential housing. The brake bands become oil soaked and slip when oil passes out at the ends of axles.

The axle: For most rear axles a heavy oil, such as steam cylinder oil, is recommended, but in some instances a semi-fluid grease or even a heavy grease is used. It is next to impossible to give any fixed rule for rear-axle lubrication. There are so many designs, that where a heavy oil or a grease will work satisfactorily in one instance, some other form is better in another. Usually, however, heavy oil is placed in the rear axle housing.

Dodge, for instance, uses 600W—steam cylinder oil, two parts, and one part of medium grease.

The rear end bearings of the drive shaft, which support the drive pinion, are greased and this particular grease cup is often overlooked, owing to its inaccessible location. Many a bearing has run dry under such conditions, because the oil cannot reach it from the rear axle housing.

Example of Lubricating the Parts of a Car

As an example, the instructions for the Allen "43," four-cylinder car will be used.

Systematic lubrication is the most important care that a car can receive. Perfect and continuous lubrication means less wear of parts, less trouble, and a better and smoother running car. Sketches are shown of each of the parts to be lubricated, so that there should be no difficulty in identifying them.

Lubricant is of little value when mixed with dirt, so before oiling or greasing a part, be sure there is absolutely no dirt on or in the parts.

The crank case should be filled daily if the car is being used very much. In this daily filling it is only necessary to add enough fresh oil to bring the level up to the upper mark on the indicator rod. Make this a daily habit and insure yourself against running out of oil unexpectedly. The capacity of the engine lubricating system is two gallons. Light engine oil is recommended for winter and medium for spring, summer, and fall use.

The engine oil level gauge, a bayonet type, is located on the left-hand side of the engine just ahead of the generator. In order to obtain accurate readings, it is necessary to take them when the engine is not running. The oil should never be below the bottom line and never above the top line of the blade. It is advisable to keep it near the top line by supplying oil to the engine at frequent intervals, rather than to allow oil to go to an extreme low level before refilling. In extremely hilly countries there will be a tendency of the pump to run out of oil when going down grade if the level is below half-way between the marks. There is no danger in this as long as the pump picks up the oil when on a level stretch or on upgrade. The **oil pressure gauge** will show whether or not this happens.

The crank case should be drained and replenished with oil every month, except when the car is new, in which case it should be done more often, as directed below. At the end of 300 miles a new engine should have the crank case drained and fresh oil should be supplied. This should be done again at the end of the first 1,000 miles. Thereafter every 1,000 miles will be enough, or every month, depending upon the mileage made during that period. Every 3,000 miles the oil pan should be removed and the entire pan carefully cleaned with kerosene in order to remove the metal and carbon sediment that collects. It is very important to do this, if long life is expected from the engine, because of the dilution of the oil due to the poor quality of fuel condensing and precipitating kerosene and the ability of this to work past the piston rings and into the lubricating oil.

Do not put kerosene in the engine, as it will work its way down to the crank case and thin the lubricating oil.

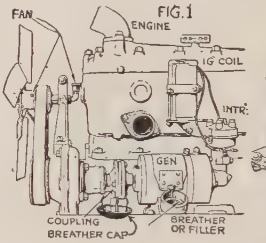

FIG. 1

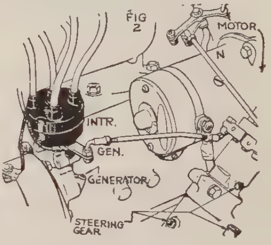

FIG 2

The fan hub is provided with an oil hole that is closed by a ball check. By depressing this plug it is possible to introduce the oil to the bearings of the fan. On some models an oil cup is provided at the rear of the fan spindle instead (Fig. 1). Use medium oil—weekly.

The electric generator and distributor bearings should receive oil monthly. They should not be flooded with oil. Five to ten drops of light oil only should be sufficient. (Fig. 2.)

The electric starting motor should be oiled at the same time as the electric generator. The same light oil should be used, and not more than five to ten drops should be applied to each bearing.

Remove the two plugs in the top of the steering gear case and fill the case with light cup-grease monthly. A grease gun will facilitate doing this. On the steering-gear housing there is a grease cup which should be turned down as far as possible and then refilled at this time.

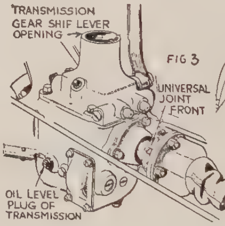

FIG 3
TRANSMISSION GEAR SHIF LEVER OPENING
UNIVERSAL JOINT FRONT
OIL LEVEL PLUG OF TRANSMISSION

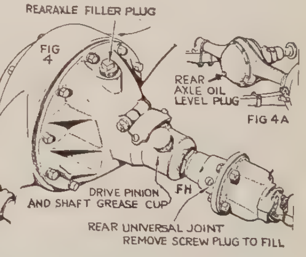

FIG 4
FIG 4A
REARAXLE FILLER PLUG
REAR AXLE OIL LEVEL PLUG
DRIVE PINION AND SHAFT GREASE CUP
FH
REAR UNIVERSAL JOINT REMOVE SCREW PLUG TO FILL

The transmission case is filled with transmission grease every month, or about every 1,000 miles. When the case is filled to a point above the counter shaft it then contains three pints of oil. A plug in the left side of the gear box (Fig. 3) determines this level. Remove the plug while filling the case. The oil is introduced through the gear-shift lever socket after the lever has been removed. The lever is easily removed by unscrewing the retaining cap and lifting lever and cap straight up out of the transmission case.

There are two universal joints between the gear box and the rear axle. These should be filled with about a teaspoonful of light cup-grease every month. Filler holes (Fig. 4) closed by plugs are provided in each universal-joint housing, so that it is not necessary to open the boot when filling them.

Every 1,000 miles **the rear axle** should be drained and flushed with kerosene, then refilled with fresh oil. Four pints of oil are required to fill the differential case of the rear axle. If more oil is used, it is liable to work out upon the brakes. The rear axle filler opening is on the front side of the rear axle and can be reached by removing the rear seat cushion (Fig. 4).

On the rear of the axle is an oil level hole (Fig. **4A**). The plug should be removed from this when replenishing the oil supply if all the oil has not been drained from the axle previous to filling and only enough oil should be added to reach the level of this oil hole. All of the axle holes are closed by plugs.

Drive pinion shaft: Fill the grease cup (Fig. 4) with transmission grease monthly. This point of lubrication is one that is often overlooked, yet it is one of the most important.

There is an oil cup on top of each **steering knuckle** and one on each end of the **front axle tie rod,** which is located just to

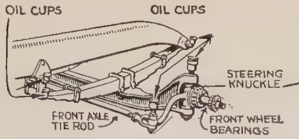

Fig. 5

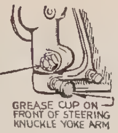

Fig. 5A

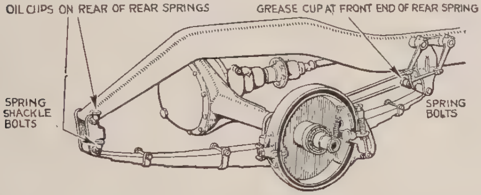
the rear of the front axle (Fig. 5). These should be filled with medium engine oil every month.

On the front of each steering knuckle (Fig. 5A) there is also a grease cup. This should be turned down each week and filled with light cup grease when the oil cups are replenished.

The **drag link** which connects the steering-gear ball arm and the steering arm on the front axle (not shown), is provided with ball-and-socket joints at each end. These should be packed with light cup grease every month, or about each 1,000 miles. In order to pack them properly, they should be taken apart. Remove the cotter pin in the ends of the sockets and screw out the sockets with a large screw driver. Great care must be taken in reassembling to see that they are tight and recotter-pinned.

The front wheel bearings (Fig. 5) should be packed with light cup grease once a month, or every 1,000 miles. To do this it is only necessary to remove the hub cap, fill with enough grease to almost fill it, and then screw it back in place. This will force the grease throughout the hub and into both front wheel bearings.



OIL CUPS ON REAR OF REAR SPRINGS
GREASE CUP AT FRONT END OF REAR SPRING
SPRING SHACKLE BOLTS
SPRING BOLTS

Fig. 6

All of the spring shackle bolts, except two, are lubricated with medium engine oil by means of oil cups provided upon the outer ends of the bolts. (Fig. 6).

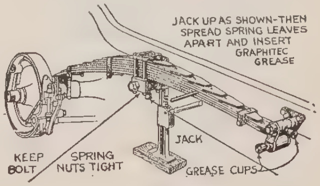
There are three cups on each front spring and two at the rear end of each rear spring. Light cup grease is used on the two bolts at the front end of the rear springs. These are on the inside of the rear springs and can be reached without getting under the car.

Miscellaneous Lubrication

The carburetor and magneto control rod bearings and connections, clutch and brake pedal shaft bearings, brake cross shaft bearings (reached through holes in the tonneau floor), and brake rod clevises, which are not provided with oil or grease cups, should be lubricated weekly with an oil can.

Lubricating Spring Leaves

Springs will become squeaky if water is allowed to enter between the leaves and rust the contact surfaces.



JACK UP AS SHOWN-THEN SPREAD SPRING LEAVES APART AND INSERT GRAPHITEC GREASE
JACK
KEEP BOLT
SPRING NUTS TIGHT
GREASE CUPS

Fig. 7

The best way to lubricate the springs (Willys Six, **Fig. 7,** is taken as an example) is to lift the car by placing a jack under the spring pad or frame, and not under the axle, and allow the weight of the wheels and the axle to pull the spring leaves apart. It will then be possible to force graphite grease between the spring leaves with a chisel or screw driver. Graphite grease is most satisfactory for this service, as the graphite will remain between the leaves and continue to act as a lubricant after the grease itself has become dry.

LUBRICATION OF A SIX-CYLINDER ENGINE AND CAR AS AN EXAMPLE

1. **Engine.** After draining, close the drain valve and fill to the level marked "full" on the measuring gauge. Inspect frequently, and keep the oil level "full." See **Fig. 8.**

2. **Transmission.** Use steam-cylinder oil for all temperatures above freezing. Thin with low cold-test motor oil sufficiently to make it liquid below freezing temperature. Remove filler cap on the left side of the transmission case and fill to the level of the opening.

3. **Rear axle.** Use steam-cylinder oil for all temperatures above freezing. Thin with low cold-test motor oil sufficiently to make it liquid below freezing temperature. Remove plug in the differential housing cover and fill to the level of the opening.

4. **Steering gear.** Use steam-cylinder oil. Insert oil until positive that the housing is full.

6. **Valve rocker arms.** Use motor oil. Insert oil can spout and fill the bracket with oil until the wick becomes thoroughly saturated.

7. **Rear spring seat.** Use motor oil. Lift the cap of the oil cup and saturate the felt in the oil pocket with oil thoroughly.

8. **King bolts.** Use motor oil. Turn the cap on the oil cup until the holes line up; fill full of oil, and give the cap a half-turn. Oil is fed automatically through a wire wick to the bolt.

9. **Tie rod bolts.** Use soft cup grease. Give grease cups half a turn. Keep filled with grease. There is one cup at each end of the tie rod.

10. **Rear spring.** Use soft cup grease. Give grease cups on spring shackles, spring blocks, and ends of springs half a turn. Keep filled with grease. There are four cups to each spring.

11. **Steering connecting rod.** Use soft cup grease. Give grease cups a turn or two. Keep filled with grease. There is one cup at each end of the rod.

12. **Brake and clutch pedals.** Use soft cup grease. Remove floor board and give grease cups one or two turns. Keep filled with grease. There is one cup on each pedal hub.

13. **Clutch release fork pin.** Use soft cup grease. Remove the clutch cover and give grease cup one or two turns. Keep filled with grease.

14. **Clutch release bearing retainer.** Use soft cup grease. Give grease cup (outside of transmission housing) one or two turns. Keep filled with grease.

15. **Brake shaft.** Use soft cup grease. Give grease cups one or two turns. Keep filled with grease. There is one cup at each end of the shaft.

16. **Starter sliding gears.** Use soft cup grease. Give grease cup half a turn. Keep filled with grease.

17. **Front spring.** Use soft cup grease. Give grease cups half a turn. Keep filled with grease. There is one cup at the front end and two at the rear end of each spring.

18. **Brake cam shaft.** Use soft cup grease. Give grease cup one or two turns. Keep filled with grease. There are four cups, two at the inner ends and two at the outer ends of the shafts.

19. **Delco generator.** A. Use soft cup grease. Swing the cover on the front end of the distributor housing near shaft to one side, and inject grease with grease gun, for lubrication of distributor gears and generator clutch.

    B. Use motor oil. Turn the oiler in the rear end of the generator until the hole is open and inject motor oil for lubrication of rear armature bearing.

    C. Use motor oil. Turn the oiler on the distributor cup and inject motor oil for lubrication of upper distributor shaft bearing.

    D. Remove the front housing cover and insert a few drops of oil for lubrication of the forward armature bearing.

Every 1,000 Miles

20. **Front wheels.** Use soft cup grease. Move or jack up car and turn wheels until the pipe plugs in the hubs appear on top. Remove the plugs, fill the hubs with soft cup grease and replace the plugs securely, and at the same time remove the hub caps and fill with grease.

21. **Rear wheels.** Use soft cup grease. Move or jack up the car and turn wheels until the pipe plug in the hubs appears on top. Remove plugs, fill hubs with soft cup grease, and replace plugs securely.

22. **Pinion-shaft bearing.** Use soft cup grease. Remove adjusting cover on pinion flange and fill with soft cup grease. Use grease gun.

23. **Fan hub.** Use motor oil. Remove plug in hub and inject a small amount of oil. Be sure and replace plug securely.

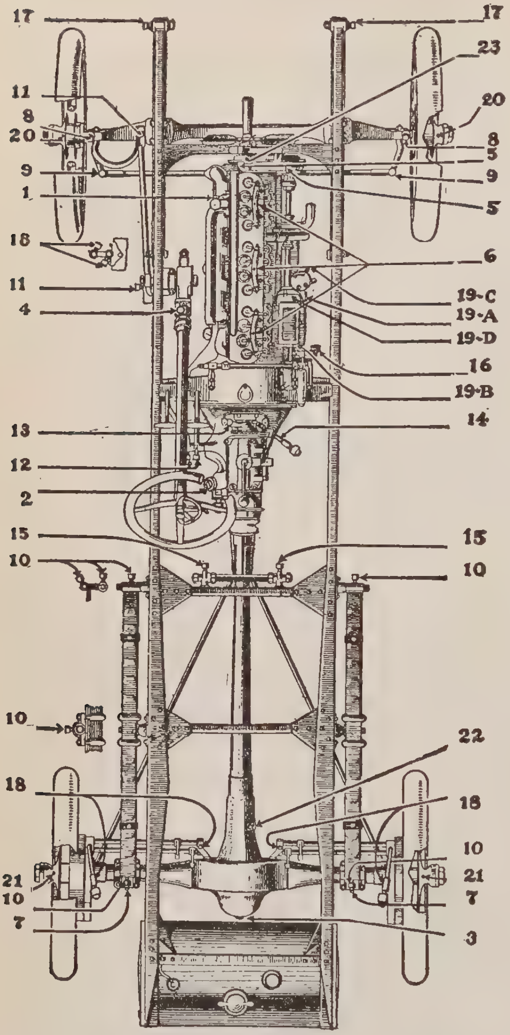


Fig. 8. Top view of a modern six cylinder car showing the location of the parts to the oil and grease.

Overhauling

Three or four times a year all the oil should be drained out of the engine, transmission, and rear axle, and these parts should be washed out thoroughly with gasoline or kerosene. It pays to change the oil in the motor frequently, or whenever it gets thin and watery. Do not use too much oil. Enough is just right, and any more will simply run out of the bearings and collect dust and dirt on other parts of the car.

At least once a year the car should receive a thorough overhauling at which time the engine, clutch, transmission, universal joint, steering gear, and front and rear axle assemblies should be taken apart and carefully cleaned and adjusted before being reassembled.

Lubricants

Motor oil used in the engine, and other places as designated, should be a high-grade, medium heavy, mineral oil, with a flash point of not less than 375° Fahr., and a viscosity of 42 to 60 seconds Saybolt at 210° Fahr., and not less than 190 seconds at 100° Fahr. for use at temperatures below freezing. The cold test of this oil should not exceed 5° Fahr. This oil should be used exclusively in the motor lubricating system, for valve rocker arms, distributor and generator bearings, spring seats, king bolts, and for all small joints not otherwise provided with lubrication, such as spark and throttle rods, brake rods, etc.

Steam cylinder oil used in the rear axle and transmission and steering gear, should be a high-grade heavy mineral oil with a viscosity of 120 to 150 seconds at 210° Fahr., and should be mixed half-and-half with motor oil of a cold test not exceeding 5° Fahr. for use at temperatures below freezing point, for the transmission gears, differential gears and steering gear. It is better for this purpose than most of the so-called "gear greases."

Soft cup grease should be a homogeneous mixture consisting of high-grade mineral oil and pure lime soap. It should be free from acids and other adulterants, and should be of a soft nature and have a sufficiently high melting point to prevent free flowing in warm weather, and should be used in all grease cups, such as those on the tie-rod bolts, starter sliding gear, brake shaft, brake cam shafts, steering connecting rod, and wheel hubs.

THE ALEMITE HIGH-PRESSURE LUBRICATING SYSTEM

This system of lubrication is now the standard method adopted by many automobile manufacturers for greasing the various parts of the car, and is a very handy method where grease cups are located in inaccessible places.

Elbow fittings are substituted for the old-style grease cups on all parts to be lubricated. The compressor is then filled with grease and coupled to the elbow with a special coupling which is easily attached. With a slight turn of the compressor handle fresh grease is forced into the parts to be lubricated and the old grease is forced out. The compressor is capable of exerting a pressure of 500 lbs.

This system can be applied to old cars, and the time saved in labor alone will soon pay for the installation.

The manufacturers are Bassick Mfg. Co., 361 West Superior St., Chicago, Ill.

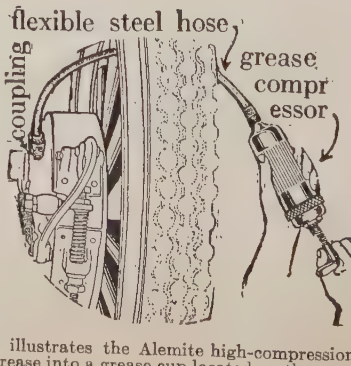

Fig. 9 illustrates the Alemite high-compression grease gun forcing grease into a grease cup located on the rear axle.

INSTRUCTION No. 17

ELEMENTARY PRINCIPLES OF ELECTRICITY AND MAGNETISM: Purpose of Ignition; Ignition Methods; Low-Tension Coil Ignition; Principle of a Low-Tension Coil

ELECTRICITY

Electricity[1]: No one can tell you what electricity is. Electricity is in everything—in your body, in your clothes, in this paper, in the chair; and the only reason you do not know of its presence is because it is not in motion.

If you put a water-wheel in the middle of a pond, the wheel will not revolve. To make the wheel revolve, in order to get any work out of it, you must place the wheel in such a position that the water may flow from a high to a low level and thus produce pressure of the water against the wheel. Thus when the water is in motion we can obtain work or energy from it.

Just so with electricity: when it is put into motion you can obtain work from it.

Before the water-wheel will move, a current of water is necessary. So in electricity, there must be a "current," or a "flowing" of electricity before you can get any work out of it, and a circuit must be provided for it to flow in.

Amperes: The current, or rate of flow, of electricity is termed "amperes." Just so is the flow of so many gallons of water per second or minute. The ampere is the unit of electric current, or the rate of flow, as, for example, so many gallons of water per second.

Electro-motive force: Before a current of electricity will flow in a circuit, there must be a force or pressure to move it. The something which is necessary to put it into motion is an electro-motive force, abrreviated e.m.f., and often referred to as "voltage."

Electro-motive force can be generated "chemically," by means of a battery, or "mechanically," by means of a generator.

When water is pumped into a tank, a pressure is required to force the water to the tank through the pipes. Just so with electricity. When a current of electricity from a generator is sent through a circuit to charge a battery, a pressure (e.m.f.) is required to force the current of electricity to the battery.

Volt: The unit of e.m.f. is the "volt." For instance, we could say a generator had an e.m.f. of 8 volts at the brush terminals at 1,000 revolutions, and at this speed, e.m.f. would force an output or rate-of-flow of current of 15 amperes through a circuit.

To make this clear, take the analogy of water flowing through a pipe under pressure. That which causes the flow is "pressure," which corresponds with e.m.f.; that which resists the flow of water through the pipe is "friction" of water against the pipe, due to the size of the pipe and the rate of flow of water through the pipe.

Just so with electricity, there is resistance offered to the flow of the electric current through a conductor forming a circuit.

Conductors: A conductor is anything that readily carries electric current, such as copper wire, carbon or gauze generator brushes, the frame of a car, the metal part of the car such as the engine, etc. All metals are conductors.

Some conductors offer less resistance to the flow of electric current than do others. The less resistance a conductor offers, the better a conductor it is.

The best conductor is silver, the next best, copper, then aluminum, zinc, brass, platinum, iron, nickel, tin, lead, German silver, antimony, mercury, bismuth, carbon, water. Thus it will be seen that iron offers more resistance than copper, and carbon and water more resistance than iron. **Non-conductors** are slate, marble (if there are no metallic veins), oils, porcelain, glass, rubber, dry paper, silk, gutta percha, shellac, ebonite, etc.

Hence the reason for using copper wire. Silver, as observed above, is the best conductor, but is too expensive. Copper is next best, and not as expensive, and is universally used.

Iron wire offers 6½ times the resistance to the flow of current that the same length and size of copper wire does; therefore if either the iron wire or copper wire is not of sufficient size to permit the free passage of current, the wire will heat. The resistance of the lamp filament is such that it heats and gets quite hot. The greater the resistance, the less total current can pass; hence the pressure or voltage will drop.[1]

Ohm: The ohm is the unit of electric resistance. We speak of a certain size of copper wire of a certain length having so many ohms-resistance.

Electric current flowing in a circuit, is therefore dependent upon something besides pressure (e.m.f., voltage) and that is the **resistance** which opposes the flow of electric current in a circuit.

Resistance is that property of an electric conductor by which it opposes the flow of an electric current. For instance, carbon, iron wire, German silver and water will permit current to flow through, but it opposes, or offers resistance to, the flow. **A rheostat** is a device for the purpose of varying the resistance of an electrical current, and is usually made with coils of iron wire or German silver wire, etc. A lamp filament of an electric lamp bulb offers resistance; in fact, it offers so much that it heats white hot.

---

[1] It is said that **atoms** of which everything is made, are composed of two different elements called **"electrons"**: one a **positive**, the other **negative**. They neutralize each other when together. Thus if electricity is to be utilized, it is necessary to separate the negative from the positive electrons, and then electricity will flow. It is easier to separate these electrons in copper than it is in hard rubber, glass, etc. Thus copper is used as a conductor and glass and rubber as insulators.

There are several methods of setting electricity in motion. One method is to pass a copper wire across a magnetic field or a magnetic field past a wire. Thus e. m. f. (electro-motive force) is generated in the wire, causing electricity to flow.

Electricity, and a current of electricity, are different. For instance, we do not notice the atmosphere we are living in until a pressure arises and the wind is caused to move. Then we feel it. Thus with electricity, it is in almost everything, but we do not notice it until it is set in motion by pressure (e.m.f.).

[1] Termed a "potential difference" or "energy lost." For instance, "two volts lost on a line" means this much pressure is lost in sending the current through the line.

Resistance opposes the flow of electric current in any circuit it may travel in. The amount of resistance offered depends upon the circuit, size of wire, etc.

As the pressure (e.m.f., voltage) increases, the rate of flow of electric current increases proportionally; as the resistance increases, the rate of flow of electric current decreases.

The greater the resistance which opposes the flow of electric current in a circuit, the less current a certain pressure will produce.

The less the resistance of the circuit, the greater the current a certain pressure will produce.

For example, if the pressure, say, is 6 volts and remains constant, the rate of flow of current will vary if the resistance varies; that is, if the resistance of the circuit be doubled by adding more lamps, etc., the current in the circuit would decrease one-half.

If the resistance of the circuit be decreased, say, one-fourth, by cutting off lamps, the current will increase four times.

Ohms law: One volt will force a current of electricity through one ohm of resistance at the rate of one ampere per hour.

Volts ÷ ohms = amperes
Volts ÷ amperes = ohms
Amperes × ohms = volts

Thus, if any two terms are known, the third can easily be found by means of this rule.

For example, suppose the pressure of a generator is 6 volts and the resistance of a lamp is 6 ohms. What amperage or current is necessary?

Current (amperes) = pressure (6 volts) ÷ resistance (6 ohms) = 1 ampere.

Again, suppose the pressure of a generator is 6 volts and there is a current of 4 amperes passing in a circuit. What is the resistance in ohms of the circuit?

Resistance (ohms) = pressure, 6 volts ÷ current, 4 amperes = 1½ ohms.

Again, suppose the resistance of a lamp is 3 ohms, what pressure would be required to produce 1 ampere through the lamp?

Pressure (volts) = resistance, 3 ohms × current, 1 ampere = 3 volts.

Coulomb is the unit of electrical quantity, or such a quantity of electricity as would pass in one second in a circuit whose resistance is 1 ohm. We are not interested in the quantity of electricity alone, but in the rate-of-flow, the ampere, and for this reason the coulomb is very little used.

The watt is the unit of electric power. 746 watts is equal to 1 horse power (h.p.). Amperes × volts = watts.

Ampere-hour: 1 ampere of current for 1 hour = 1 ampere-hour.

How Electricity Is Transmitted

Electricity produced in one place may be transmitted to another place, providing a path or circuit is arranged so that it may return to where it started. If the circuit is broken, the flow will immediately stop and will not start again until the circuit is completed.

A switch is usually placed in all electrical circuits to stop the current from flowing when not desired.

Electricity flows from the **positive** (+) **terminal** through the circuit back to the **negative** (−) **terminal.** Therefore in tracing a circuit, always start with the source of electric supply at the + terminal. The copper wire in which the current starts is called the "lead" (pronounced "leed"), and the return path is called the "return."

Insulators: Substances such as rubber, china, porcelain, glass, wood, fiber and mica are called non-conductors or insulators.

A wire is insulated to prevent leakage of current into any metallic substance it may touch, by wrapping it with cotton or silk, which is soaked with rubber to prevent dampness from getting in.

When dry, cotton and silk are insulators, but as water is a conductor, damp cotton and silk cease to be insulators.

Ground: This word is used to express two meanings. It has nothing whatever to do with the ground.

One meaning of a "ground" is a leak. For instance, if there is any way by which the current may "leak" from the wires conducting the current, and return to the starting point without going through the entire circuit, this is termed a "bad ground" or "short-circuit." If the leak is only slight, and not enough to short-circuit the path, then it is termed a "ground," and part of the current may reach its destination and return, but part of it will leak through the "ground," such as damp or oil-soaked insulated wires, or wires too near the hot engine, etc. See Index for the meaning of "grounds" and "short circuits."

Another meaning of "ground" is where a wire is intentionally "grounded" or connected to the metal part of the car, such as the frame, engine, etc. One wire of an ignition coil, contact-breaker, and one terminal of a generator and storage battery are often "grounded" to some metal part of the car. This permits using the frame as a return path, and also less wire is used.

Ignition coil terminals often have one of the terminals marked "GRND," meaning that this terminal should be grounded.

When a battery negative terminal (−) is grounded, the generator − terminal must also be grounded, and vice-versa, if the positive terminal (+) is grounded. The − terminals are usually grounded; however, on some systems, the + terminals are grounded.

Electricity will always take the path that offers least resistance.[1] Air offers considerable resistance to the flow of electricity. This is the reason why such a high pressure (voltage) is required to cause current to jump across the gap of a spark plug (see Fig. 1, page 188, for a spark plug).

---

[1] The velocity of electricity through a copper wire is said to be 186,000 miles per second.

HYDRAULIC ANALOGY OF CONNECTING CELLS

In order to explain the meaning of voltage and amperage more clearly, and how these vary through making different connections, we shall use a hydraulic analogy as follows:

Suppose an ignition coil was wound with a certain number of turns of wire, and that a pressure of 6 volts was required to force a current of 5 amperes of electricity through the wire; and suppose we wanted to use dry-cell batteries for this purpose.

A dry cell usually gives about 1¼ to 1½ volts and its rated output or capacity is from 20 to 25 ampere hours, that is, it will deliver 1 ampere for 20 or 25 hours, or 20 or 25 amperes for 1 hour.[1]

If we connected one dry cell to the primary winding of the coil, the pressure of the one dry cell would not supply sufficient electromotive-force to carry the required current through the winding of the coil. It would be necessary to increase the pressure (voltage). As the pressure (voltage) increases, the rate of current (amperage) flow increases. Therefore it would be necessary to add more cells.

If one cell gives 1½ volts pressure, 4 cells would give 6 volts. Therefore if we connected 4 cells in series, we should obtain 6 volts, but inasmuch as the voltage of a dry cell drops quickly to 1¼ volts or less, we should then use 5 cells connected in series.

It is not advisable to use more cells in series than are needed, because the excess of pressure (voltage) would force the electricity through the circuit at too great a rate or amperage, and this would cause sparking at the vibrator points of the contact-breaker of the coil ignition system and would also likely cause such an increase of voltage in the secondary winding that it would puncture the insulation of the secondary winding (if a high tension coil).

Meaning of "Series," "Parallel," and "Multiple" Connections

This can be explained by referring to our hydraulic analogy, as follows: Suppose we had three pails of water, each of them 1 foot high (giving 1 foot pressure), as shown in Fig. 1, and suppose we had three dry cells, each of them giving a pressure of 1 volt. By connecting them in different ways we obtain different pressures.

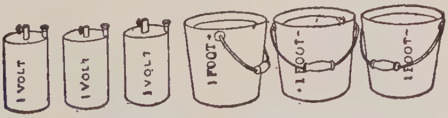

Fig. 1. Comparing dry cells or storage-battery cells with pails of water.

Series connection: In the illustration (Fig. 2), three dry cells are connected in "series," similar to pails of water placed one above the other; the pressure (voltage) is three times as great as if only one pail or cell is used, or 3 volts. The capacity would be that of one cell.

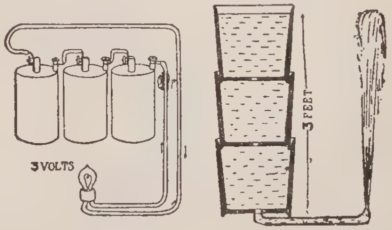

Fig. 2. Dry cells connected in "series," similar to pails of water placed one above the other.

When connecting dry cells mentioned above in series, the carbon terminal (+) is connected with the zinc (−) terminal of the next cell. Thus at the final two terminals, we have one (+) and one (−) terminal, and the voltage at these terminals would be 3×1 volt, or 3 volts.

Note. Illustrations of dry cells are represented as giving 1 volt, and each pail of water as 1 foot pressure, as a matter of easy comparison.

Parallel or multiple connection: The three dry cells are connected in "parallel" or "multiple," similar to pails of water connected one with the other as shown in Fig. 3. The pressure (voltage), is equal to only one pail or one cell. The capacity would be that of three cells.

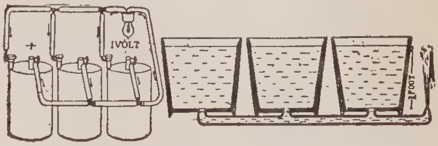

Fig. 3. Dry cells connected in "parallel" or "multiple," similar to pails of water connected one with the other, as shown, to increase the capacity. Voltage is reduced to one cell.

The (+) terminals are connected together and all of the (−) terminals are connected together. The circuit is then between the (+) and (−) group, and the voltage at the terminals would be that of one cell, or 1½ volts.

"Series-parallel" or "series-multiple" connection: Two sets of cells are connected in "parallel." Each set of three cells is connected in "series." This connection is termed "series multiple" or "series-parallel." The pressure is equal to three pails or three cells. The capacity would be that of two cells.

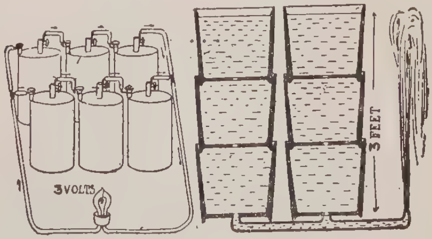

Fig. 4. Two sets of dry cells connected in "parallel," each set connected in "series," similar to pails of water placed and connected as shown, to increase the capacity to two cells and the voltage to three cells.

The two sets of three cells are connected in "series"; then the two series sets would be connected in "parallel" or "multiple." Each of these two sets would then have a (+) and a (−) terminal. The two (+) terminals are connected together, and the two (−) terminals are connected together. The voltage at the terminals would be 3×1½ volts, or 4½ volts.

---

[1] A dry cell, in actual practice, would not deliver current steadily for any great period of time, due to the fact that its voltage would drop on continued use; but if used intermittently, such as for such service as ignition starting, and then being switched off, and used off and on for short periods of time, it would deliver somewhere near its capacity as mentioned above. In other words, it is so constructed that the ampere-hour capacity is greater when producing small current than when producing large current. If a dry cell exceeds 25 ampere capacity of the usual standard size, it will likely polarize and set up a counter-electromotive-force. Thus the terminal voltage would drop more quickly than one of normal capacity (20 to 25 amperes).

Where several dry cells are connected together, if there are weak cells in the circuit, they will absorb the strength from the strong ones, as they will then offer resistance to the good ones, thus **bringing the capacity down to that of the weak ones.** A storage-battery cell which delivers 2 volts pressure would hold its pressure nearer to a constant value until discharged.

When connecting two sets of cells in "parallel" it is important that they have the same internal resistance and produce the same pressures, in order that they divide the total current equally. The same thing is true of storage batteries.

If one set has a lower voltage than the other set, then there will be a current through the lower voltage set from the higher voltage set, in a direction opposite to its own pressure. The one of higher pressure will send a current through the one of lower pressure and also the current through the main circuit.

Where dry cells are used for ignition, it is advisable to use two sets of 5 or 6 cells connected in "series." One set is used for a while, then the other set. If both sets give out, as an emergency, connect the two sets in "series-parallel" as shown in Fig. 4.

METHODS OF GENERATING ELECTRICITY

Electrical energy or e.m.f. which forces electric current to flow in a circuit, **can be generated by two general methods,** as used on the automobile. One method is by a **chemical action,** which is the principle of the battery; the other is the conversion of mechanical energy into electrical energy by means of **electromagnetic induction,** which is the principle of the generator and magneto.

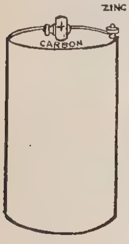

Fig. 5

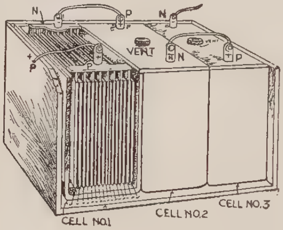

Fig. 6

Fig. 5. Dry cell; a primary cell; a chemical generator.

Fig. 6. Storage battery; secondary cell; a chemical generator.

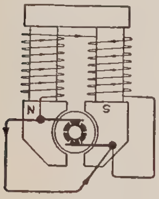

Fig. 7

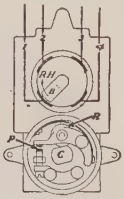

Fig. 8

Fig. 7. Dynamo; a mechanical generator; direct current.

Fig. 8. Magneto; a mechanical generator; alternating current.

Direct current (D.C.), means electric current which flows in one continuous direction.

Alternating current (A.C.), means electric current which alternates in its flow.

Chemical Generators

Chemical generators are of two kinds, "primary cells" and "secondary cells." Only direct current is produced by a chemical generator.

Primary cells[1] (Fig. 5) are usually referred to as "dry cells," and electrical current in a circuit is produced from them by converting chemical energy into electrical energy by a consumption in it of some substance, such as zinc.

Secondary cells[1] (Fig. 6) refer to the cells of a storage battery, where a current of electricity must first be sent through the cell to cause a chemical action, called "charging," which will put it in such a condition that it is capable of producing a current on "discharge," or whereby it will convert chemical energy into electrical energy.

On most cars three cells of 2 volts each, are used thus making a six-volt battery. On some cars, such as the Dodge and Franklin, six cells of 2 volts each, or a 12-volt battery, are used.

There is a set of positive (+) plates and a set of negative (−) plates to each cell, and the cells are usually connected in series. The (+) terminal is usually a dark-brown color, whereas the (−) terminal is gray.

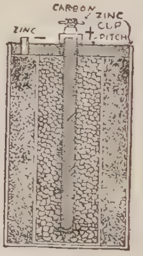

Fig. 9

A dry cell (primary cell, Fig. 9) consists of a zinc cup (−) in which a carbon stick (+) is placed as shown. The space between the carbon and zinc is packed with bits of carbon and the necessary chemicals.

The dry cell contains no liquid, but merely moisture, hence its name—"dry cell."

The chemicals used vary, one formula being chloride of zinc, sal-ammoniac, sulphate of lime, and powdered charcoal.

When the circuit is closed from one terminal to the other, a chemical action takes place between the carbon (+) plate and zinc (−) plate, thus generating an electromotive-force which causes the current to flow.

A dry cell has a pressure or voltage of about 1¼ to 1½ volts, and the capacity or volume of current it will produce, called amperage, depends upon the size of the cell. The average is 20 to 30 amperes.

When in use, a primary cell becomes exhausted, and the voltage drops gradually. It will, however, recuperate if disconnected for a period of time. When it has reached a point where it does not recuperate to give sufficient current, it must be discarded and replaced with a new one.

It should be remembered that dry cells are intended for "intermittent" service, as for ignition starting where a magneto is used, after starting the engine, but for continuous service the dry cell is not a suitable source of current. After the engine has started, dry cells for ignition are not very satisfactory, for they become exhausted in a short time. The less continuous current is used from a dry cell, the longer it will last, and the more efficient it will be.

---

[1] Wet cells (not the storage-battery cell) are also referred to as primary cells, but are not used for automobile work.

[1] Secondary cells are also called "storage-battery cells" or "accumulators." One cell, no matter how large or how small, will show a voltage of a little over 2 volts when fully charged, and will drop to about 1.8 volts when discharged.

For continuous-current service, the most efficient means of obtaining current is by means of **a storage battery** consisting of a battery of "secondary cells," or, as it is sometimes called, an "accumulator." This chemical type of electric generator, in connection with a dynamo, is in more common use for ignition than the dry cells.

Mechanical Generators

A mechanical generator of electricity on an automobile is usually driven by the engine and thus produces electromotive-force in the armature coils. This causes electric current to flow out of the armature through the (+) brush, through the external circuit to the (−) generator brush. This action depends upon **electromagnetic induction,** which will be explained farther on.

There are two general types of mechanical generators for automobile work:

1. **The alternating-current magneto-generator** (Figs. 10 and 8) is driven by the engine and is used **only for ignition** purposes, and can be a low-tension (voltage) or a high-tension (voltage) generator. It generates alternating current; therefore it would not charge a storage battery.

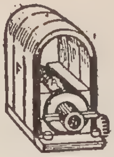

Fig. 10

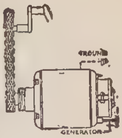

Fig. 11

Fig. 10. A magneto. Generates alternating current.

Fig. 11. A direct-current generator (dynamo). Both magneto and generator are driven mechanically by the engine.

2. **The direct-current electric generator** or dynamo (Figs. 11 and 7) is driven by the engine and generates alternating current. In fact, all mechanical generators generate alternating current in their armatures, but this is changed to direct current at the commutator. Thus, from the brushes the current is direct. This direct-current generator is used **to charge the storage battery and to supply current for the lights and ignition.** When it is running at its normal speed its voltage is higher than that of the storage battery. At other times, the storage battery supplies current for the lights, ignition, and also the starting motor. Approximately, the **generator** gives only from 15 to 20 amperes at 6 or 12 volts. The **starting motor** requires from 150 to 450 amperes of current, depending on how stiff the engine is. Thus only the storage battery could supply this great quantity of current.

PRINCIPLES OF ELECTRICITY AND MAGNETISM

In order to understand the action of an **ignition coil, magneto, and generator,** it is necessary to understand: (1) magnetism; (2) magnetic induction; (3) electromagnetism; (4) electromagnetic induction.

Magnetism

Magnetic circuit: Magnetic lines-of-force are invisible waves that pass from one pole of the magnet to the other. The lines-of-force pass from the north (N) pole to the south pole (S), *outside* of a permanent magnet, and from (S) to (N) *inside*, thus forming a closed magnetic circuit. Magnetism cannot be transmitted through wires like electricity.

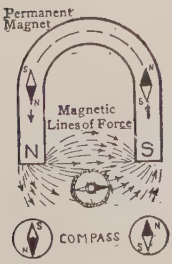

Fig. 1

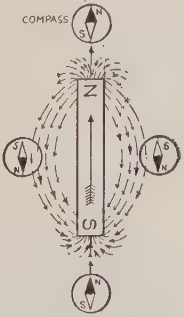

Fig. 1A

Fig. 1. A horseshoe type of permanent magnet.

Fig. 1A. A bar type of permanent magnet.

Polarity of a magnet: If a compass (Figs. 1 and 1A) is placed at the (N) pole end of a magnet the (N) end of needle will point away from the (N) pole, or with the direction of the flow of lines-of-force, which is always *out* at (N) and *in* at (S) pole. This is why the (N) pole of a magnet attracts the (S) pole of a compass needle, and why the (S) pole of a magnet attracts the (N) pole of a compass needle.

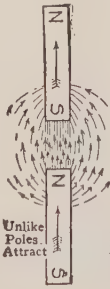

Fig. 2

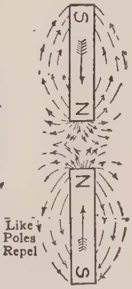

Fig. 2A

Fig. 2. Unlike poles attract.

Fig. 2A. Like poles repel.

This is also the reason why the (N) pole attracts the (S) pole of another magnet (Fig. 2), and why the (N) pole repels the (N) pole (Fig. 2A). Like poles repel, and unlike poles attract, because other lines-of-force pass in a circuit (N) to (S), outside, and (S) to (N) inside of a magnet.

A bar magnet is shown in Figs. 1A, 2, and 2A. Note that the **magnetic circuit** is the same as in the horseshoe magnet (Fig. 1). The magnetic lines flow through the air from (N) to (S) pole outside of the magnet and through the magnet from (S) to (N).

If an iron bar is placed between the poles of a magnet, as in Fig. 3, the lines-of-force will flow freely through the iron bar, because the air-gap between the poles offers 280 times the resistance

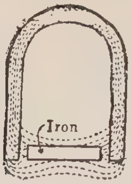

Fig. 3

that iron does. The iron bar tends to gather and collect stray lines-of-force and to concentrate the lines. Thus we obtain a great many more lines-of-force by using the iron bar.

Soft iron is generally used for the armature core on a magneto and also on generators, and for cores of ignition coils also, because soft iron will not retain its magnetism after the magnetic effect has been removed. In generating electric current this is an important factor, that is, the iron bar must become magnetized and demagnetized quickly, as this change of action, explained farther on, is desirable.

Permanent magnet: If hard steel is used, it tends to retain its magnetism, just as the magnets in Figs. 1, 2, and 3 do. Thus they are called permanent magnets on this account. Permanent magnets are used **principally on magnetos.**

When permanent magnets are heated, the iron has a tendency to soften; thus, the more it is heated, the more it loses its magnetism.

Magnetic Induction

Magnetic induction: If a piece of iron or steel is placed in a magnetic field of a magnet, it will become a magnet. Magnetism is "induced" into the iron or steel. See Fig. 4 and note how one magnet will induce magnetism into another magnet if unlike poles are placed together so the lines-of-force will flow from (N) to (S).

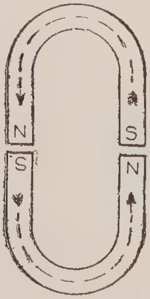

Fig. 4

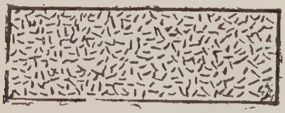

Fig. 5. Not magnetized.

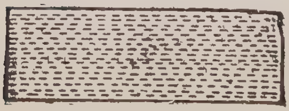

Fig. 5A. Magnetized.

An explanation or theory why hard steel retains the magnetism, and why soft iron does not, is that steel or iron composed, like all matter, of small **molecules,** is made up of minute magnets. If the steel or iron is not magnetized, the molecules have no definite arrangement (Fig. 5). If, however, it is magnetized (Fig. 5**A**), the molecules, like small magnets, all arrange themselves with the (N) pole of each pointing (N), and thus these molecules or little magnets all point in the direction from which the magnetizing force is being applied, and thus form one large magnet.

When all of the molecules or little magnets have been turned around, the iron or steel is then said to be completely magnetized or "saturated," and cannot be further magnetized.

Soft iron permits these molecules or little magnets to return to their original position, and almost all of its magnetism is lost when the magnetic influence is removed. This condition is termed "de-magnetized."

There is, however, always some magnetism left in a soft iron core, called **"residual magnetism"** on generators, where the field poles are wound with wire. When the generator first starts, enough **residual magnetism** is in the iron to supply lines-of-force for the armature wires to cut and thus build up. This is a very important factor when generating current in a dynamo with electromagnetic fields.

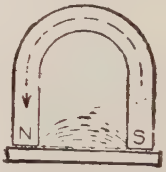

Fig. 5B. Keeper.

Steel requires more magnetic force to magnetize it, but the molecules retain their position if a "keeper" (Fig. 5**B**) is placed on the end of the poles; otherwise the molecules will eventually return to normal condition and the permanent magnet will gradually lose its magnetism.

A permanent magnet would be suitable for magneto field poles, but not for an armature. It is not suitable for any part of a generator or ignition coil, but lines-of-force are very necessary, and, owing to the fact that the lines-of-force must change in value from zero to maximum, soft iron is used for magneto armatures, generator armatures, and field poles and cores of ignition coils.

Magnetic-field-of-force[1] is the space around or between the magnet where the magnetic lines-of-force pass.

Electricity is in almost everything, but requires force to move it in order to produce energy or work.

Electromotive force (abbreviated e.m.f.) is the force or **pressure** which moves electricity, and the unit of electromotive force is a volt. When current is sent through a wire or coil from some source, the e.m.f. is supplied from that source.

Electromagnetism

Electromagnetism differs from magnetism in that the magnetism exists only when the current is flowing through the conductor or wire.

---

[1] "Magnetic flux" is a term often used to express the total number of lines-of-force flowing through a magnetic circuit.

If electric current is sent through a straight wire, as in Fig. 6, a magnetic field will be set up around the wire. Its strength or intensity will be in proportion to the amount of electric current flowing through the wire.

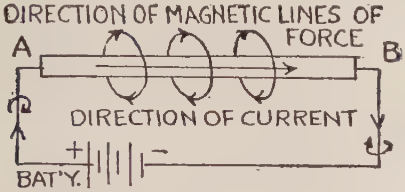

Fig. 6. Magnetic "whirls" around a wire in which direct electric current is flowing.

Electric current always flows from positive (+) to negative (−). Therefore, in Fig. 6, the current is flowing from (+) of the battery, through wire, to (−) of the battery. The magnetic lines-of-force will whirl around the wire in a right-hand or clockwise direction *with* the flow of electric current.

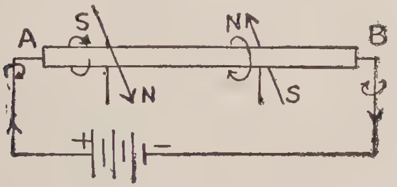

Fig. 6A. Note that the magnetic whirl above the wire is in one direction, and underneath in the opposite direction.

Direction of magnetic whirls around a wire: If a compass is placed above the wire (Fig. 6A), when looking at the end **A**, where the current is going *in*, the lines-of-force will whirl clockwise as in Fig. 6B, and the (N) end of the compass needle will point *with* the direction of the flow of the lines-of-force. If the compass is placed *below* the wire, the (N) end of the compass needle will point in the opposite direction, thus proving that there is a magnetic field circling around the wire.

If the compass is placed above the wire, when looking at the end (**B**) (Fig. 6**C**), where the flow of current is coming *out* instead of going in, the lines-of-force will be whirling around the wire in a counter-clockwise direction, but the magnetic whirls are still clockwise following the direction of the flow of the current in a clockwise direction.

In other words, the lines-of-force are in the same direction, but we are looking at it from the other end; just as the engine of an automobile revolves in a clockwise direction if we look from the front, but it revolves in a counter-clockwise direction if we look from the rear.

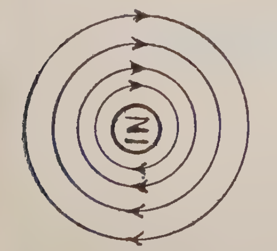

Fig. 6B

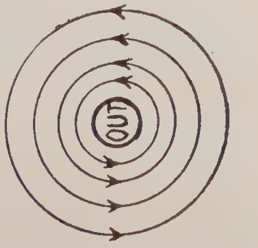

Fig. 6C

Fig. 6B. Note that the magnetic whirls are clockwise when the current is going in the front end of the wire, and counter-clockwise when leaving at the rear end (6C) where the current is coming out.

If electric current is sent through a wire at end (**B**) instead of (**A**), the magnetic whirls would be clockwise, or in a right-hand direction with the flow of electric current, but in the opposite direction to what they were formerly, because the current has been reversed.

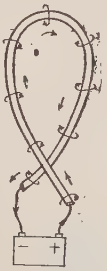

Fig. 7

If an electric current is sent through a wire in the **form of a coil** (Fig. 7), the direction of the magnetic whirls of lines-of-force is clockwise with the flow of electric current in the wire. Note that the whirls are in an opposite direction on either side of the wire. However, the whirls are clockwise with the direction of the flow of current at all points of the circle. Start at (+) and follow the circle in a right-hand direction all the way around, and the explanation will be made clear..

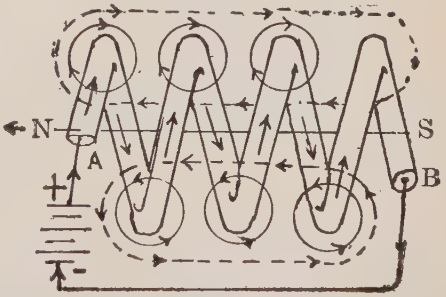

Fig. 7A

If an electric current is sent through several turns of wires or coils (Fig. 7**A**), which would be termed a **"solenoid"** or "helix," the lines-of-force would join together, because when current flows in two wires side by side (Fig. 7**B**), in the same direction, the lines-of-force join, because they are circling around the wire in the same direction.

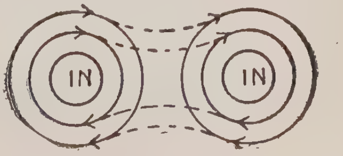

Fig. 7B

Where there are several coils side by side, as in Fig. 7A, note the (+) current is going in the wires at (**A**) and coming out (−) at (**B**), at the other end of the coil. The lines-of-force would then whirl clockwise with the flow of electric current, but in doing so they would whirl at the top, in one direction, and in another direction at the bottom. This is due to the current flowing around a circle. However, if the magnetic whirl is followed in its path around the circle, it will be observed that the direction is right hand or clockwise with the flow of current at any point of the circle.

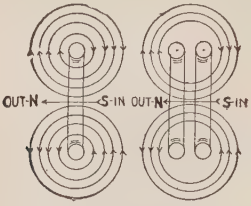

Fig. 7C

Polarity of a helix or solenoid: In Fig. 7C, one coil of wire is cut in half to make the explanation clearer, because the point we wish to arrive at is the advantage of the lines-of-force joining and passing around all of the turns of wire of the coil, which is to make one end of the coil (N) pole, and the other end (S) pole.

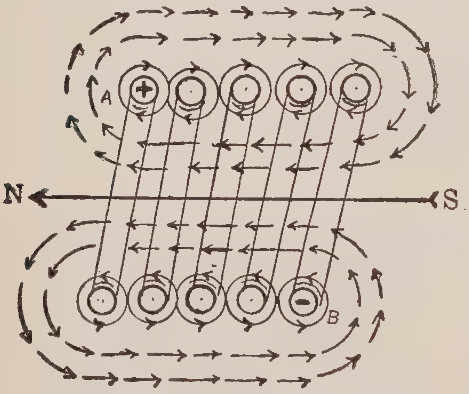

Fig. 7X

We observed in Fig. **1A** that on a permanent magnet, the lines-of-force passed *outside* of the magnet from (N) pole to (S) pole, then from (S) to (N) *inside*. The same effect is taking place in this coil of wire or helix (also called a solenoid), because when the lines-of-force whirl clockwise with the current going in at (**A**) (Fig. **7A**), the lines would whirl *out* of the (N) or left end of the coil, pass over and under and around the coil, and go into the other end (S) (see Fig. **7X**), through the inside of the coil, back to end (N) again. Thus we have the lines whirling *out* at (N) pole and *in* at (S) pole, and we have established a (N) and (S) pole **polarity** of the coil, which is clearly shown in Figs. **7A** and **7X**.

If the electric current was sent into the end at (**B**) of the coil (Fig. **7A**) instead of at (**A**), the whirl would be in an opposite direction. Thus the end (**B**) would be (N) pole, and the end (**A**) would be (S) pole.

The next question is, What is the advantage of having these lines-of-force passing around a coil of wire in this manner? The answer is, To form an electro-magnet.

Electro-magnets: If we place a soft-iron wire core (Fig. **7Z**) inside of a coil or helix which is carrying current, the iron core will offer a great deal less resistance to the passage of the lines-of-force through the center of the coil than does the air. This is due to the fact that the iron will collect a lot of stray lines-of-force and produce a great many more, and thus strengthen the magnetic field (lines-of-force around the coils of wire), as it is this magnetic field which, when the circuit is opened, collapses and passes back into the core and, in doing so, cuts the coils of wires and produces a greatly increased electromotive force. In other words, the magnetic lines-of-force produced from the current flowing through the turns of wires are going to be utilized to transform the primary low-voltage current passing through the turns of wires (primary winding) into a high-voltage current for ignition purposes, as will be more fully explained farther on.

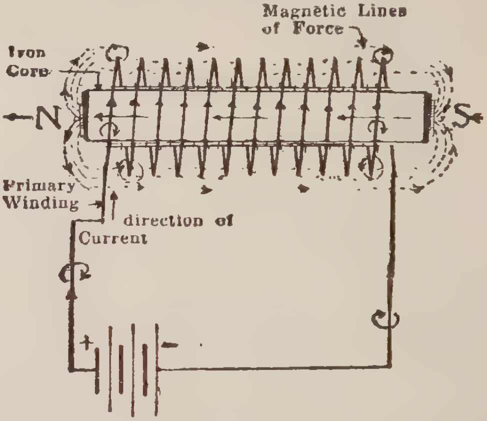

Fig. 7Z. How the magnetic whirls around the wires join forces to produce an electro-magnet.

The strength of an electro-magnet is dependent upon the number of ampere **turns**[1] of wire on the coil. The number of amperes flowing through the turns, multiplied by the number of turns, will determine the magnetic strength of the core.

For instance, if one ampere is carried around the core for 100 turns (100 ampere turns), it will equal in effect ten amperes flowing through ten turns. The effect of the turns decreases as the distance from the core increases. A rule is to wind wire 1 inch deep on a core of about 1 inch in diameter.

Polarity of electro-magnets: In Fig. 8, the (+) current is going in at the right-hand end of the coil, and lines-of-force around the wire would whirl **into** (S) end of the core and then pass through the core and come **out** at the other end of the core (N), thence around the core and coil outside to (S) end again.

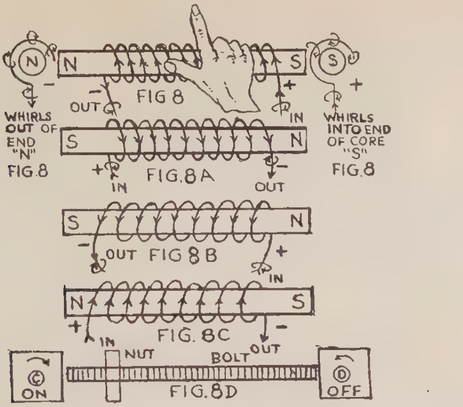
The end *into* which the lines whirl would be (S) pole end, and the end they whirl *out* would be (N) pole end.

In Fig. 8**A**, the (+) current is going into the coil at the opposite end from that of Fig. 8. Therefore the magnetic lines-of-force would whirl *in* at end (S) and *out* at end (N). Thus the polarity would be reversed from what it was in Fig. 8, owing to the electric current flowing in the wire in an opposite direction.

In Fig. 8**B**, the electric current enters the wire coil at the same end as in Fig. 8, but the wire is wound *under* instead of *over*. Thus if we follow the magnetic whirl in a right-hand direction where it enters wire (+), we note that the whirl is *out* of

---

[1] "Ampere turn" is one turn of a winding through which a current of 1 ampere flows.



Figs. 8, 8A, 8B, 8C, and 8D. Explaining how the direction of the current through the wire and the direction of the wire wound on the iron core produces different polarities of an electro-magnet.

core instead of *into* core; thus it is (N) pole at the right-hand end and (S) pole at the left-hand end.

In Fig. 8C, the electric current enters the wire coil at the same end as in Fig. 8A, but the wire is wound *over* instead of *under;* thus the magnetic lines-of-force around the wire at the left end whirl out of core and the left end is (N) and the right end (S).

A good way to remember the direction of the whirl of the lines-of-force around a wire, when the current is flowing in the wire, is to think of a rod with right-hand threads on it (Fig. 8D). If, for example, the current enters *in* the end of rod where nut (C) would be screwed on, the nut would turn in a right-hand or clockwise direction with the flow of current. If, however, you were looking at the end where the nut is screwed off, and where the current came *out*, the nut (D) would still be turning clockwise with the flow of current, but the nut would be turning counter-clockwise when looking at that end.

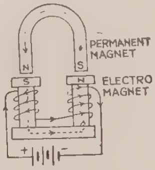


Fig. 9

The difference between a permanent magnet and an electro-magnet is shown in Fig. 9. Note in this instance that the electro-magnet is being used to induce magnetism into a permanent steel magnet. Note that the flow of magnetic lines-of-force is out (N) pole into (S) pole. The permanent magnet of hard steel will retain its induced magnetism, whereas the soft-iron core of the electro-magnet will lose its magnetism when the electric current flow is open. This is an important point to remember in connection with the principle of the action of a coil.

The principle of the ignition coil, magneto, and generator is based on electromagnetism and electromagnetic induction.

How are we going to apply this information to the production of a high electromotive force in an ignition coil, and to the generating of electric current in a magneto, and the generating of electric current in a dynamo or generator?

The reverse-current cut-out, the electromagnetic vibrator type of generator regulator, in fact very nearly all parts of the electric system on a car, have their fundamental principle based on magnetism in some form, especially electromagnetic induction.

Electromagnetic Induction

Electromagnetic induction refers to **an electromotive force, or electrical pressure, set up by induction** at the terminals of a conductor, such as a wire, which is moved in such a way as to cut across the magnetic lines-of-force, or magnetic field, at right angles.[1]

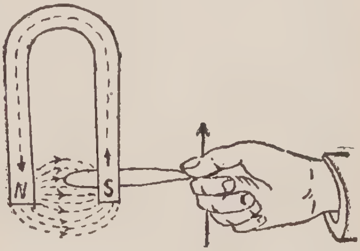

Fig. 10

If the wire is a closed loop the electromotive force (voltage pressure) produced in the wire loop will cause a current of electricity to flow in the circuit. Thus we can produce electric current in a wire by merely moving it across a magnetic field, as in Fig. 10.

How and why the electricity is in the wire we do not know, but if electromotive force is applied to the electricity in the wire, and the wire forms a circuit, the electricity will be made to move.

Copper wire offers less resistance to the flow of electric current, therefore it is used most. Electric currents thus produced are termed **induction currents,** and the principle or method is termed **electromagnetic induction.**

The question then is, How can the e.m.f. be obtained, in order to cause the electricity to move?

The e.m.f. induced in a wire by a magnet is one method of producing electric current in a wire.

For example, if a wire is quickly moved down, so that it will cut the magnetic lines-of-force which flow from the (N) to (S) pole of magnets, a momen-

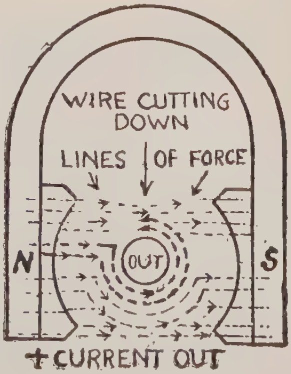

Fig. 10A

---

[1] We might also say that whenever a loop of wire forming a closed circuit is placed in a magnetic field, an e.m.f. will be generated in the wire, causing electric current to flow whenever the strength of the magnetic field changes.

tary current will flow in the wire (as in Fig. 10A) which is in a direction *out* of the wire or toward the surface of the paper. This is because the lines-of-force, when forced *down*, will act like rubber bands, i.e., first stretch, then loosen from the (S) pole (the weakest point), and tend to wrap around the wire and whirl counter-clockwise.

These magnetic whirls of lines-of-force around the wire, which are taken from the magnetic field of the magnets flowing from (N) to (S) induce an e.m.f. in the wire which causes electric current to flow which was already in the wire but not in motion.

This momentarily induced e.m.f. is greatest when the wire is moved so that it will cut the magnetic lines-of-force at right angles, or across the magnetic field, the position the wire is cutting, as shown in the illustrations.

An e.m.f. would also be induced in the wire when moved, even though it did not form a closed circuit, and the e.m.f. would be at the terminals the same as on the terminals of a battery on open circuit.

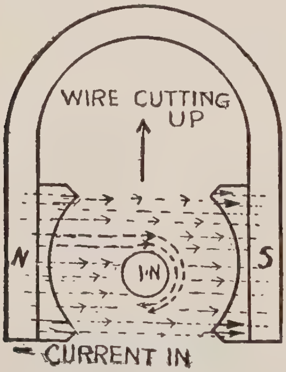

Fig. 10B

When the wire is quickly moved up, as in Fig. 10B, the magnetic lines-of-force will tend to circle around the wire in an opposite direction to that when moving down. Therefore another momentary current will flow *into* the wire. Thus if the wire is moved up and down rapidly, the flow of current in the wire would be first in one direction, then in another direction, or **alternating** in its flow.

Principle of Low-Tension Coil

The e.m.f.[1] induced in a wire of an electro-magnet is another method of causing electric current to flow in a wire. Instead of moving a wire so as to cut the lines-of-force, the lines-of-force, or magnetic field, moves and cuts the wires.

For instance, take an electro-magnet (Fig. 11), which would represent a primary coil, also called a "self-induction coil," or "low-tension coil," which is used to produce a spark or flash inside of an engine cylinder or in the combustion chamber, when the circuit is suddenly opened. This primary or low-tension coil consists of a core made of a bundle of soft iron wires, around which is wrapped about 200 turns and several layers of No. 19 to 24 B. & S. gauge copper insulated wire. When the circuit is closed, the lines-of-force start to build up, and in doing so they spring from the center of the wire and cut the wire up.

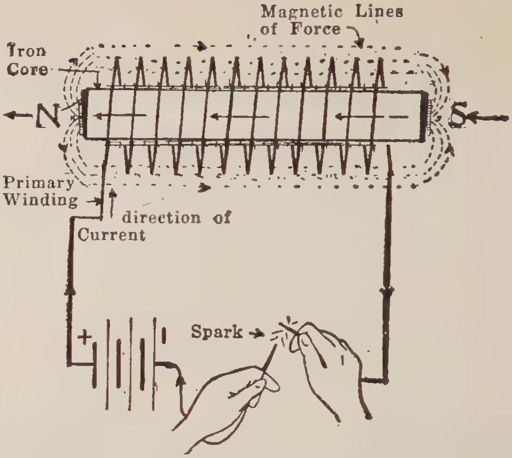

Fig. 11. An electro-magnet being used to produce a spark, by the circuit being opened, thus causing the magnetic lines-of-force to collapse into the core. This generates a self-induced e.m.f. in wires caused by the collapsing lines-of-force cutting the turns of wires. Such a coil is termed a "low-tension coil," or "self-induction coil," or "primary coil."

The **principle or action** is the same as that shown in Fig. **10A**, where the wire was moved down to cut the lines. Therefore this electromagnetic induction or self-induction would tend to cause the lines-of-force to whirl around the wire in a counter-clockwise rotation, causing the generated e.m.f. to buck or oppose the battery e.m.f., called "counter-electromotive force." In other words, we have two electromotive forces to deal with in the same wire: the induced e.m.f. produced by the magnetic whirls caused by current from the battery passing through the wire, and a generated e.m.f., caused by these same magnetic whirls, cutting the coils of wires as they build up around the coil.

The generated self-induced e.m.f. or counter-e.m.f., however, is only momentary, as the steady e.m.f. from the battery will force its current through, and in a brief interval of time the lines-of-force around the wires will have been established at their normal value.

The point to remember in connection with the above is that **when the circuit is closed, the e.m.f. or voltage would not be as great as when the circuit is opened,** principally due to the fact that the action of magnetizing the core when the circuit is closed is slower (due to this counter-electromotive force just mentioned) than the action of demagnetizing the core when the circuit is opened.

The question then is, What effect does the magnetizing and demagnetizing of the core have on producing a higher voltage (e.m.f.) in the wires which will cause a spark or flash at the wires when suddenly separated? This is answered as follows:

The amount of voltage (e.m.f.) and of current induced in a coil depends upon three factors:

1. **The strength of the magnetic field** (number of lines-of-force per unit area).

2. **The speed or rate at which the lines-of-force** cut through the windings or coil.

3. **The number of turns of the wires** that are on the coil into which the e.m.f. is to be induced.

When the circuit was closed, the lines-of-force were established around the turns of wires, which pass outside, from (N) to (S) of the core and inside (S) to (N), thus forming a magnetic circuit around the turns of wires (see Fig. 11).

---

[1] If it is difficult to understand the meaning of e.m.f., just consider it as voltage or pressure, or the electric force which moves electric current or causes electricity to move in a wire.

We can greatly increase the rate of speed with which the lines-of-force will cut the turns of wires if the battery circuit is opened, so that the iron core will become demagnetized and thus permit the lines-of-force to die down or collapse more quickly into the iron core.

Thus, when the lines-of-force collapse, they cut the turns of wires at a much more rapid rate than when they were built up; this "self-induced" action causes a greatly increased e.m.f. to be generated in the turns of wires, and is the basic principle of all ignition coils.

The third factor mentioned above, relative to the turns of wires on the coil, also assists in increasing the e.m.f.

For instance, when a conductor is cut by the lines-of-force at the rate of 100,000,000 per second, a pressure of 1 volt is set up at the terminals.

If a single straight wire is cut by a certain number of lines-of-force per second, causing a certain pressure, say 1 volt, and if three wires joined in series are cut by the same number of lines-of-force as the single wire, three times the pressure or 3 volts would be the result. Therefore where there are many turns of wire in a coil and several layers of wire, the induced pressure will be greatly increased, as very nearly all of the lines-of-force produced by each turn of the coil will cut all of the other turns, and the total number of lines-of-force are therefore greatly increased.

From this we learn that when the circuit is opened on a primary coil, we have increased the number of lines-of-force and also the rate of speed at which the lines-of-force cut the turns of wires as they collapse, greatly increasing the "self-induced" pressure in the wires.

Furthermore, the "self-induced" generated e.m.f. in the turns of wires, when the circuit is opened, is in the same direction as the original battery current was. This current from the battery through the primary winding, when opened, did not instantly stop flowing, and with the high "self-induced" e.m.f. flowing in the same direction, the result was a very bright flashy spark at the points of the break, as in Fig. 11. This is what is often seen when a flash follows from the switch-blades when a switch connected with a motor or generator is opened.[1]

This principle might be compared to holding your hand over a water nozzle when water is flowing. At the instant of release, the pressure is greater, due to momentum, although the original pressure which set the water in motion was several times less.

The "self-induced" e.m.f. or voltage (pressure) in a low-tension coil in series with the battery voltage may reach from 150 to 250 volts, owing to the number of turns of wires, length of wire, and strength of current in the wires to build up the original lines-of-force.

Low-Tension Coil Ignition "Make-and-Break" System

The low-tension coil, described in the preceding pages and illustrated in Fig. 11, was formerly used with early ignition systems, such as the "make-and-break" igniter shown in Fig. 12. The principle is clearly shown.

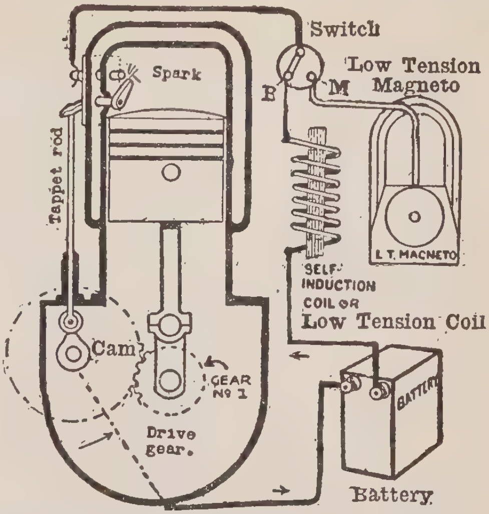

Fig. 12 .A "make-and-break" ignition system using a battery (chemical generator) as a source of electric supply. The current is intensified, or the voltage raised, so as to produce a spark at the break of the igniter points.

Although the low-tension coil ignition system is not now used for ignition on automobile engines, it is very important that the principle be studied carefully, as the low-tension or primary coil is used on the cores of high-tension coils and magneto armatures, but with another winding over the primary, called the secondary winding. Therefore the primary winding is the foundation of high-tension coil and magneto ignition.

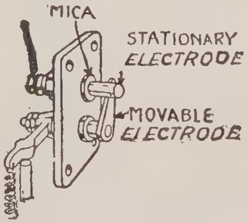

Fig. 13. A clearer view of the make-and-break igniter.

The make-and-break igniter (Figs. 12 and 13) consists of a stationary and a movable electrode insulated from each other and connected with a low-tension coil.

The "movable electrode" is operated by a cam arrangement, exactly as the exhaust valve of the engine is operated. As the spark is needed only once during two revolutions of the crank shaft, the cam is attached to the half-time shaft, and operates the electrode by a rod called a tappet rod, in a manner similar to that in which the valves are operated on a side-valve engine.

The "stationary electrode" is insulated from the cylinder with mica, and one wire of the circuit is connected to it. The "movable electrode" is operated by a cam, which is in contact with the current from the grounded wire of the battery and which allows the current to pass from it to the metal of the cylinder.

When the two points are in contact, the current flows from the positive pole of the battery by a wire to the low-tension coil, through a switch (**B**), to the stationary electrode, then to the movable, because the two are in contact, and back to the battery by the ground.

---

[1] This is why a condenser is used in connection with a high-tension coil, as will be explained farther on. While the flashy spark is desirable on a low-tension ignition coil, as in Fig. 11, or as used with a "make-and-break" low-tension ignition system, it is very undesirable at contact points in connection with a high-tension system.

When the two electrodes are separated by the cam acting on the movable one, the circuit is broken, and a spark is formed between them.

Fig. 12 shows the make-and-break ignition system connected with a low-tension coil and battery through the (B) side of the switch and with a low-tension magneto when the switch-blade is on the (M) side of the switch.

When the battery and low-tension coil are used, the magneto is cut out entirely in this example.

Purpose of Ignition

There are three things required before a gasoline engine will run. These are absolutely essential.

First, it is necessary to have a mixture of gasoline and air in the engine cylinders.

Second, this mixture must be compressed.

Third, there must be a spark to set fire to the compressed mixture at the correct time.

In order thoroughly to understand the principles upon which the various ignition systems are built up, and how these systems are operated and maintained, it is well to start at the beginning.

The original and first method for igniting the gas in a gasoline engine was by means of a **"hot tube"** or flame, but this method being now obsolete, we shall deal only with the electric ignition.

The ignition systems used on automobile engines at the present time are all electrical systems giving an electric spark which passes in the cylinder of the engine and sets fire to the compressed mixture. As you will be dealing with electricity and electrical apparatus in these systems, the first thing to know is how electricity acts and how you can make it do work for you, all of which has now been explained and should be studied carefully.

Ignition Systems

There are two general systems of ignition used for automobile engines: the "low-tension system" and the "high-tension system"; the source of electric supply being either by "chemical" means, as dry cells, or a storage battery; or "mechanical" means, as a magneto or dynamo (also called a generator). (The magneto is explained farther on.)

The word **"tension"** means pressure or voltage; high tension being high voltage, and low tension low voltage.

The low-tension system of ignition is not now used on automobiles. The low-tension system was formerly used, to a great extent on boat engines, and is still used to a great extent on stationary engines.

The low-tension system uses a low-tension single-wound primary coil as in Fig. 11, page 184, and its source of electric supply can be a dry or storage battery, or dynamo. Low-tension magnetos are also used, but the coil is wound on the armature (treated under "Low-Tension Magnetos.")

The high-tension system of ignition is the approved system now in use on very nearly all makes of cars. The high-tension system may be either by a high-tension coil and a battery; a high-tension coil and low-tension magneto; a high-tension coil and dynamo in connection with a battery, or by a high-tension "magneto" alone.

Thus we have four principles underlying the production of a spark in a gasoline engine, as follows:

1. **Low-tension coil.**
2. **Low-tension magneto.**
3. **High-tension coil.**
4. **High-tension magneto.**

These four fundamental principles are used either singly or in combination. Thus when the reader masters these four principles he will understand all ignition systems, although the construction may vary in different makes.

In this instruction and in Instruction No. 18, we deal only with coil ignition, both low-tension and high-tension. Low-tension and high-tension magnetos will be treated farther on.

When a low-tension magneto is used with a make-and-break igniter (Fig. 12), the engine is usually started with the battery and low-tension coil, by turning a switch-blade on the (B) side of the switch.

After the engine is started, the switch-blade is turned to the (M) side and the low-tension (single-wound armature) magneto supplies the current, which, by the way, is alternating current. The low-tension coil is not used with the magneto, as the armature of the magneto, which has a single primary winding, serves in place of the low-tension coil.

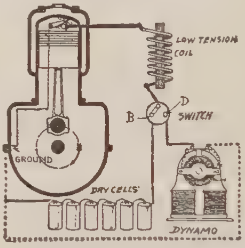

Fig. 14

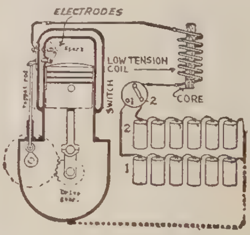

Fig. 15

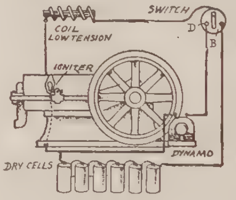

Fig. 16

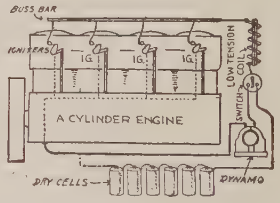

Fig. 17

Fig. 14. Make-and-break ignition, using dry cells to start on when the switch is on the (B) side; after the engine is started the switch is placed on the (D) side and a direct-current dynamo supplies the electric current and the dry cells are cut out of service. The low-tension coil is used with either the dry cells or the dynamo.

Fig. 15. Make-and-break ignition using two sets of dry cells. Set No. 1 is used when the switch-blade is on 1, and No. 2 set is used when the switch-blade is on side 2. Low-tension coil is used.

Fig. 16. Make-and-break ignition on a stationary engine. This principle is similar to that shown in Fig. 14.

Fig. 17. Make-and-break ignition on a four-cylinder engine. The principle is similar to that shown in Fig. 16. Note that the igniters are operated by tappet rods on the side by cams on a cam shaft, similar to a cam shaft operating the valves. The shaft with the cams on are driven by the gears, as in Fig. 12.

Low-Tension Coil Ignition "Wipe Spark" System

The wipe spark igniter, Fig. 18, is another form of ignition used considerably on large slow-speed stationary gasoline engines.

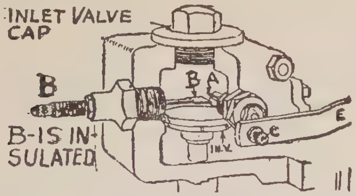

Fig. 18. Wipe-spark igniter. Eccentric "C" can be shifted forward to advance and backward to retard.

Wipe spark ignition is similar to the "Make and Break" in every respect, except that it makes a wiping and rotary motion as the electrode (**A**) of the igniter revolves; being operated by an eccentric rod (**E**) from the cam gear.

The other electrode (**B**) is stationary and looks very much like a spark plug. This type of ignition is never used on the automobile; but is here shown so that the reader can master the elementary principles of the different ignition systems. This system is used mostly on stationary engines.

Remarks On Low-Tension Ignition

The true low-tension ignition system would consist of a make-and-break igniter, as shown in Fig. 13, page 185, or a wipe-spark igniter **arrangement,** shown in Fig. 18.

The make-and-break igniter was at one time used on automobile engines, and is now used on many stationary and marine engines. It is practically obsolete for automobile use.

The wipe-spark igniter was never used on automobile engines, but was and is now used on many stationary engines.

The low-tension coil is used with both igniters when a direct-current source is used, as a battery or a dynamo, as in Figs. 12 to 17.

Where the low-tension magneto, which delivers an "alternating" current, is used, the low-tension coil is not used, because the primary winding on the armature of the low-tension magneto serves in place of the low-tension coil, and the magneto current is alternating in flow, that is, first in one direction, then in another, as explained on pages 250, 253, and 254.

In Fig. 12, a low-tension system of ignition is shown, whereby a storage battery is used for a source of direct electric current for starting, by the switch lever being placed on the "B" side of the switch. After the engine is started, the switch lever is placed on the "M" side of the switch; thus the battery and low-tension coil are cut out of service and the low-tension magneto (explained farther on) takes the place of both the battery and the low-tension coil.

An oscillating type of low-tension magneto ignition system, using a make-and-break igniter and arranged different from that mentioned above, is shown on page 255 (see Fig. 48).

A magnetic plug, instead of an igniter, could also be used for a low-tension ignition system, as shown in Figs. 49, 50, and 51 (page 255).

The Ford magneto (pages 248 and 249) **is also a low-tension magneto, but is not a low-tension ignition system,** because the low-tension current of the magneto is transformed to a high-tension current by means of a high-tension coil, all of which will be explained farther on.

Where a dynamo, which delivers a "direct" current of low-tension is used, as in Figs. 14, 16, and 17, note that the low-tension coil is used in connection with the batteries or with the dynamo, because the dynamo delivers a direct current flowing in one direction and at a low voltage, or approximately the same voltage as the batteries and thus merely acts as a mechanical source of electric supply instead of a chemical source.

Disadvantage of the true low-tension ignition system, using a make-and-break igniter and a low-tension coil: It would appear that this system would be a very simple and effective ignition system, as it requires less care in wiring than a high-tension or jump-spark system, but while this feature may predominate, there are several disadvantages.

For example, the word "make-and-break" refers to the igniter as shown in Figs. 12 and 13 (page 185). The movable electrode first makes contact with the stationary electrode, and after "making" contact, it then "breaks" the contact (due to the action of the tappet rod); thus the derivation of the name, "make-and-break."

On each of the electrodes there are platinum points. When the contact "breaks," a spark occurs just as it did as shown in Fig. 11 (page 184). This spark soon pits the points, burns them off rapidly, and they often stick. Platinum is used because it withstands this action better than any other metal, but even so, where the mechanical arrangement is all within the cylinder, exposed to the combustion heat, it is a difficult matter to keep the points from pitting.

Then another difficulty was in insulating the stationary spark point or electrode, and making an easy working but tight joint for the movable electrode.

Still another disadvantage was in the great advance and retard range of ignition as required on **variable-speed automobile engines,** where the engine varies in speed from 200 to 1,500 r.p.m. This action is limited with the make-and-break system.

Where a slow, constant-speed engine is used, this system serves fairly well.

The low-tension ignition systems are not now used on automobile engines, but were formerly used in the early days of motoring.

The reason for explaining these early systems of ignition is the fact that the **underlying principles** of the more modern systems are founded upon the principles of these early days. Therefore it is essential that they be mastered first in order more clearly to understand the modern systems treated farther on.

The next subject will be that of a high-tension coil ignition system using a magnetic vibrator. This system is now seldom used, but must be understood before the modern battery and coil-ignition system can be thoroughly understood.

INSTRUCTION No. 18

HIGH-TENSION COIL IGNITION: Vibrator Type Coil; Condenser Principle; Master Vibrator Coil; Distributor Principle

The Jump Spark

The voltage produced by a low-tension coil as used for the "make-and-break" ignition system, explained on page 185, would not have enough pressure to jump across the gap of a spark plug. It must therefore be intensified (or the pressure must be increased) still more.

Where simple low-tension coils are used for the make-and-break system, coils of another kind, called "high-tension induction coils," are used to intensify or transform the current to a high voltage in order to force the current to jump across the open space or gap of a spark-plug point (Fig. 1). Therefore it is called the "jump spark" or "high tension" (meaning high pressure).

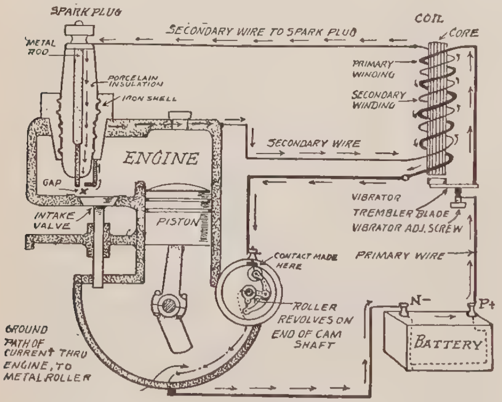

Fig. 1. Relation of the spark plug to the cylinder and to the commutator.

A spark plug (Fig. 1) is screwed into the cylinder of the engine, and when the piston is in the right position to receive a spark, a high-tension current of electricity is sent along the metal center rod (called the "electrode") of the spark plug and across the small air-gap (**X**) at the bottom and into the outer sleeve or iron shell of the spark plug which screws into the cylinder.

Although this air gap (**X**) is only about 1/64" to 1/32" wide, the air in the gap offers such a tremendous resistance to the current that it requires in the neighborhood of 5,000 or more volts' pressure to force a very small quantity of current across the gap. In other words, the current must be of such high pressure that it will jump across a space between two points, forming a spark as it passes.

The amperage of current across this gap is so small a quantity that it cannot be measured with a meter, but is measured with an instrument called an **oscillograph** and the current is measured in terms of **milliamperes** (one-thousandth of an ampere).

To give an idea of the quantity represented by a milliampere, suppose we have a high-tension coil with 5 amperes at 6 volts pressure flowing through the primary winding and the voltage at the secondary terminal or gap is 10,000 volts, what would be the amperage of the secondary?

5 amp. × 6 volts = 30 watts. 30/10,000 = 3/1,000 part of an ampere.

K-W ignition coils are constructed to operate on a current consumption in the primary from the battery of 1 to 1 2/10 amperes at 6 to 8 volts. The "self-induced" voltage in the primary has a sufficient number of turns to give 145 volts when the circuit is broken. The voltage at the secondary is 5,000 and up, depending on the number of turns. High-tension coils which give a ½" spark, in the open air, require about 10,000 volts at the secondary, and if the coil is of a vibrator type, the voltage can be still further increased when the spring tension on the vibrator spring is increased, so that the coil will draw a heavier current (amperage). This, however, should not be made a practice, inasmuch as the insulation is not designed to stand current values above those recommended by the manufacturer. Always adjust according to instructions. See Index for Ford vibrator coil adjustments.

Note that the battery or primary current does not jump the spark-plug gap. It is used to magnetize the iron core; and when the circuit is opened and this core is suddenly demagnetized, a high voltage is induced from the primary winding into the secondary winding. This is due to approximately 12,000 turns of fine wire used in the secondary winding, wound over the primary winding.

Construction of a High-Tension Vibrator Coil

The high-tension coil (also called a "jump-spark coil," "secondary coil," "transformer coil," etc.) differs from the low-tension coil in that there are two windings on the coil core; one, a coarse wire winding, called the **primary** winding, just the same as in a low-tension coil and the other, a **secondary** fine wire winding which is wrapped over the primary winding, both windings being insulated.

There are usually about 200 turns of No. 19 to 24 B. & S. gauge insulated copper wire for the primary winding, and about 12,000 turns of very fine No. 34 to 38 B. & S. gauge enameled silk-covered thin insulated copper wire in the secondary winding, so that the layers can be close together and with as many turns as possible. Thus the ratio of the primary winding to the secondary is about 60 to 1.

The windings can be in either direction. They are usually in the same direction, because it is more practical from a manufacturing standpoint.

The original and early form of a high-tension coil ignition system consisted of the parts as shown in Fig. 2. This system is termed a **"magnetic vibrator-coil"** ignition system.

A commutator, which is nothing more than a revolving switch, has a roller (**R**) connected to an arm which is connected to the cam shaft. This roller, therefore, makes one revolution while the crank shaft makes two revolutions. Thus on a

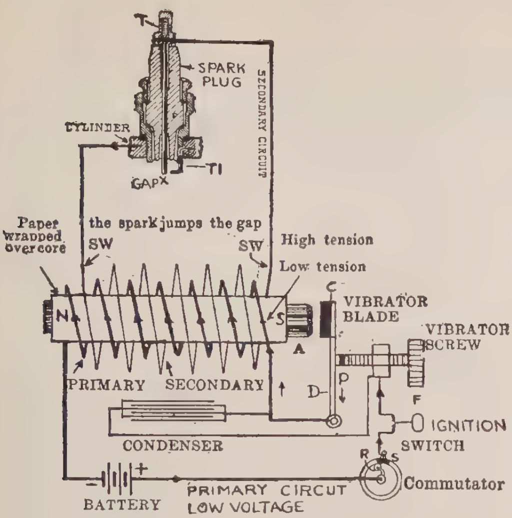

Fig. 2. A high-tension coil using a magnetic vibrator.

single-cylinder engine, there would be one insulated commutator contact segment (S), and one spark would occur during two revolutions of the crank shaft.

Primary circuit: The current flows from the positive terminal (+) of the battery, through the roller (R) and segment (S), through the ignition switch, vibrator screw and points (P), through the trembler or vibrator blade (D), through the primary winding wrapped around the coil iron core, to the (−) terminal of the battery.

If the roller (R) is on contact with the commutator segment (S), and the ignition switch is "on," the current would then pass through the entire primary circuit.

The moment the primary circuit is completed, the vibrator blade (trembler blade—D) is drawn to the soft iron core (A), because the soft iron core becomes magnetized the moment the primary circuit is completed.

When the vibrator blade (D) is drawn to the soft iron core (A), the primary circuit is opened between the platinum points (P) on the vibrator blade and on the vibrator screw. Thereupon the core loses its magnetism and the vibrator blade is released; on account of its spring tension, it rebounds, closing the primary circuit again at the point (P).

This action takes place repeatedly and the blade vibrates back and forth, so long as the circuit is closed by the roller (R) of the commutator being on contact with the segment (S).

The moment the roller (R) leaves contact with the segment (S), the coil is out of action. Thus we have what is termed a "magnetic" method of making and breaking the primary circuit, instead of a "mechanical" method. The mechanical method, however, is a popular method and will be explained farther on.

Secondary circuit: When the primary circuit is opened and closed by the magnetism of the core (A), which is produced by the current flowing through the primary winding, a very high electromotive force is induced into the secondary winding, which is wrapped around the primary winding. This induced e.m.f. in the secondary winding causes current of a very high voltage to flow in the secondary winding, of sufficient intensity to jump a gap (X) of about 1/32″ at the points of the spark plug, which is screwed into the engine cylinder and to cause a spark which ignites the compressed gas.

To develop a high voltage (e.m.f.) at the secondary terminals it is necessary that a very large number of turns be used. For instance, if the primary winding consisted, say, of ten turns of wire and the secondary consisted of one hundred turns, the "induced" voltage in the secondary would be ten times as high as that in the primary, but the current value (amperage) in the secondary would be ten times less than in the primary.

The secondary winding is insulated wire, as is also the primary winding. One end of the secondary winding leads to the metal rod connection of the spark plug which is insulated from the engine by porcelain, then passes through it, jumps the gap (X) to the metal point of the spark-plug shell, which is an iron shell screwed into the cylinder, and then passes through the frame of the engine back to the other end of the secondary winding. As the vibrator on the coil vibrates, a "succession of sparks" is produced at the spark-plug gap (X). Bear in mind, however, that there is but one spark produced at each break of the contact points (P). Sometimes the secondary and primary windings are connected together inside of the coil, and one wire leads from both, to a ground connection on the engine. But it should be noted that the secondary circuit and the primary circuit are two independent circuits. Of course the secondary circuit, which is of a very high voltage, is dependent upon the primary circuit, not by means of metallic connections, but only by induction, as will be explained farther on.

The magnetic vibrator blade (D) (Fig. 2), as previously stated, vibrates rapidly and opens and closes the circuit a great number of times, during the time the commutator roller is in contact with the segment (S).

This is the principle of **the Ford ignition coil,** and by adjusting the tension of the vibrator, by screwing the adjusting screw in or out, the number of times it opens and closes the primary circuit can be regulated. The more times it opens and closes the primary circuit during a given period of time, the higher the voltage (see Index under "Ford ignition coil").

Time of spark: The commutator roller is set so that it makes contact with the segment (S) when the piston is at the top, or slightly over the top, of the compression stroke. This is termed "ignition timing" and is treated farther on.

Condenser: A condenser is always used with high-tension coils, by placing it across the interrupter points, to prevent a spark at the interrupter points, which would otherwise occur as shown in Fig. 11, page 184, if a condenser were not used. The condenser is not shown in Fig. 1, but is shown in Fig. 3. The condenser is fully explained farther on.

How and why the **high tension, or voltage is induced into the secondary winding** of sufficient intensity to jump the spark-plug gap (X) is explained in the text following.

Note. In Fig. 1, the circuit is slightly different from that in Fig. 2. The principle is the same. Fig. 1 explains the relation of the spark plug to the cylinder and also how the current flows through the engine frame. The connections from the battery to the coil, etc., could be as in Fig. 1 or 2. The connections shown in Fig. 2, however, are in conformity with the general practice.

Note that, as shown in Fig. 2, the (−) terminal of the battery is usually grounded. The secondary and primary windings are also usually grounded together. For instance, if the left ends of both primary and secondary winding were connected together in the coil and then grounded, and if the (−) terminal of the battery was grounded, the circuit would be a "grounded" system instead of an "insulated" system, as shown in Fig. 2.

Principle of a High-Tension Coil

How a high-tension current is induced in the secondary winding can best be understood after first reading the explanation of the principle of the low-tension coil on pages 182, 184; since the **self-induction** action of the primary winding is the base for building up the high-tension voltage in the secondary, by what is termed **mutual-induction.**

The difference between "self-induction" and "mutual-induction" is that self-inductance is produced in the same coil in which the current was allowed to flow, as the primary winding. Mutual inductance is where an e.m.f. or current is induced into a separate coil of wire, as in the secondary winding.

We learned on page 184 that the greater the number of lines-of-force and the greater the rate of speed at which the lines cut the turns of wires, the greater the induced e.m.f. for voltage.

Therefore, as we have several thousand turns of wire in the secondary and a few hundred turns of wire in the primary, we thus have a greater number of cuttings of lines-of-force, because very nearly all the magnetic lines-of-force produced by each turn in the primary will cut all the turns in the secondary coil, hence the total number of cuttings of lines-of-force will be greatly increased. The lines-of-force will cut the turns of wires at a greater rate of speed when contact is broken than when contact is made, thus the voltage developed at the "break" of the circuit is enormously greater than at the "make." This is explained as follows:

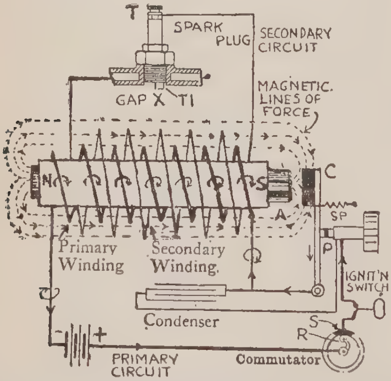

Fig. 3. Showing how the lines-of-force build up around the windings when contact is closed, and how they collapse and cut the turns of wire when the circuit is opened.

When the primary circuit is closed by the commutator (Fig. 3), the primary circuit is completed through the points (P) on the vibrator screw and blade (C), and the lines-of-force spring from the primary turns of the wires, and a magnetic field is built up around the wires, as explained on page 181. This magnetic field in building-up forms an electro-magnet, with lines-of-force flowing from (N) to (S), therefore these lines must necessarily cut (*up*) through the turns of wires on the iron core as they build up. In doing so, they generate an induced e.m.f. which has a tendency to create a counter-voltage, or counter-electromotive force, which bucks or opposes the incoming current from the battery (see page 184). Consequently the magnetic field is momentarily retarded and builds up with comparative slowness, and thus we do not obtain a very high rate of speed of the lines-of-force cutting the wires during the building-up process.

In building up this field, the lines-of-force cut through the secondary as well as through the primary. In doing so, an e.m.f. is generated in the secondary which flows in an opposite direction, due to the movement-up of the lines-of-force, which is an operation similar to that of moving a wire *down* in a magnetic field (Fig. 10**A**, page 183).

The induced voltage in the secondary is thus not great enough to jump the spark-plug gap (**X**). Therefore we must make use of another action. This is accomplished by breaking, or interrupting or opening the primary circuit. In other words, the moment the lines-of-force build-up, the core (**A**) becomes an electro-magnet and draws the interrupter blade (**C**) to it, thus interrupting, or opening, the primary circuit.

When the primary circuit is opened or interrupted quickly, an entirely different action takes place. The magnetic field of lines-of-force, which have by this time built-up around both windings and reached maximum value, collapse or recede into the iron core. In doing so, the lines-of-force cut at a great deal more rapid rate than when being built up. Therefore, as the lines-of-force collapse or recede to the iron core with great rapidity, they cut the secondary turns of wire in an opposite direction to that in which they did so in building-up, and the current then flows in the same direction as the dying primary circuit. They thus assist in causing self-induction[1] in both the secondary and primary circuits, which generates a very high voltage, but still not as high as necessary.

Bear in mind that the primary circuit is now open. Thus we are dealing with "self-induced" current, produced by the lines-of-force cutting the turns of wires as they collapse or recede to the core.

The point to be noted is, that if this iron core is demagnetized, so that the lines-of-force can pass back to it at a greater speed, the turns of the wires would be cut at a greater rate, correspondingly increasing the induced e.m.f. in the turns of the wires.

Owing to the fact that this primary circuit is now carrying a self-induced current, caused by the line cutting its own turns of the wires, this prevents the rapid demagnetization of the iron core, and a heavy spark will occur at the interrupter points (P), just as it did on the break of the low-tension coil (Fig. 11, page 184).

The condenser assists in demagnetizing the core. Therefore, if we could absorb this spark at the interrupter points (which comes from the self-induced current in the primary winding) in some way, and thus cause a more rapid demagnetization of the iron core, the lines-of-force would then pass back to the iron core more quickly and would thus cut the secondary turns of wires at a still greater rate of speed. In other words, it is the secondary winding into which we wish to induce a very high voltage. Therefore, by placing in the coil a **condenser** which is connected across the interrupter points (P, Fig. 3), we can absorb or suppress the spark across the interrupter points (P) of the primary circuit and stop the flow of self-induced current which is still trying to build up lines-of-force in the core, and thus aid the primary current to fall to zero value more quickly. Hence the reason for placing the condenser (Fig. 3) across interrupter points (P) of the primary circuit.

---

[1] **"Self-induction"** means induction produced in a circuit at the moment of starting or stopping the currents flowing therein, by induction of the current on itself. For instance, when starting current to flow through the primary circuit, if the circuit is closed, lines-of-force spring out from the center of the wire through which the current is flowing, and thus produce a temporary "self-induced" current in an opposite direction, thus momentarily retarding the building-up of the lines-of-force.

When stopping or opening the circuit of the primary, the lines-of-force collapse into the core and, in doing so, cut in an opposite direction, or in the same direction as that in which the battery current was flowing.

Purpose of the Condenser

1. To **absorb** the self-induced current of the primary, thereby allowing the magnetic field to collapse with the greatest possible speed, and also eliminating the spark at the contact points.
2. To **discharge** in an oscillating (alternating) manner back and forth into the primary circuit, thus completely neutralizing or demagnetizing the iron core and thereby preparing it for repeated action.

Condenser Construction

The condenser consists of a series of sheets of tinfoil separated from each other by a good insulator, such as mica, or several sheets of wax paper.[1] These are built up in a pile, somewhat as shown in Fig. 4. The even-numbered sheets of tinfoil, 2-4-6, etc., are connected, making one terminal (T) of the condenser. The odd-numbered sheets, 1-3-5, etc., are likewise connected, making the second terminal (T1) of the condenser. There is no connection between the two series of sheets. These connections are then made across the primary circuit at the contact points, as shown in Fig. 7.

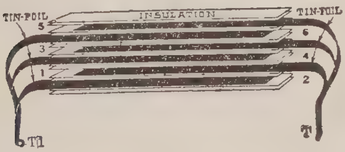

Fig. 4

Fig. 4A

Condenser Action

With contact points (P) closed (Fig. 5), the current flows as shown by arrows through the primary winding. The condenser and secondary winding are not considered, as they are inactive. A current of low value is induced in the secondary in a direction opposite to that of the primary-current flow.

With contact points (P) open (Fig. 6), the condenser is charging. The spark of highest value is now at the secondary terminals. Note that when points (P) open, the magnetic field of lines-of-force collapse, and the induced current in the secondary is then flowing in the same direction as that in the primary. This spark is greatest just as the points open, because the condenser absorbs the self-induced current of the primary and thereby stops its flow, thus preventing it building up lines-of-force in the core. On the other hand, it neutralizes the core, and also eliminates any flow of current or of sparking at the contact points.

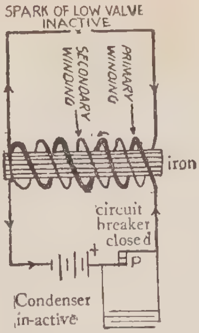

Fig. 5

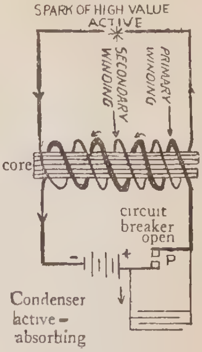

Fig. 6

On account of this action the lines-of-force or magnetic field can collapse with greater rapidity and cut the turns of wires faster, thus inducing a current in the secondary winding of a much higher voltage.

The current flows into the condenser in one direction when charging, which action takes place immediately the points are opened.

When the condenser is charged with the (+) positive current flowing into the (+) side, it will establish a (−) negative charge on the other side.

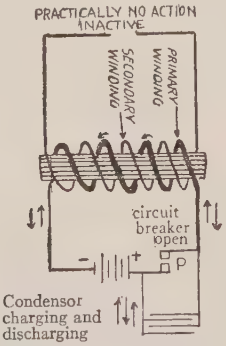

Fig. 7

The condenser, after being charged, makes an oscillating discharge of high voltage and frequency through the primary winding and battery (Fig. 7). That is, the discharge is first in one direction and then in the other, the strength of this current gradually decreasing (owing to the resistance of the circuit) until it dies down to zero. This alternation or reversal of the current flow is very rapid, sometimes reversing from one direction to the other as many as two hundred thousand times every second, and its discharge can therefore be considered almost instantaneous.

The main purpose of the alternate discharges shown in Fig. 7 is to completely demagnetize or neutralize the iron core, thereby preparing the core for a repeated action of building-up again as shown in Fig. 5, and collapsing, as shown in Fig. 6.

As this is written out, or as it is read, it seems a rather long action. The process, however, does not require one-thousandth of a second, inasmuch as the current alternates at an extremely high frequency, sometimes having as many as 100,000 cycles per second.

---

[1] **Never attempt to open a condenser,** as this will destroy it. In the manufacturing process the tinfoil and insulating sheets, with the aid of an insulating compound, are pressed closely together under heat, with high pressure (Fig. 4A). Obtain a new one when necessary.

Meaning of Cycle and Frequency

A cycle means a series of events which continually reoccur. In the case of a condenser, for example, the current discharge at one instant is a maximum (+), as shown at (C) (Fig. 7A). It gradually declines to 0 at (A), then builds up to a maximum (−) as shown at (D), again declining to 0 at (B), reversing in direction and building up to a maximum (+) at (E), which is the same condition as at (C), thus reversing the direction twice at (A) and (B) and completing the cycle evolution, which is repeated over and over again until the discharge dies down to 0 (zero).

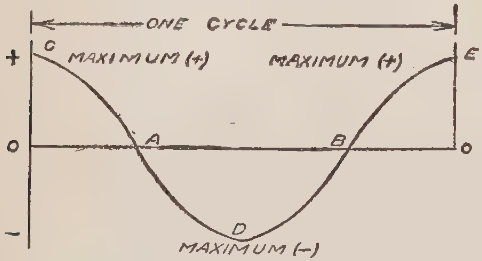

Fig. 7A. Explanation of the meaning of cycle.

Frequency means the number of cycles completed per second. As mentioned above, it is 100,000.

The Ignition Commutator

Because the secondary current is only needed when it is time for the spark to pass and ignite the mixture, the primary current is switched into the primary winding only once during two revolutions on a single-cylinder engine. The switching is done by a commutator, which might be termed a revolving switch.

Where there are four cylinders to an engine, then it would be necessary to have four segments (S) on the commutator, because four sparks are required during two revolutions of the crank shaft.

A four-cylinder ignition commutator is shown in Fig. 8. An ignition commutator is used only with a vibrator-type coil, as on the Ford. The vibrator-type coil and commutator are seldom used on any other make of car.

The spark timing device (commutator) is so named because it "times" the spark at the right time. In other words, the roller makes contact with one of the segments (1, 2, 3, or 4 on a four-cylinder engine). Each segment controls one of the spark plugs (through a coil) in one of the four cylinders. When the right cylinder is ready to fire, the timer makes contact and starts the vibrator on the coil, which causes a spark at the points of the spark plug. This device is called a "commutator," and is used only with a high-tension coil using a vibrator.

COMMUTATOR

Fig. 9. Circuit of a four-cylinder vibrator coil ignition system using a commutator (exaggerated) and two sets of batteries.

Commutator construction: There are many different constructions. One which will explain the principle of a commutator is shown in Fig. 8.

The metal roller hub is connected to the cam shaft of the engine. A roller (**R**) revolves in a housing lined with an insulated, non-conducting material, usually fiber. Metal segments (**S**) are placed 90° apart for a four-cylinder engine. These segments are connected with one terminal of the primary winding of the coil. There are as many segments on the commutator and as many coils as there are cylinders. Since the cam shaft makes one revolution while the crank shaft makes two revolutions, then the roller (**R**) would revolve the same number of times as the cam shaft, because it is connected with it. Thus roller (**R**) would make contact with each of the four segments during one revolution, and so would produce four sparks in the engine cylinders, or one spark for each cylinder during one revolution of the roller (**R**), or two revolutions of the crank shaft of the engine.

Electric Circuit of a Four-Cylinder Vibrator Coil Ignition System

The illustration (Fig. 9) explains how a commutator is driven from the cam shaft of a four-cylinder engine and how it is connected with the primary windings of four-vibrator type coils contained in one coil box.

The illustration also shows the primary wiring connection from the battery, through one of the coils and connections to the other three coils and to the commutator, back to the battery; also the secondary circuit from coil to spark plugs, back to the coil.

Primary circuit: Place your pencil on the drawing at the positive pole (P+) of No. 1 battery, and follow out the circuit.

We will begin with the positive pole connection of No. 1 battery; there are two sets of batteries, but only one set is used at the time. If one runs down, the other one is thrown into service by a switch on the coil.

The switch is now on No. 1 contact, and the circuit is from No. 1 battery to the switch, through the switch lever to the bus-bar on the front of the coil, which connects to the contact screw (V) of the coil, thence through the platinum points, through the magnetic vibrator spring, to the primary winding which is wrapped around a core or bundle of soft iron wires.

The other end of this primary wire of coil connects with the segment on the commutator; the current is closed here at the proper time. The commutator roller-contact revolves as explained previously. When this contact is completed, the primary circuit is closed on one of the four coils (it is now closed on No. 1 coil). When this circuit is closed, the bundle of iron wires (core) becomes magnetized and draws the vibrator down, but the moment the vibrator is drawn away from the contact with the vibrator screw, the circuit is broken and the vibrator springs back and makes contact again, but is immediately drawn down again; this, of course, is quick and rapid. This vibration is kept up as long as the contact is made on the timer, which, of course, is only for a moment, but during that time the vibrator makes several vibrations or "buzzes" as explained previously.

Secondary circuit: When these vibrations, or interruption of current, occur, a current is "induced" into the secondary winding of fine insulated wire wrapped around the primary winding of the coil, called a "secondary winding." (How and why this current is induced into the secondary winding without any metallic connection was explained).

This secondary winding, of course, has two terminals; one end goes to a spark plug, and the other end connects to one side of the primary wire, which grounds it through the commutator roller to the engine, when the roller makes contact; thence the circuit is to the metal shell of the spark plug in the engine, across the spark-plug gap, to the insulated part of the spark plug, back to the coil. A separate coil unit is provided for each cylinder.

The duty of the commutator, therefore, is to make contact at a certain time in order that the right coil will operate and supply an electric spark to the right cylinder at the right time.

Note. When one wire (on any wiring diagram) passes over another wire without making contact, a half-circle is made, as shown above.

How the Commutator Helps Control the Speed

The commutator is connected to the spark lever on the steering wheel (Fig. 10). When the spark-lever is pushed forward, the commutator is shifted forward so that the metal roller makes contact earlier with the contact segment. This is called "advancing" the spark.

If the commutator is shifted back instead of forward, the contact is made later. This is called "retarding" the spark.

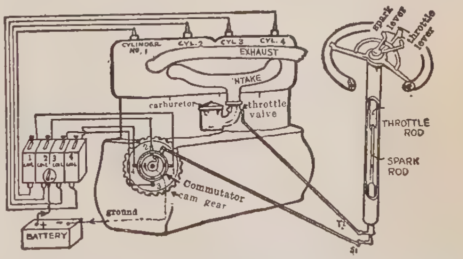

Fig. 10. Note the manual (hand) method of "advancing" and "retarding" the commutator. (Four-cylinder engine as example.) If the roller is revolving to the left, by shifting the commutator housing to the right, contact would be made earlier. This would be called "advancing" the spark. If the commutator is shifted to the left, contact would be made later—called "retarding."

When using a vibrator coil (which is the case here), the time of the spark is set earlier than when using the single-spark system, because plenty of time must be given the spark to ignite the gas so that it will ignite and combust when the piston is at the top of its stroke instead of after the top. (Note the connections to the commutator for firing order of 1, 2, 4, 3.)

The setting for the time of spark to occur is done by placing the contact roller at a certain position, as will be explained under "Ignition timing."

The gas-throttle lever is the lever used to run on, and is used to increase or decrease the speed of an engine. This is done by opening and closing the throttle, as explained under the subject of Carburetors.

It is well to run with the spark lever as well forward, or advanced, as possible, as it will tend to keep the speed of the engine up and consume less gasoline and create less heat. If the spark lever is too far advanced, then the engine will pound or knock, because the ignition will take place before the piston is over the center. A retarded spark produces heat.

The amount of advancing and retarding of the spark by hand must be learned by actual practice, in order to get the best results.

High-Tension Vibrator Coil Using a Commutator as Used on One, Two, and Four-Cylinder Engines

As previously stated, the vibrator-type coil is now seldom used on automobile engines. It will often be found on small marine and stationary engines. A few examples of connections are shown below.

There are as many coil units and as many commutator segments as there are cylinders.

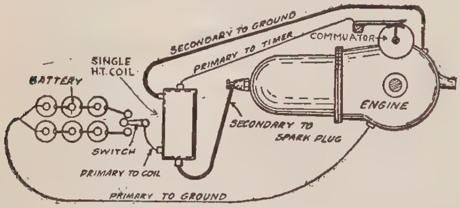

Fig. 11. One-cylinder engine with a vibrator type of jump-spark coil and two sets of dry batteries for ignition. Only one set of batteries is in use at the time. The commutator revolves at one-half the speed of the crank shaft. Note that there is one commutator segment.

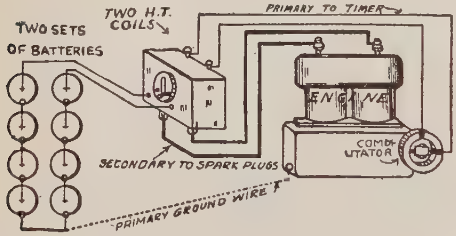

Fig. 12. Two-cylinder vertical engine (180° crank shaft) with a vibrator-type of jump spark coil and two sets of dry cells for ignition. Note the position of the segments on the commutator. The commutator revolves at one-half the speed of the crank shaft. (This type of engine is seldom used.)

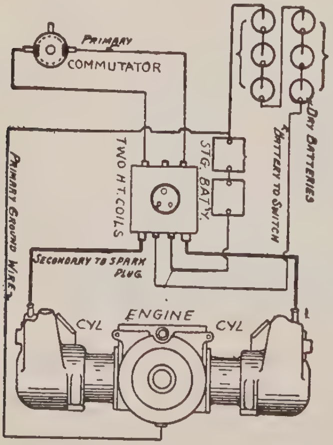

Fig. 13. A two-cylinder opposed-type of engine with a two-cylinder jump-spark coil and a set of dry cells and a storage battery, either of which may be used. The two contacts on the commutator are placed opposite. This revolves at one-half the speed of the crank shaft.

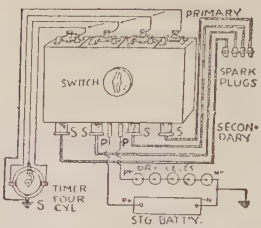

Fig. 14. A four-cylinder vibrator-type coil, using a commutator with four segments and a set of dry cells and a storage battery, either of which may be used. (S) are secondary terminal connections to the spark plugs.

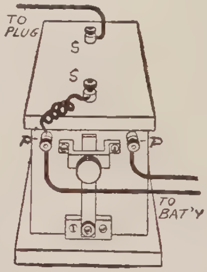

Fig. 15. A single-cylinder vibrator-type of jump-spark coil. This type is usually called a "box coil," and is only used on small marine or stationary engines. Quite frequently a single-cylinder box coil has but one secondary connection on top. In this case the secondary connection shown at the front of the coil is connected inside of the coil to the primary wire which connects to binding post (P).

The Master Vibrator Coil

With the "high-tension" vibrator coil system, just described, as many coil units, each with vibrators, would be provided as the engine had cylinders. If a four-cylinder engine, four vibrator coil units would be necessary. If a six-cylinder engine, six vibrator coil units would be necessary.

It will be noted that with this number of vibrators, one or more would be constantly sticking, unless a great deal of attention was given to them.

Therefore, by using a **master vibrator,** only one vibrator coil is used, which is connected with the other coils as shown in Fig. 16 (page 195).

The master vibrator coil has but a **single primary winding,** and is connected in series, so the primary current must travel through it before reaching any of the coils. The usual commutator is employed.

The master-vibrator coil can be connected with a "multiple" of coils, by screwing down the vibrators on all coils and short-circuiting them, by connecting as shown in Fig. 16A. Note that the coils are the regular double-wound, high-tension coils.

The advantage of such a system is that there is but **one vibrator** to keep in adjustment, since this vibrator serves for all the cylinders; whereas, with several vibrator-coil units the difficulty of keeping several adjustments is a considerable factor.

The disadvantage is the great amount of wiring necessary with the multiple-coil system. Although the master vibrator is easily connected and requires very little wiring, the "distributor" system, which will be explained next, requires considerably less wiring. The master vibrator is an excellent addition to be applied to a multiple system of ignition, already installed, which uses vibrator-type coils.

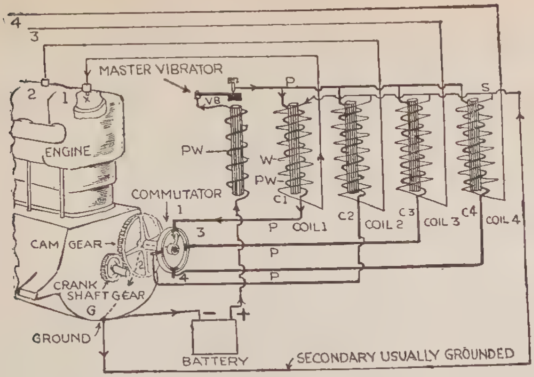

Fig. 16. A simplified illustration of a **master vibrator coil** on a four-cylinder engine, as an example. (**W**) secondary winding; (**PW**) primary winding; (**P**) primary wire; (**VB**) vibrator; (**C**) coils; (**G**) secondary ground wire; Fig. 16A, shows how the vibrator on the coils **C1**, **C2**, **C3**, and **C4** are short-circuited.

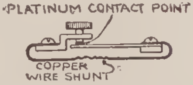

Fig. 16A. How to short-circuit vibrators on coils.

The firing order is 1, 2, 4, 3. No. 1 segment of the commutator is now connected; therefore coil (C1) is firing No. 1 cylinder. Note that the master vibrator is in series with this coil. The primary circuit in this instance is from (+) battery, through the winding of the master vibrator, through the vibrator points, through the primary winding of coil (C1), to the commutator segment, through the metal roller, through the ground of the engine, to the other terminal of the battery.

The secondary circuit is from wire (S) to the spark plug, through the engine, back to the other end of the secondary winding on the coil.

The next cylinder to fire will be No. 2, and coil (C2) will be the next one connected by the roller on the commutator. The next to fire will be cylinder No. 4 through coil (C4), then cylinder No. 3. through coil (C3).

The "Distributor" or Synchronous System of Ignition

In the foregoing examples it will have been noted that the amount of wiring required for engines having more than one cylinder becomes increasingly complicated. A system now generally used, known as the "distributor system," very considerably simplifies the wiring, and at the same time a more accurate timing of firing of the respective cylinder is obtained. (See Fig. 17).

One vibrator coil only is necessary, this having the high-tension terminal joined up to the "distributor," which is a special form of rotating switch highly insulated, which directs the high-tension current to the cylinders in the required order.

The secondary distributor brush (B) rotates at the same speed as the commutator roller contact-maker, and in perfect unison with it; that is to say, when the low-tension circuit is completed, the high-tension circuit is completed likewise. The diagram should make the system clear, it being borne in mind that the distributor is rotating as well as the contact maker, and in perfect "synchronism" with it.

The secondary distributor is made in combination with a commutator, each with as many contacts as the engine has cylinders, and with the moving parts of each attached to the same shaft and revolving. (See Fig. 18).

The battery is connected to the single coil in the usual manner, and a wire is run from the primary terminal of the coil to the commutator, where it is connected to the four segments of the commutator. Thus when the commutator revolves, the current is passed through the one coil every time that contact is made.

If with this arrangement a wire was run from the secondary terminal of the coil to the four spark plugs, sparks would pass in all four cylinders whenever the timer made contact. Instead of this, one secondary wire is run from the secondary terminal to the moving part of the distributor, termed the "distributor brush," or "rotor," and from each contact point, or distributor segment of the distributor to the proper spark plug.

When the commutator makes contact, and the secondary current is formed, it flows to the secondary distributor, which at that instant has made contact with one of its segments, so that that secondary current flows across the contact and to the spark plug that is connected.

The advantage of this system is that there is only one vibrator to keep in adjustment, and only one coil, thus fewer parts. The disadvantage is that the constant action of the vibrator is liable to burn the vibrator points, and destroy them. Electrical lag is also a factor to be considered, as is also a greater consumption of current.

The more modern ignition system uses a distributor for distributing the secondary current to the spark plugs in a similar manner, but instead of using a coil with a magnetic type of vibrator, or interrupter, a coil without a vibrator, termed a "non-vibrating" high-tension double-wound coil, is used, and instead of using a commutator, a timer or "interrupter," which is mechanically operated from the engine, is used. This system will be treated in the next instruction.

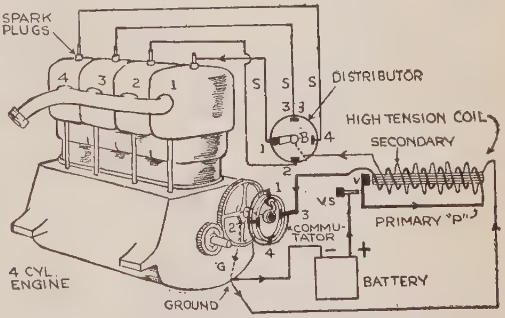

Fig. 17. A simplified illustration showing the principle of a high-tension **distributor or synchronous system** of ignition using a vibrator type of coil. Not in general use. (**P**) primary winding; (**S**) secondary. Note that one end grounds to the engine (usually grounded on the coil). (**VS**) vibrator screw.

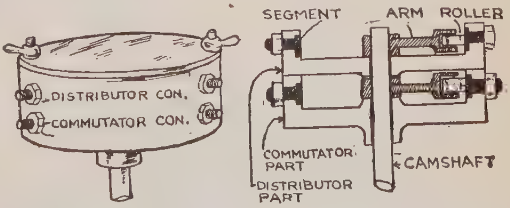

Fig. 18. Simplified illustrations to explain the principle of a **distributor and commutator** in one housing and operated by one drive shaft, used in connection with a vibrator type of coil. This method is obsolete, but a similar principle, of different construction, is the modern method, as will be explained farther on. Note that the distributor and commutator are together. The wiring diagram (Fig. 17) shows the two separated merely to explain the action.

INSTRUCTION No. 19

MODERN BATTERY AND COIL-IGNITION SYSTEMS: High-Tension Coil (Non-Vibrator Type); Open and Closed-Circuit Ignition System; Distributor; Resistance Unit; Safety Gap

THE MODERN BATTERY AND COIL IGNITION SYSTEMS

In order to understand the modern "coil and battery" ignition systems, it was necessary that the reader study the elementary principles of the early forms or methods used for ignition, such as the low-tension coil, the high-tension vibrator coil, the commutator and the distributor, which have all been explained. It ought not therefore to be difficult for the reader to grasp the principle of and the difference between the various modern ignition systems now to be treated.

The battery and coil system is the modern ignition system, such as used on the Atwater-Kent, Delco, Remy, and others which are supplied with a "constant" source of electric supply when used in connection with a storage battery which is kept charged by the generator.

"Constant source of supply" means that the ignition apparatus is not dependent upon a mechanical method of generating current, as in a magneto, but the supply of electric current is constantly supplied by a storage battery and the storage battery is constantly supplied with current (direct) by a generator.

The Non-Vibrator Coil Ignition System

The same underlying principle of operation of a vibrator-type coil, explained on the preceding pages, applies to the non-vibrator coil. The only difference to be noted is that the commutator is dispensed with, and instead of having a "magnetically operated vibrator" or "interrupter" on the coil, a "mechanically operated timer," or "interrupter," is driven from the same shaft as the secondary distributor and is used for exactly the same purpose.

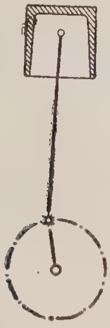

Fig. 1

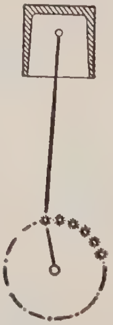

Fig. 2

Fig. 1 represents the **"single spark"**—a hot one at the right time, which causes the gas to ignite quickly without lag, and consumes very little current, as produced by a high-tension coil ignition system of the non-vibrator type.

Fig. 2. Note the **succession of sparks.** This represents the sparks as they occur on the old-style magnetic vibrator coil—several after top of stroke. The hottest one ignites the gas, but usually late.

The non-vibrator coil uses a mechanical interrupter and gives but one "single spark" (see Figs. 3, 4 and 5).

Open and Closed-Circuit Interrupters

The non-vibrator coil system of ignition can be classified as an **open-circuit** system and a **closed-circuit** system. It gives a "single spark."

The open-circuit system consists of a single non-vibrator coil, timer, and distributor (if a multiple-cylinder engine).

Timer.

Fig. 3. A non-vibrating high-tension coil ignition system, using an open-circuit timer.

The open-circuit timer contact points (Fig. 3), used in connection with this system, are normally **open.** The cam is attached to a shaft, usually driven from the cam shaft, and must therefore be set so that the high point or lobe on the cam will raise the arm (C) so that it will make contact at the proper time. The spark does not occur at the spark plug when the contact is made, but when the contact is opened. This is therefore, a double operation, which causes "electrical and mechanical lag," and this is eliminated by the use of a contact arrangement which is normally **closed.** Thus the improved method (Fig. 4) is termed a "closed-circuit" system, and is the system in general use today.

"Electrical lag" means that the spark will not occur in the same position as regards piston travel at any and all engine speeds. With a very high speed the piston might have a tendency to travel past the point of ignition before the open-circuit timer made and opened contact, whereas with the closed-circuit principle it merely opens the contact.

While all lag factors deal with time in seconds, their effect on the engine is the number of degrees they cause the spark to occur off the point where it should. Consequently a time factor of only one-thousandth of a second means only a variation of 3° at 500 r.p.m., yet means 12° at 2,000 r.p.m., and 18° at 3,000 r.p.m.

Mechanical lag is eliminated much for the same reason, and the quicker and simpler the mechanism to "interrupt" the flow in the primary, the quicker the spark.

Compare the **timer** in Fig. 3 with the **interrupter** in Fig. 4.

Note that in Fig. 3 the cam raises the arm (C) which makes contact at points (P), which are normally open. The strong spark does not occur when contact is made, but when it is opened.

Fig. 4. A non-vibrating high-tension coil ignition system, using a **closed circuit** interrupter (also called contact-breaker).

Note that in Fig. 4 the contact points (P) are normally **closed**, and the high point on the cam raises the interrupter arm, thus opening the points (P) with one single operation. Thus the closed primary circuit of the coil is interrupted; hence its name "interrupter," or "contact breaker" as it is also often called.

The closed-circuit ignition system using a non-vibrator coil and a closed-circuit "interrupter" in connection with a distributor is more clearly shown in Fig. 5. This represents a modern "battery-and-coil" ignition system.

Note that the distributor shaft, which is driven from the cam shaft of the engine, operates the interrupter cam which opens the interrupter contact points. The same shaft operates the distributor brush which distributes the secondary high-tension current to the spark plugs.

The cam has as many high places, or lobes, as there are cylinders. On the cam in Fig. 5 there are four high places. This would, therefore, be suitable for a four-cylinder engine. It is fastened to a shaft which is driven at cam-shaft speed. It is set or timed so that the high point on the cam pushes the moving contact blade point away from the stationary contact point, thus opening the primary circuit of the coil. By this method the operation of first closing the circuit, then opening it, as on the open-circuit timer is eliminated, and makes the action much quicker.

Circuit of the Modern Closed-Circuit System

The primary circuit of the closed-circuit system (Fig. 5, below), is from (+) of the battery, through the ignition switch, through the resistance, through the primary winding, through the insulated stationary contact point, through the movable interrupter or contact points, through the frame of the interrupter, to which it is grounded, to a ground connection of the frame of the car, to (−) ground of the battery.

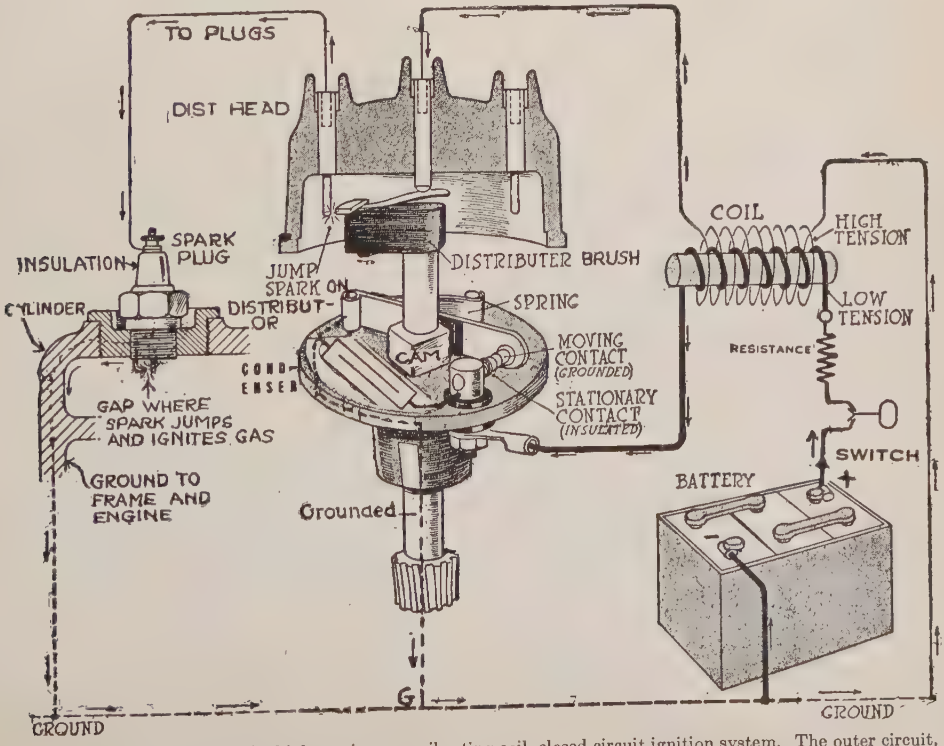

Fig. 5. A simplified illustration of a high-tension non-vibrating coil, closed circuit ignition system. The outer circuit, in light lines, is the secondary; the inner circuit, in heavy lines, is the primary circuit.

The condenser in this instance is placed across the contact points of the interrupter and in the interrupter, one end being connected with the insulated stationary contact and the other end grounded to the frame of the interrupter. The condenser could be in the coil, which it is, in some systems; in such cases it must connect directly across the contact points, as explained on page 189.

The secondary circuit and distributor: One terminal is grounded. The other leads to the center terminal of the distributor, and makes contact with the metal spring on the insulated rotating distributor brush, also called the "rotor."

The other end of the spring on the rotor passes close to, but not touching, the metal distributor terminals of the distributor head (made of insulated material) which leads to the spark plugs (termed the "distributor gap"[1]); thence through the center terminal of the spark plug; it then jumps the gap at the spark-plug points, thence to the shell of the plug to the engine, back to the grounded connection of the secondary.

The distributor rotor, of course, is synchronized or set so that the rotor spring makes contact with the spark plug in the cylinder to be fired; at the same time the interrupter cam opens the circuit.

The ignition switch of course is supposed to be opened when the engine is idle. However, the operator may not always think to open the ignition switch, and therefore an **ignition resistance unit** is placed in series with the primary winding on very nearly all closed-circuit battery and coil-ignition systems, to take care of any possible damage that might occur.

Ignition Resistance Unit

The purpose of the ignition resistance unit is twofold, one being to protect the battery from discharging back through the primary winding and thus overheating the winding and discharging the battery, if the switch is left on and engine is not running.

The ignition resistance is made of iron wire, usually mounted on a porcelain spool on the ignition coil. It turns a cherry red when the primary current flows through it for any length of time. When iron heats it offers resistance; thus the discharge through the primary winding is greatly decreased. If current is left on for a long period of time when the engine is idle, the resistance may burn out and open the circuit and a new resistance unit becomes necessary. This sort of thing happens frequently.

When the engine is running, the circuit is continually opened and closed and thus the heating effect is not as great.

In the instruction on the principle of the ignition coil (page 190), we learned that the coil core is slow in its action of "building up" lines-of-force, or in being magnetized, when the circuit is closed. This being the case, it would appear that at high engine speeds the interruption or opening of the circuit would take place before the iron core of the coil was fully magnetized, thus producing a weak spark. This is quite true and possible.

To overcome this, the coil is wound so that it takes an excess of current, or more than is required in order to compensate for this slow action of magnetizing the core. The question next to arise is, if the excess of current takes care of high speeds, what is the situation in the case of low speeds? At low speeds, the points are closed for a longer period and the excess of current would injure the coil.

The answer is, that the resistance unit heats when the circuit is closed for a longer period of time and offers resistance which cuts down the flow of current to normal. At high speeds it does not heat so much and the resistance is less, and the current is permitted to pass at full value through the winding at high speed, thus assisting in quickly building up magnetism in the core.[1]

High-Tension Safety Gap

Safety gap: The fact that the distributor spring does not make full contact with the distributor terminals leading to the spark plugs brings up the subject of safety gaps.

The safety gap on the ignition coil is always a "shunt" gap placed across the secondary circuit, usually on the coil. If the external secondary circuit is open, the safety gap provides another path to ground (see Fig. 6). It is used more on high-tension magnetos than it is on ignition coils. It is practically a safety valve for the high-tension current. The safety gap is usually set slightly farther apart than the spark-plug gap, or about 5/16″. As long as the wires to the spark plug are connected, the safety gap is inactive, but if the spark-plug wire should come loose, then the safety gap becomes active by a spark jumping across its gap instead of trying to jump from the end of the loose wire to the engine. If this were a greater distance than ½″, which it might well be, it might cause the high-tension current to force a circuit through its own insulated winding to its ground, thus damaging the coil.

CONNECTICUT IGNITION, CLOSED-CIRCUIT SYSTEMS: MODELS 16, 14, AND 15

As an example of an ignition system using a "safety gap" and a "thermostat resistance," the Connecticut ignition system as used on the Dort and also on the "model 89" Willy-Knight six, is shown in Fig. 6. The diagram represents that of the Dort. The Connecticut ignition system using the Connecticut automatic thermostat switch, is clearly shown in this illustration. This ignition system is known as the model "16."

The purpose of the thermostat switch. It must be understood that the timer, or interrupter (Fig. 7) is a closed-circuit type; therefore if the engine is not running and the switch is left "on," a waste of current and heating of the ignition coil results, therefore this automatic switch is used to open the circuit.

There are **two types of Connecticut thermostat switches:** one which is operated by **magnet coils,**

---

[1] The gap between the distributor brush and the spark-plug terminals (Fig. 5) is about .010″. It may vary .003″ or .004″ either way.

The prime advantage of this gap is the fact that no rubbing parts are employed; therefore there is no friction or wear.

The high-voltage secondary current is able to jump the gap, and as soon as the gap is broken down its resistance becomes very low and the secondary discharge passes without noticeable loss.

[1] It is a very easy matter to check the resistance unit, by observing its heating when the ignition button is out and the contacts of the interrupter are closed. If it is shorted out, it will not heat up, and will cause missing at low speeds.

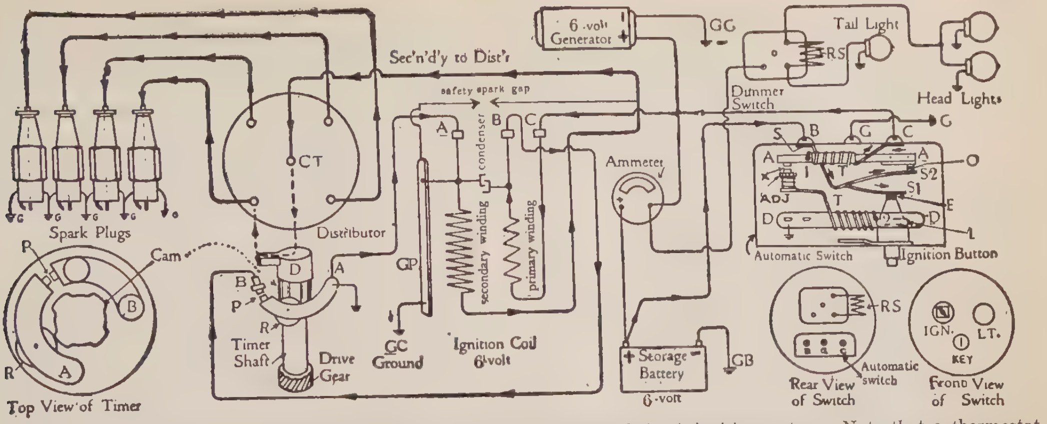

Fig. 6. The Connecticut model "16" high-tension non-vibrating coil closed-circuit ignition system. Note that a thermostat of the **thermal** type, termed "automatic switch," is used to open the circuit if the ignition switch should be left "on." Type "GA" coil is used in this system. Note that the interrupter is grounded at (A).

which is an early type described in Figs. 13 and 14, and a later model where a thermal, or **thermostat blade** (D), (Figs. 6 and 8) takes the place of the magnets. We shall describe the later model, using the thermal blade. "Thermal" refers to heat.

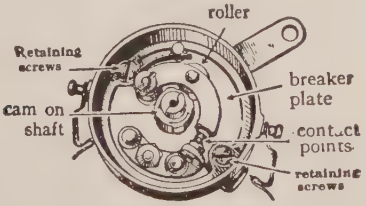

Fig. 7. Top view of Connecticut interrupter or contact-breaker.

Thermostat action (see Figs. 6 and 8). The battery current flows from battery (+), to (B), then through insulated spring (S, Figs. 6 and 8). If the ignition button is pushed in, then an insulated plunger (E) on the switch button presses against spring (S1) causing spring (S2) to close points (O). The current then travels through (A) to (1), through resistance wire ribbon (T) (thermostat wire which is insulated from **A**, except where grounded to **A** at 1), to insulated connection (C), to (C) connection on the coil.

So long as the engine is running, the intermittent opening and closing of timer contact points prevents (T) from heating blade (A).

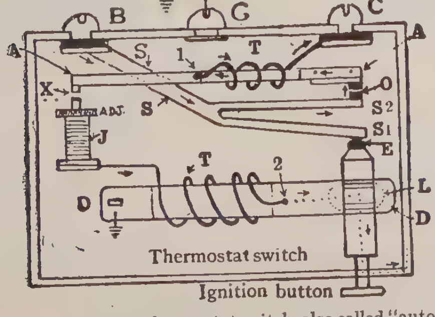

Fig. 8. Connecticut thermostat switch, also called "automatic switch."

If the engine stops with ignition switch "in," then the timer points are closed, and within for 30 or 40 seconds the continuous current passing through resistance wire (T) heats spring blade (A), causing it to bend down, thus making contact with (J) at (X). The current then flows through (J) to (T) on blade (D), through (2) to ground connection of switch box at (G).

Blade (D) then becomes heated and bends up, releasing a wedge-shaped lug (L) which is attached to under part of (D), from a groove in the ignition button shaft. The spring (S1) then easily forces the ignition button "out," thus opening the circuit at (O) and (X).

The primary ignition coil circuit can be traced by starting at (+) of battery (Fig. 6) to thermostat connection (B) through spring (S) to connection (C) (when ignition button is "in"), thence to the primary winding of coil (C), through the coil, out coil terminal (B) to stationary contact (B) on model 16 timer, through points (P) to movable contact (A) (which is grounded), to the grounded terminal of the coil primary winding at (A), through ground plate (GP) to ground (−) of battery (type **GA** coil).

The secondary ignition-coil circuit is from the secondary winding to center terminal (CT) of the distributor, to distributor arm (D) which passes the secondary current as it revolves, to spark plugs, thence through center terminals of spark plugs across spark-plug gaps to the shell of the spark plug to the engine frame, thence back to ground plate (GP) on the coil to the grounded terminal of the secondary winding.

The safety gap is shunted across the secondary circuit of the coil, as shown in Fig. 6, and explained above.

The condenser (Fig. 6) is shunted across the contact points of the timer, but is located in the coil.

The lighting and ignition switch (type K.V.B.) is combined with the Connecticut automatic thermostat ignition switch; a front and rear view is shown in Fig. 6. It has two buttons.

When the button at the left is pushed in, the ignition is "on." **When it is pulled out,** the ignition is "off."

When the button at the right is pushed all the way in, the headlights will burn "dim," as the dimmer resistance (RS) is in series with the circuit. **When pulled all the way out,** the headlights will burn "bright," as the resistance (**RS**) is then cut out of the circuit. When **placed in the center**, the lights are "out."

The fuse for the lights is under the hood on the right side, and a fuse for the horn is on the left side. If all lights fail to burn or the horn fails to operate, see if the fuse is blown. The fuses are 7 volt, 10 ampere enclosed No. 1 type, di. ¼″ x ⅝″ glass tube.

Timing ignition (Dort). Open priming cocks. Turn starting crank until 1 and 4DC (cylinders No. 1 and 4 are on dead center of compression stroke) appears on the flywheel and is in line with the center mark on the crank case; then turn flywheel 1″ past this dead-center line.

Retard the spark lever and loosen the set screw on the distributor shaft.

Push in the ignition-switch button. Disconnect the spark-plug wire on cylinder No. 1, and place it so that the terminal may be about 1/16″ from the metallic part of the spark plug.

Turn the distributor shaft very slowly, in a clockwise direction, till a spark is seen between the spark plug and the wire terminal, and stop.

Screw securely the set screw on the distributor shaft, put the handles of the priming cups in a vertical position, and the spark is correctly timed.

The firing order is 1, 3, 4, 2, and the wires to spark plugs should be attached to the distributor in this order. No. 1 cylinder is the one next to the fan. Spark plug is ⅞–18 thread, and the gap should be .022″ to .025″.

The generator shown in Fig. 6 (which is the electric diagram on the Dort) is the Westinghouse, using a third-brush regulation with a cut-out switch (reverse-current type) contained in the generator. Note that one terminal of the generator is grounded, likewise the (−) terminal of the battery. **When starting,** the ignition current is taken from the battery. **After starting,** and generator gains sufficient speed (8 or 9 miles per hour car speed), and then the generator supplies current for ignition and charges the battery. The generator produces 12 to 15 amperes at 18 miles per hour. At higher speeds the charging rate decreases slightly.

The starting motor (not shown) is located on the left side of the engine, at the rear. It is fitted with a Bendix drive which automatically engages and disengages the fly-wheel gear, as explained in the instruction on starting motors. One terminal of the starting motor is grounded, the other terminal connects with the starter switch, from the starter switch to battery (+), through the battery to ground.

Renewing Interrupter Points

To dissassemble interrupter (timer), model 16: first, unclamp the spring and remove the distributor cover (Fig. 9); second, remove the distributor arm (Fig. 10); third, unscrew the retaining screws (Fig. 11); fourth, lift the breaker-plate, unscrew nut and loosen the primary wire. Install new breaker plate (Fig. 12). After **installing a new breaker-plate, which is always necessary when renewing interrupter points,** reassemble and adjust.

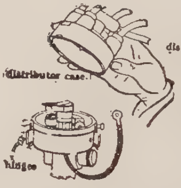

Fig. 9

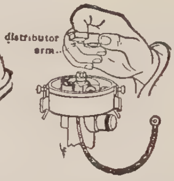

Fig. 10

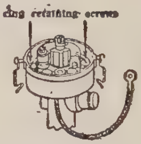

Fig. 11

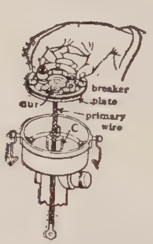

Fig. 12

Interrupter (Timer) Adjustment

The opening of contact-points should be .016″ for a six-cylinder engine, .020″ for a four-cylinder, and .012″ for an eight-cylinder engine. When adjusting, the roller should rest on the point of the cam. Set spark-plug gap .022″ to .025″.

Connecticut Ignition; Models 14 and 15; Closed-Circuit System

This ignition system was used on many of the Overland cars. The thermostat switch was controlled by **magnets** and enclosed in rear of a switch mounted on the dash. In many of the Overland cars this switch, called a "combination switch" box, was placed on the steering column.

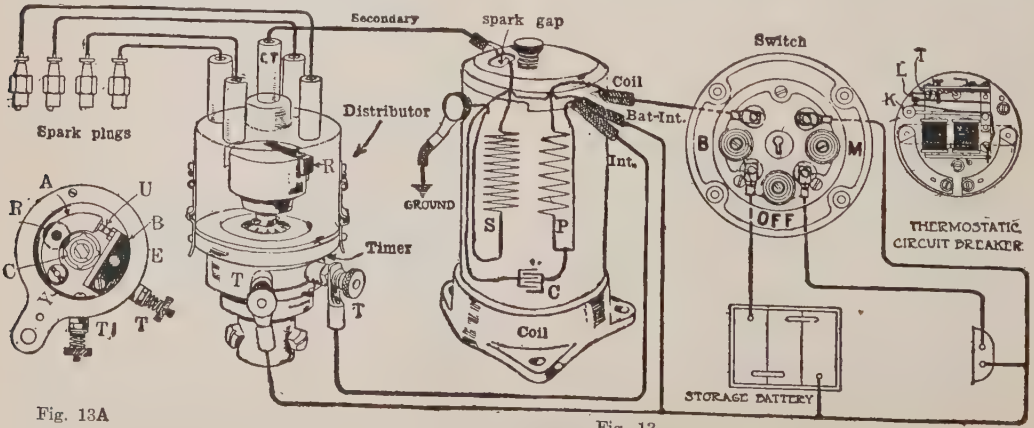

Fig. 13A

Fig. 13

Fig. 13. The Connecticut models "14" and "15," high-tension non-vibrating coil, closed-circuit ignition system, using a magnetic thermostat switch.

Fig. 13A. Top view of the closed-circuit interrupter or contact-breaker. Note that the interrupter is not grounded, as in Fig. 6, but insulated.

The timer or interrupter (Figs. 13 and 13A) is the model 14 and 15, where both contact points (U), one on arm (A), the other on arm (B), are insulated from each other and two wires connect with terminals (T) and T1) from coil, battery, and switch. (R) is a fiber roller and (C) a cam, which turns at one-half the engine speed and has as many lobes as there are cylinders. Both contact-points are normally closed until separated by cam (C). It is thus a closed-circuit type.

The distributor sets above the timer, and the rotor or distributor arm sets on top of the cam shaft and revolves at the same speed as the timer cam. The rotor in models 14 and 15 is of the "brush-type" contact (R), which makes a wiping contact.

The model 16 timer-distributor (Fig. 6) is very similar, except, instead of having two binding-posts to the timer, there is one binding-post and a wire, and the distributor rotor (or arm) is of the "gap-type."

The coil is a non-vibrating type. A safety-gap is provided to protect the coil from liability to a puncture of the winding insulation if the spark plug or secondary wires come loose.

The switch on this system is the model G. When (B) button is pressed, the storage battery supplies current for ignition. When (M) button is pressed, the magneto supplies current for ignition. When the lower button is pressed, it will release either of the above, whichever may be in.

The thermostat, as explained below and also shown at the right in Fig. 13, is contained in the back of the switch. This switch is now seldom used except where magneto ignition is employed. The switch below is the model 41Y ignition and lighting switch with thermostat. Where a generator is on the car, it is connected with a separate cut-out, between battery and switch.

The thermostat consists of blade (T) (see Figs. 13 and 14), which heats when current passes through it for from 30 seconds to 4 minutes without interruption, and causes it to bend to contact with (L).

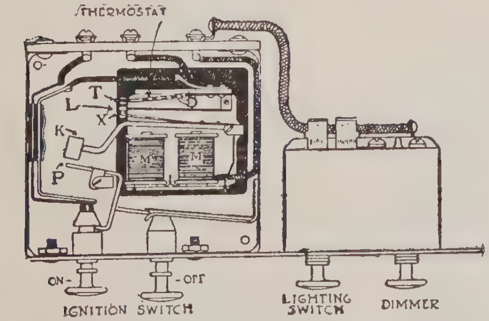

Fig. 14. Connecticut magnetic thermostat switch (early model, as used in Fig. 13). An automatic thermostat in the Connecticut system breaks the circuit in the event that the switch is left in the "on" position with the motor idle. The light switch and dimmer are housed at the right.

This completes an electrical circuit which energizes the magnets (M), causing releasing hammer (K) to operate like the clapper in an electric bell. This arm strikes against a plate (P) which releases whichever of the two ignition switch buttons in switch may be depressed or "on." The thermostat can be set to act from ½ to 4 min.

An adjusting screw (Fig. 13, right illustration) is provided directly over the thermostat spring (T) which regulates the time. If the thermostat was made to disconnect in less than 30 seconds it would probably "kick-off" when putting on ignition, before the engine could be started.

The condenser (C) (Fig. 13) is located in the coil, but by tracing the coil primary circuit it will be observed that it is shunted across the timer contact points.

Example of Timing Connecticut Ignition System

To time the breaker and distributor six-cylinder engine as example): When replacing, if for any cause it becomes necessary to remove the breaker and distributor, crank the engine by hand until the piston of No. 1 cylinder (first from front end of car) comes up on its compression stroke, and stop when the 1-6 mark on the flywheel is on top in a line with the flywheel indicator. At this point the piston is at the uppermost point of the compression stroke or "dead center." You can determine when the piston is coming up on the compression stroke by opening the relief cock on the cylinder and holding your finger over the opening.

Now advance the spark lever on the steering wheel one-quarter of the way. Remove the distributor cap, then set the combination breaker and distributor on the driving shaft with set screws loose; connect the advance lever, turn the hub on the shaft in the direction of rotation (counter-clockwise) until the contact points are just opening, which is the point at which the spark takes place; then tighten the hub set screws.

Now replace the distributor cap, carefully noticing which segment of the distributor brush is opposite, for this is the connection to the spark plug of No. 1 cylinder. Now connect up the balance of the spark plugs in their firing order—1, 5, 3, 6, 2, 4.

The Chevrolet timing: Place the piston on top of the compression stroke. Retard spark, loosen set screw and turn igniter unit until contact points are just opening, which is the point for spark. Tighten the set screw. The firing order is 1, 2, 4, 3. Therefore connect the plug terminals accordingly.

See also Index under "Lexington ignition timing," which is another example of the Connecticut system.

Testing Ignition Circuits and Parts

Testing coil: In order to determine if the coil is operating properly, secure a piece of wire and, holding one end to the frame of the car, engine casting, or other metallic "ground," bring the other end to within one-quarter inch from the point where the high-tension wire (running from the coil to the central terminal of the distributor) leads from the coil, and turn the engine over by hand with the switch on. If a spark occurs at this point and not at the distributor, the trouble is in the high-tension wire which leads from the coil to the distributor. If, however, no spark occurs at either point, see if the safety gap in the top of the coil is wet. In this case dry out the coil for several hours in a warm oven. The safety gap may be observed by removing the cover on the top of the coil.

---

[1] To suit individual requirements it may be necessary to advance the ignition slightly when timing, if greater speed is required, or to retard it slightly for very slow running. This is done by loosening set screw and turning timer with rotation of shaft if it is found to be timed early—or against rotation if it is found to be timed late.

The thermostat (or ignition resistance unit in other systems) would cause missing if burned out.

The condenser, if shorted, will cause a weak spark. These subjects are treated farther on.

If this does not correct the trouble and the primary circuit is intact, it is evident that the coil should be replaced or returned for repairs.

It is a good plan regularly to examine the clamping rods holding the coil to the generator, tightening when needed to prevent vibration from loosening the terminals or breaking them.

Test of primary circuit: When testing the primary circuit, there are practically only two things to be taken into consideration, namely, the condition of the contact points in the breaker box and the wiring.

When tracing the primary circuit, first see if any of the fuses have "blown," then trace all the wiring of the ignition circuit.

Testing ignition switch: In order to test the switch and determine if current flows through it, attach a wire to the negative terminal on the storage battery and remove the wire from the terminal on the coil. Then push the ignition button on the left end of the switch in and make and break the circuit with the two wires by touching their free ends together. If a spark occurs, there is a circuit through the switch. If a spark is not obtained, there is doubtless an open circuit in the interior; therefore it should be returned for repairs.

(The address of the Connecticut Tel. and Electric Co. is Meriden, Conn.)

ATWATER KENT OPEN-CIRCUIT IGNITION SYSTEM

As an example of a **coil and battery ignition system, using an open-circuit timer system of ignition,** we will take the Atwater-Kent type K2 open-circuit system. (This concern also manufactures a closed-circuit system, as illustrated on page 205.)

The distributor and timer (called the Unisparker) is illustrated in Figs. 1 to 7. It consists of a timer with its contact breaker, or "maker," which would be more appropriate, mounted on the timer shaft, but independent of each other.

The timer is illustrated in Fig. 3.

The parts consist of: (1) the distributor and timer, which is called the Unisparker; (2) the coil, which consists of a simple primary and secondary winding, sealed in an insulated cylinder; the coil has no vibrators, contacts, or other moving parts; (3) the depolarizer switch; (4) the automatic spark advance.

The function of the Atwater-Kent ignition system is to produce a single hot spark for each power-impulse of the engine, accurately timed to occur at the right instant to produce the greatest possible power and efficiency.

FIG 3.

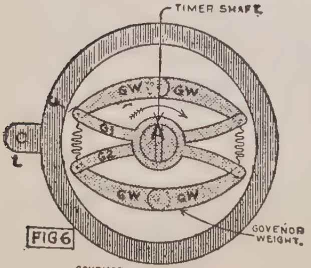

FIG 6

GOVENOR WHEN RUNNING SLOW.

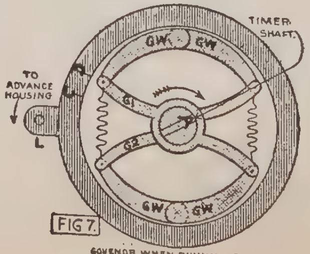

FIG 7.

GOVENOR WHEN RUNNING FAST.

The timer shaft is a half-inch shaft, driven usually from the cam shaft and at cam-shaft speed. It is also quite often mounted on the generator and driven from it, as shown on page 210. It should always be installed in the coolest location available.

The contact points in the timer (Fig. 3) do not touch except during the brief instant of the spark. The ignition circuit is therefore normally open and no current flows, even though the ignition switch be left "closed." This dispenses with the use of a resistance unit, or thermostat.

Where the hand-spark control lever is also used, it should be so proportioned as to give not more than one-quarter to one-half inch of movement for the entire range of the spark lever on the steering-wheel sector.

Range of spark advance: The high-tension distributor is carried on a central shaft, which connects below the governor, so that the distributor block is not moved by the automatic advance mechanism. This permits of a wide range of spark advance without affecting the synchronism. The maximum advance is about 45° of crank-shaft travel, at 2,400 r.p.m.

The source of electric supply for this system, also all other systems of this kind, is from the storage battery. The storage battery, as previously explained, is charged from an electric generator run from the engine.

The current consumption is very small, but the strength or pressure of current as required by the coil is necessary for a single-spark system. Therefore keep the battery fully charged at all times.

In case of an emergency, dry cells can be used connected six in series.

Adjusting A.K. Open-Circuit Timer

Adjustment of the gap between contact-points should be .010″, when the lifter (**D**) (Fig. 3), is in the notch. This adjustment can be made by placing more or less thin shim washers (see **W**), (Fig. 3) on the contact screw.

When taking up this distance between points, arising from natural wear, remove both screws and dress with a very fine file; then replace and shim up to .010″. The points are made of tungsten steel, which is very hard.

Remember that when the points are working properly, small particles of tungsten will be carried from one point to the other, forming a roughness of a dark gray color. This, however, does not in any way affect the working of the points, as the rough surfaces fit each other perfectly. The spark-plug gap should be .025″.

Do not think that the parts of the timer (Figs. 8 to 11) do not work properly because you cannot see their movement. The contact maker of the Unisparker may be likened to a watch, which, because of the small size and extreme accuracy and hardness of its moving parts, is subject to very little wear. Don't change the tension of spring or alter the parts.

Polarity Switch

The polarity switch, also termed a "pole-changing switch" and "depolarizing switch," is intended to prevent the points on (**B**) and (**C**) (Fig. 3) from becoming worn and pitted. "Direct" current is used, which has a tendency to burn and pit the points, whereas an alternating current is much easier on the points. Therefore the purpose and principle of this style of switch is to alternate the flow of current from (**N**) to (**S**) and (**S**) to (**N**), or from positive to negative and negative to positive.

As stated above, "direct" current is used with all battery systems; therefore a steady flow in one direction has a tendency to deposit the metal from one point to the other—but by changing this flow of current occasionally, the deposit will be put back to the other point again. This is similar to electroplating.

Note the action of the polarity switch (Fig. 5): (**C**) to (**A**) is now flowing positive, and (**D**) to (**B**) is flowing negative. By turning the switch one-quarter turn, the poles are changed; (**C**) to (**D**) will become positive and (**A**) to (**B**) will become negative. This change is made occasionally when running, and has a tendency to keep the contact points clean.

Automatic Governor

The governor (Figs. 6 and 7) is mounted directly under the timer. One arm of the governor (**G1**), is attached to the upper part of the timer shaft which is free to advance with the action of the governor. The other arm of the governor automatically advances the time of spark as the speed of the engine increases, by centrifugal action of the governor weights (**GW**), as shown. Note the position of the end of the timer shaft (**A**), at retard (Fig. 6), and advance (Fig. 7). Note that at "retard," the governor arm (**G1**) is at (**C**), whereas at full speed it has advanced to (**D**) (marks shown on left-hand side of housing).

Explanation of the Automatic Advance of Spark

Governor: The Delco, Remy, Atwater Kent, and many other systems employ a mechanical governor for advancing the spark when the engine is speeded. A governor of the centrifugal type is usually employed, but of slightly different construction on different systems. The purpose of the governor is to cause the timer notched shaft to turn in the direction of rotation, causing the contact to make and break earlier as the speed increases.

For instance, refer to Fig. 6, page 202. Assume that the engine is running slow and that the governor is in retarded position. Note the position of the notch (**A**) and the governor weights at the top of the timer shaft. If the engine is speeded up, the governor weights (**GW**) fly outward (Fig. 7), causing the timer shaft to turn a farther advance in the direction of rotation. It is clear that the contact would be made earlier at contact points. The top of the timer shaft is driven through the governor arm—(**G1**) (Fig. 2); thus as weights (**GW**, Fig. 7) are forced outward by centrifugal force, (**G1**) moves the timer shaft (Fig. 2) in the direction of rotation.

The automatic spark control is for the purpose of securing the proper control due to variations in speed alone, and all that is required for normal driving is to secure the proper spark control for slow driving from 10 to 15 miles per hour (set the spark lever about two-thirds advanced), and the automatic feature will give the proper spark position for all higher speeds and for all lower speeds, excepting when the throttle is wide open, at which time the spark lever should be slightly retarded.

The advantage of the automatic spark advance, as further explained is this: With the spark lever set at the running position on the steering wheel, the "automatic" feature gives the proper spark for all speeds excepting a wide-open throttle at low speeds, at which time the spark lever should be slightly retarded. When the ignition is too far advanced, it causes loss of power and a knocking sound within the engine. With too late a spark there is a loss of power (which is usually not noticed excepting by an experienced driver or one very familiar with the car), and heating of the engine and excessive consumption of fuel are the results.

Manual and Hand Advance of Spark

In addition to the governor advance—**the distributor housing can also be advanced by hand,** the two working independent of each other (see Fig. 3). (**L**) is connected with the spark lever on the steering wheel. This is termed "manual control."

The manual or hand control is for the purpose of securing the proper ignition control for carburetor adjusting, slow idling, retard for starting, and variable conditions which cannot be held constant. See explanation below.

The reason for using the manual (**hand**) **control of spark,** where a system is equipped with an automatic advance, is as follows: a heavy charge burns quicker than a light one. For this reason the engine will stand more advance with a half-open throttle than with a wide-open throttle. The hand control is therefore installed in order to secure the proper timing of the ignition due to these variations and to retard the spark for "starting," "idling," and "carburetor adjusting."

The automatic advance mechanism varies slightly in construction on different makes, but almost all are of the centrifugal type.

When starting the engine, where ignition is manual and with automatic advance, the spark lever should be retarded. After starting, move the hand spark lever to a position on the quadrant on top of the steering wheel, known as "driving position." It can then be advanced or retarded as occasion demands.

Operation of [the Atwater Kent Open-Circuit Timer

The operation of the timer: This consists of a pair of contact points, normally open, which are connected in series with a battery and the primary circuit of a simple non-vibrating induction coil.

A hardened steel latch, against which the trigger strikes on its recoil and which in turn operates the contact points, completes the device (see Figs. 8, 9, 10 and 11).

The distributor forms the upper part of the Unisparker; the high-tension current from the coil is conveyed by the rotating distributor block arm (**DA**) (Fig. 2), thence to the spark plugs in their proper order of firing.

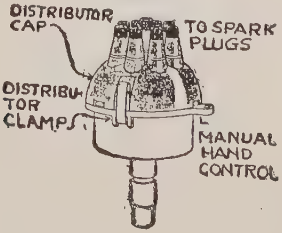

Fig. 7A. Illustrating the distributor and timer unit as shown in Fig. 2. Termed the "Unisparker."

The distributor, which distributes the current to the spark plugs (six, in this instance) in their respective firing order of 1, 4, 2, 6, 3, 5, is mounted on the upper end of the shaft. The distributor arm (**DA**), revolves with the timer shaft and passes the high-tension current to the terminals of the distributor. As six sparks are required per revolution, there are six notches on the timer cam, and the distributor points are spaced 60° apart. Fig. **7A** shows the parts of the distributor. A secondary cable of 5/16″ outside diameter is used for the secondary circuit.

Gap type distributor: The distributor arm (**DA,** Fig. 2) does not touch the contacts above it, but passes close to them (gap .010 in.) as it revolves, and the high-tension current jumps the slight gap. It is therefore termed a "gap-type" distributor.

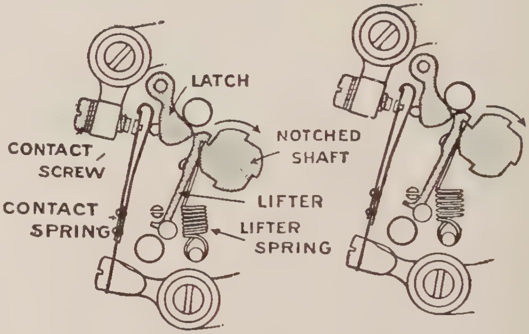

Fig. 8. Contact open. Fig. 9. Contact still open.

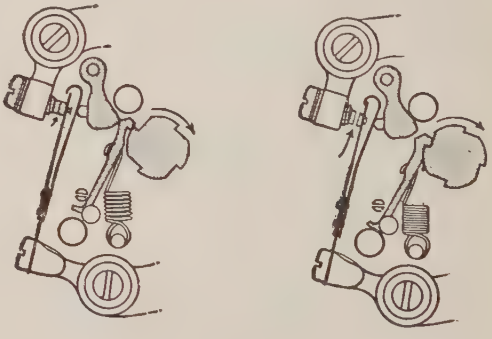

Fig. 10. Contact made. Fig. 11. Contact broken.

Figs. 8, 9, 10, and 11. Atwater Kent open-circuit timer operation.

Figs. 8, 9, 10, and 11 show the operation of the Atwater-Kent open-circuit timer clearly. It will be noted that in Fig. 8, the lifter is being pulled forward by the notched shaft. When pulled forward as far as the shaft will carry it (Fig. 9), the lifter is suddenly pulled back by the recoil of the lifter spring. In returning, it strikes against the latch, throwing this against the contact spring and closing the contact for a very brief instant—far too quickly for the eye to follow the movement (Fig. 10). Note that the circuit is closed only during the instant of the spark.

Fig. 11 shows the lifter ready to be pulled forward by the next notch. There are as many notches in the timer shaft as there are cylinders, and as many leads from the distributor to the spark plugs as there are cylinders.

The ignition coil (Fig. 4) is a box-type coil with a secondary and a primary winding. The primary current (6 volts), coming from the battery or generator, is carried through a pole-changing switch (Fig. 5) through timer contacts, where the current is opened and closed at the proper time by the contact arm (**D**) (Fig. 3) coming in contact with notches (**N**, Fig. 2), which raises latch (**E**), causing contacts (**B** and **C**), which are insulated from each other, to come in contact, thereby closing the primary circuit in the coil. This causes a secondary current to be set up in the secondary winding of high voltage. This secondary current is then distributed to the spark plugs by the distributor. (Cylindrical type coil is now used.)

The condenser in this system, using the box-type coil, is mounted in the coil, as shown in Fig. 4. The condenser is connected or shunted across the timer contact points.

Where a cylindrical type of coil is used, the condenser is mounted on the timer (Fig. 12A), and connects across the timer contact points.

A box-type coil is the type as shown in Fig. 4, page 202.

A cylindrical type coil is the type shown in Fig. 14, this page.

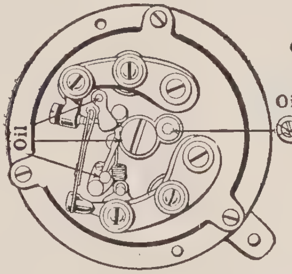

Fig. 12. Atwater Kent open-circuit timer, as shown in Fig. 3. The condenser is in the coil box (Fig. 4).

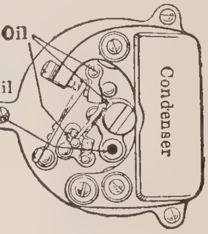

Fig. 12A. "A.K." open-circuit timer with condenser mounted on the timer. In this instance a cylindrical type of coil is used.

THE ATWATER-KENT CLOSED-CIRCUIT IGNITION SYSTEM

The closed-circuit system is similar in many respects to the open-circuit system, except that the timer, or interrupter, is constructed differently. The points are normally closed instead of open. This system is termed the type "CC." When it is equipped with a governor or automatic advance it is termed the type "CA."

When using a closed-circuit timer, it is necessary to use resistance in connection with the primary winding of the coil, else the coil might be damaged if the switch was left on when the engine is not running, as the timer points are normally closed. The resistance unit also protects the coil during variations of speed of the generator, which slightly increases in voltage at high speeds, when the generator supplies current for ignition. At low speeds the battery (6 volts) supplies current for ignition.

At medium and high speeds the generator supplies current for ignition (about 8 or 9 volts).

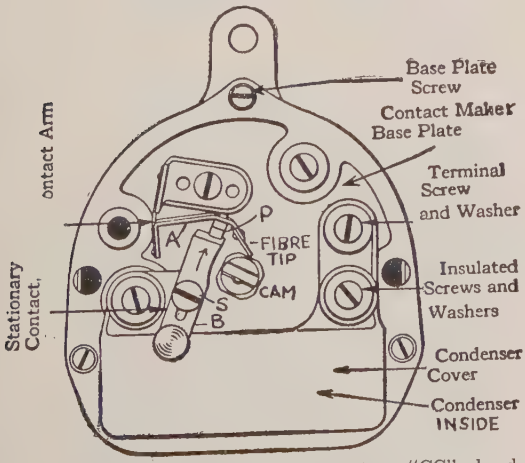

Fig. 13. Top view of Atwater Kent type "CC" closed-circuit timer (also called interrupter and contact-breaker).

The closed-circuit timer (we will term it an "interrupter," because it interrupts the flow of current in the primary winding instead of first closing and then opening) is shown in Fig. 13. Contacts are normally closed by a spring on the contact arm. Rotation of cam brings it in contact with a fibre tip on contact arm (**A**), thus separating contact-points (**P**) and breaking the circuit, at which instant the coil delivers the strongest current).

ROTOR MADE OF NON-CONDUCTING MATERIAL

Fig. 13A. Top and side view of the distributor rotor which is placed on the top of the cam (Fig. 13), and serves to distribute the secondary current to the spark plugs in a manner similar to (**DA**) (Fig. 2).

Adjustment of the interrupter points on a closed-circuit system can be made by loosening screw (**S**) (Fig. 13) and moving arm (**B**).

The gap between contact points should be .006″; the spark-plug gap, .025″.

The wiring of the AK closed-circuit system is shown in illustration below (Fig. 14).

Fig. 14. Wiring of the Atwater Kent closed-circuit ignition system. Note that a cylindrical type of coil is used.

Circuit of the AK closed-circuit interrupter and distributor (Fig. 14): Note one wire from the timer and one wire from the battery is grounded; therefore it is a "single-wire" system. The open or closed-circuit system could also use either a "single" or "two-wire" system.

To trace the primary circuit, start at the switch, follow the black line to the insulated terminal (4), then to the insulated contact point through grounded contact point to grounded terminal, to ground (GT), to ground on battery (GB). (Note that the condenser connects across the contact points.)

To trace the secondary circuit, start at (S1) thence to distributor rotor, through spark plug to ground (SG).

The Atwater Kent Condenser

The condenser on the type "CC" closed-circuit system, instead of being in the coil, is located on the interrupter (Figs. 13 and 14). Note the circuit in Fig. 14. The condenser short-circuits across the timer contact-points for reasons stated on page 190.

To understand how the condenser is connected, see Figs. 14, 15, and 16. A metal cover (Fig. 15) is placed over the condenser to protect it, and to this is attached the insulated contact-point of the interrupter.

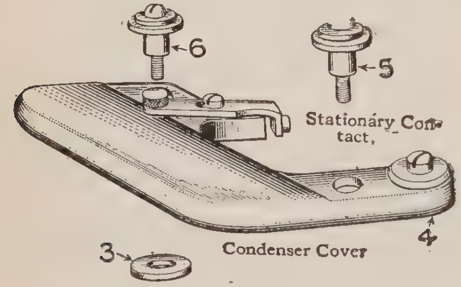

Fig. 15

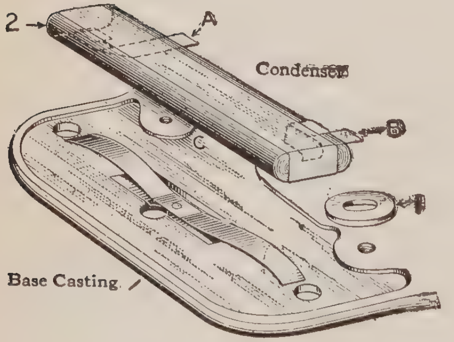

Fig. 16

Figs. 15, 16. Sequence of operations in installing condenser: (1) insulated washer placed in position; (2) condenser placed in pocket; (3) insulated washer laid on top of condenser terminal; (4) condenser cover placed in position; (5 and 6) insulated screws put in; (7) Note that contact adjustment is O.K.

This condenser cover is insulated from the base of the interrupter by screws 5 and 6 which have insulated washers on them.

Note the terminals (A) and (B) of the condenser (Fig. 16). Terminal (A) is grounded to base (C) of the timer below it, then an insulated washer (3) is placed over (A). The other terminal (B) has an insulated washer (1) under it to insulate terminal (B) from the base. Cover (4) is then placed over the condenser and terminal (B) makes contact with the cover. We then have one terminal (A) of the condenser grounded to base (C) and the other terminal (B) connected with cover (4) which is insulated from the base. The circuit would then be as shown in Fig. 14.

It is seldom necessary to remove the condenser, but if ignition fails in case the timer should become water-soaked, feel the coil, with switch on. It should show some heat from current passing through resistance unit in the coil. You will then know that current is passing through the coil all right; therefore open the switch. Then remove the distributor cover and condenser cover and clean all contacts and screws and replace the condenser cover; also wipe water from the other parts and wires. The ignition may also fail by these screws coming loose; however, this seldom happens, but if ignition fails, and you know that current is passing through the coil, and if no spark can be obtained, then this might be investigated.

Oil: Use light machine oil at points shown by the lines on the open-circuit timer (Figs. 12 and 12A). Oil lightly about every 1,000 miles. See that the contact-breaker points are free from oil.

Testing

If the engine misses without regard to speed, test each cylinder separately by short-circuiting the plug with a screw driver, allowing a spark to jump. If all cylinders produce a good, regular spark, the trouble is not with the ignition.

If any one cylinder sparks regularly, this will indicate that the system is in working order, so far as the Unisparker and coil are concerned, and the trouble is probably in the high-tension wiring between the distributor and plugs, or in the plugs themselves. Examine carefully the plugs and wiring. Leaky secondary wiring is frequently the cause of missing and back-firing.

Frequently, when high-tension wires are run from the distributor to the spark plugs through metal or fiber tubing, trouble is experienced with missing and back-firing, which is due to **induction between the various wires in the tube.** This trouble is especially likely to happen if the main secondary wire from the coil to the center of the distributor runs through this tube with the spark-plug wires.

Wherever possible, the **distributor wires should be separated by at least half an inch of space,** and should be supported by brackets or insulators rather than run through a tube. In no case should the main distributor wire be run through a conduit with the other wires.

If irregular sparking is noted at all plugs, examine first the battery and connections therefrom. If the trouble commences suddenly, it is probably due to a loose connection in the wiring. If gradually, the batteries may be weakening or the contact points may require attention. See that contacts are clean and bright, and also that the moving parts are not gummed with oil or rusted.

Timing Atwater Kent Ignition System—Open and Closed-Circuit Type

Open-circuit type when hand-spark control is not used (automatic advance): First, place the piston of No. 1 cylinder on top of the compression stroke. Second, slowly turn the Unisparker backwards until a click is heard, which is the exact instant of the spark. Third, tighten the set screw on the timer shaft which was loosened when starting to time. Be careful not to change position. Fourth, remove the distributor cover and note the position of the distributor block or rotor. It should be on the terminal for No. 1 cylinder. Then see if the wires from the distributor are connected properly, in accordance with the firing order of the cylinders, keeping in mind the direction in which the rotor turns.

The spark set thus, is on top-dead-center retarded, and the governor action will take care of the advance as the speed increases.

The closed-circuit type when the hand-spark control is not used (automatic advance): The timing is the same as above, except that the timer should be turned backwards until the contact-points commence to open. As they open the spark occurs. A good way to test is to have spark plugs on top of the cylinders and current on, so that the spark can be seen at points of plugs. If the timer with automatic advance is used in connection with the regular spark lever on the steering wheel, then do not give over five-eighths or three-quarters of an inch movement of the timer from full retard to full advance.

Open-circuit type with hand-spark control: The setting is the same, except that the position of the spark-advance lever on the steering wheel should be within half an inch of full retard and the lug on the timer should have three-eighths to one-half an inch movement from full retard to full advance. After retarding the spark lever to within one-half an inch full retard, then with the driving member loose, and piston on top of the compression stroke, turn backwards until a click is heard, at which point set the timer. Then see "Fourth" procedure above.

Closed-circuit type with hand-spark control: Same as above, except that the timer is turned backwards until contact points commence to open, at which point set the timer by set screw or clamp, or if driven by a shaft on which the timer cannot be loosened, then the setting can be made with the advance lever shaft or drive gears loosened. The lug on the timer should have seven-eighths to one inch movement from full retard to full advance. (The address of the Atwater-Kent Mfg. Co. is Philadelphia, Pa.)

THE WESTINGHOUSE VERTICAL IGNITION SYSTEM

The Westinghouse battery and coil vertical type ignition system (Fig. 17) is of the closed-circuit type.

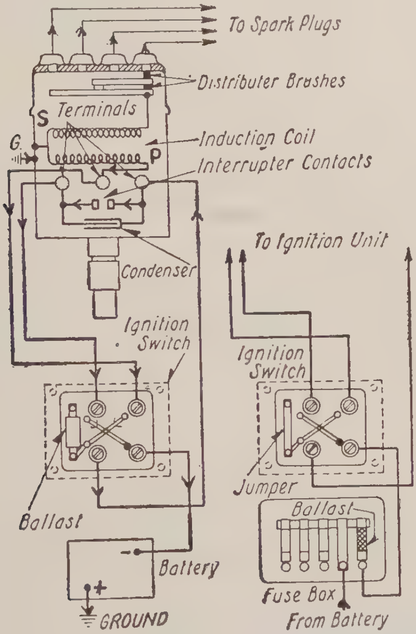

Fig. 17. Westinghouse high-tension non-vibrating coil, closed-circuit ignition system.

The timer-distributor unit is vertically mounted and is operated from the cam shaft or can be attached to the generator, as all other systems of this type can be. Only hand-operated advance is provided.

The condenser is mounted close to the breaker mechanism, being below the coil and distributor. Note the condenser, coil, and contact-breaker are all in one unit.

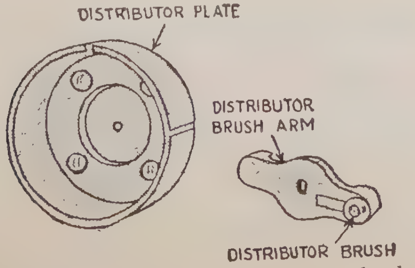

Fig. 17A. Distributor plate and distributor brush.

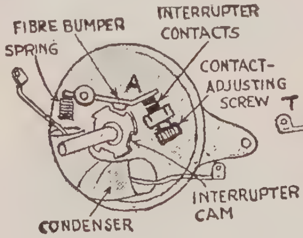
A metal ring can be slipped upward so as to permit of inspection or adjustment of the several contacts.

The distributor (Fig. 17A) is the same as that used in the regular Westinghouse systems in which a circular carbon brush on the distributor brush arm makes contact with terminals embedded in the cover of the distributor plate.

The standard ignition switch is of the snap type and combines the lighting switches in one plate which is mounted flush on the dash. Each time the ignition switch is turned, the polarity of the current is reversed. On this account, it would be termed a polarity or "pole-changing" switch.

In the back of the switch plate there is what is termed a **"ballast coil."** This is a small resistance in series with the final winding, and is intended to protect the winding and prevent excessive drain on the battery, in case the engine should at any time remain idle with the switch in the "on" position. If this "ballast coil" should at any time be accidentally broken the ballast terminals may be temporarily short-circuited with a piece of wire or with a standard 5-amp. fuse, as will be understood by an examination of Fig. 17.

Westinghouse adjustment: In adjusting the breaker the contacts should be dressed with a fine file and should be so adjusted that the maximum opening of the interrupter contact points is .012″, as shown in Fig. 18. The **spark-plug gaps** should be .025″.



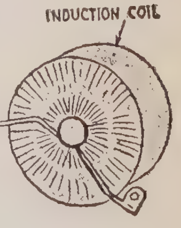


Fig. 18. Contact-breaker or interrupter with condenser.

Fig. 18A (right). The double-wound, high-tension ignition coil winding shown as (S) in Fig. 17.

This **cam** (Fig. 18) has four high points; therefore it is intended for a four-cylinder engine. These high points will raise the contact-breaker arm, or interrupter arm, four times during one revolution of the cam.

We can thus tell that this is a **closed-circuit ignition system** by observing the interrupter points or contacts and the cam—because, normally, the contact points are closed and are opened by the cam, whereas with an open-circuit ignition system, as explained on page 204, the contact points are first closed, then opened.

The Westinghouse Co. makes several different constructions of ignition systems. This is only one example. Manufacturers are Westinghouse Electric Co., Pittsburgh, Pa.

THE BOSCH IGNITION SYSTEM

One type of the Bosch battery and coil ignition system is shown in the illustrations below. The **distributor** and **contact-breaker** are shown in Figs. 19 and 20.

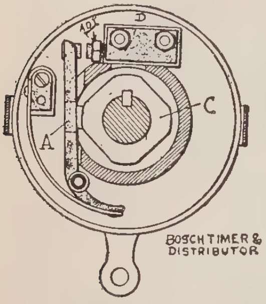

Fig. 19

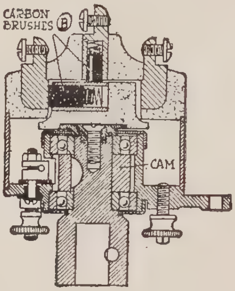

Fig. 20

The contact-breaker (also called "timer" and "interrupter"), is shown in a cross-sectional view in Fig. 20. The distributor is mounted above the interrupter mechanism. In Fig. 19, a top view of the interrupter is shown.

The contact-breaker arm (**A**) (Fig. 19), is actuated by the high points on cam (**C**) pressing against a fiber block on arm (**A**), thus separating the contact points which are normally closed by the tension of the spring. It is thus a closed-circuit type of interrupter.

The distributor is fully as simple and is mounted directly over the breaker, as shown in Fig. 20. Only hand-operated advance of spark is provided.

The switch (Fig. 21), incorporates a vibrator attachment to facilitate starting when the engine is cold or the carburetor is out of adjustment. This mechanism is controlled by the pointed button in the center of the switch plug. Under normal starting conditions, momentary pressure on the button will produce a single spark at the plug. Turning the plug to the right and depressing it makes the necessary connection to provide a continuous stream of sparks at the plug. If desired the button can be locked in this position until the engine has started.

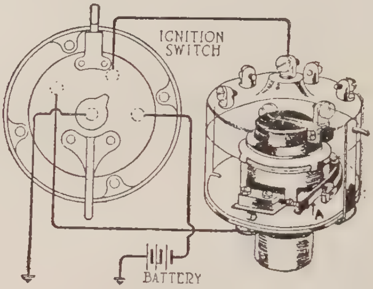

Fig. 21

The switch provides for the use of a magneto, the engine running on the magneto with the switch in one position and on the battery with the switch in the other position.

Adjustment for the gap at the contacts: With the fiber block (Fig. 19) resting on top of the cam, the contacts should be separated about .016″. To alter the adjustment the lock nut must be released first, and carefully secured after the adjustment is made. Occasionally expansion of the fiber bushing prevents the free movement of the lever, and in this case the bore of the bushing can be slightly enlarged with a reamer.

The spark-plug gap should be .020″ to .025″.

The manufacturers are: American Bosch Magneto Corpn., Springfield, Mass.

REMY DISTRIBUTOR, INTERRUPTER, AND IGNITION COILS

The waterproof type of Remy distributor and interrupter, as used on many different cars is shown in Fig. 22. The Remy automatic advance distributor is shown on pages 211 and 212. The systems are of the closed-circuit type.

Parts are as follows: (**A**) Distributor for the center terminal connecting with the secondary terminal of coil; (**B**) one of the spark-plug terminals of the distributor; note that the lower part (**Z**) is not in contact with (**Y**), but 1/64″ from it; (**C**) rotor or segment insulated; (**D**) lock nuts holding interrupter cam in place; (**E**) reference pin; (**F**) interrupter on the contact-breaker cam; (**G**) fiber block on the breaker lever arm; (**H**) spring with a carbon button on the rotor which connects the secondary circuit coming in at (**A**) with the rotor metal plate (**Y**); thus as the rotor (**C**) revolves, the secondary current jumps an air-gap clearance of 1/64″ to the spark-plug terminal (**Z**) and other spark-plug terminals as it revolves; (**K**) end of the shaft above the cam which the distributor rotor fits over; (**L**) pin in cam (**F**) which fits into the under part of the rotor to drive it; (**S**) shaft driven from the engine which drives the interrupter cam (**F**) and rotor (**C**). Note that cam (**F**) is fitted on top of this shaft (**S**) which is tapered; thus lock nuts (**D**) force it down; (**Y**) adjustable metal plate on rotor or segment (**C**).

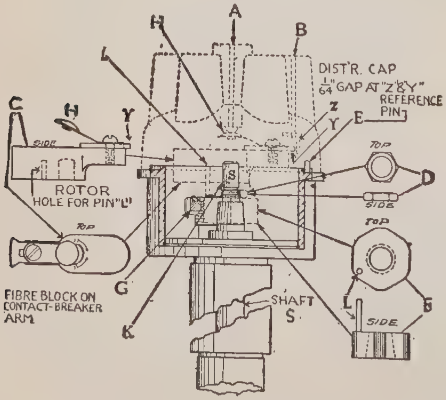

Fig. 22. Remy distributor and interrupter (contact-breaker).

To Check Distributor Settings and How to Time When Putting in New Parts

For distributors with counter-clockwise rotation: In observing Fig. 22A, from the top, the cam appears to be revolving in a clockwise rotation; however, by referring to the standard practice of determining rotation (looking from the drive end), it is seen really to be rotating counter-clockwise.

The spark-control lever (**I**) (Fig. 22A) connects with the lever on the steering wheel and should be in a fully retarded position after having located the

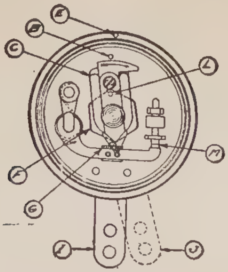

Fig. 22A

Note. "Clockwise rotation" is from right to left, in the same direction as the clock hands rotate. "Counter-clockwise" (or "anti-clockwise") is in an opposite direction to clockwise. When considering the rotation of ignition devices or generators the drive end is the point from which to consider rotation.

cylinder attached to the terminal (B) (Fig. 22) on top of the dead-center compression stroke with the distributor coupling connected up.

(E) is the reference pin (Figs. 22 and 22A) over which the reference slot of the distributor cap is set; (B) is the exact location of the pin in the distributor cap when the distributor cap is installed; therefore, always time by bringing the piston in the cylinder on top of dead-center of the compression stroke, which is attached by high-tension lead to the terminal (B), or to the terminal opposite reference pin (E).

Remove the segment or rotor and cam lock nut (D) (Fig. 22), and lift the cam. Replace the distributor segment (C) in its original position over shaft (K) and cam pin (L) with the cam loose. Then turn cam (F) around (with distributor shaft stationary) in the direction of rotation until the distributor segment (C) is opposite the reference pin (E) with one point of the cam (F) against the fiber block (G), and the breaker points are just ready to separate.

Again remove the segment (C) without disturbing the setting of the cam, install the cam lock-nut (D), tightening it up securely, then install the rotor or segment (C) and the distributor cap, being sure that all high-tension leads are connected to it, in accordance with the direction of rotation and of firing-order.

For counter-clockwise distributors use the instructions just given, transposing the control position so that the segment and cam rotate in the opposite direction.

When installing new high-tension wiring always connect cylinder No. 1 to high-tension terminal (B), connecting the rest of the cylinders in accordance with the direction of rotation, and as per the segments and firing order (unless the distributor cap is marked otherwise).

Spark-plug gaps should be .025″ to .030″.

If the engine misses when idling or at light loads, the gaps at the plugs should be wider. If the engine misses at high speed or when pulling hard, the gaps should be narrower.

The oiler on the shaft should be kept filled with medium cup grease and screwed down two or three turns occasionally. On some instruments a wick oiler is used. In this case use pure vaseline instead of grease.

For adjusting Remy interrupter, see page 211.

Manufacturers are Remy Electric Co., Anderson, Ind.

Remy Ignition Coils

Coils are usually classified as **"two-terminal"** and **"three-terminal"** coils. The designation "two-terminal" or "three-terminal" applies to the top of a cylindrical coil, and not to all of the terminals on a coil.

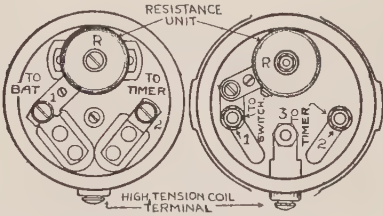

Fig. 23 Fig. 24

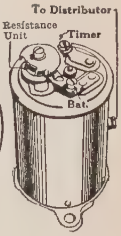

Fig. 25

Fig. 23. Remy two-terminal coil.

Fig. 24. Remy three-terminal coil.

Fig. 25. Side view of Remy ignition coil (cylindrical type).

A two-terminal ignition coil, top view, is shown in Fig. 23, a wiring diagram in Fig. 26, and a top and side view in Fig. 25. This coil is known as model 284B, F, G, and A, and has a condenser in the coil.

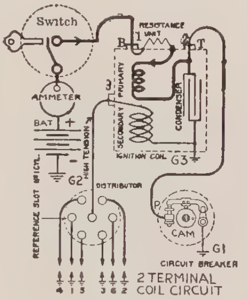

Fig. 26

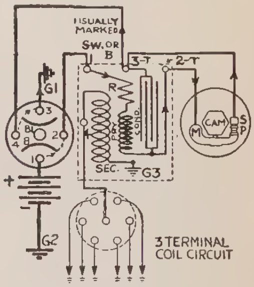

Fig. 27

Fig. 26. Circuit of Remy two-terminal coil (grounded contact-breaker).

Fig. 27. Circuit of Remy three-terminal coil (insulated contact-breaker).

The primary circuit (Fig. 26) would be from (+) of battery, through the ammeter, through the ignition switch, to terminal 1, through the resistance unit, through the primary winding, out terminal 2, to the stationary insulated contact point on the interrupter, through the points, through the movable arm, to ground (G1), to ground of battery (G2), thus completing the primary circuit. (This is termed a "grounded" system.)

The condenser is connected across the contact points, one end being grounded at (G3).

The secondary circuit is from the secondary winding which is wrapped around the same core as the primary, to the center terminal of distributor, to the rotor arm of the distributor, to the spark plugs, through the frame of the engine to ground (G3) of the coil.

Marks on coils vary. Note that terminal 1 is marked "B," meaning to battery, or sometimes "SW," meaning to switch. Terminal 2 is marked "T" or "INT," meaning to timer or interrupter. Where a coil has a mark on the terminal as "MAG," it usually means that it is intended to be used in connection with a magneto.

When testing a coil, by connecting with (B) and (T), the primary circuit can be tested, including the resistance unit.

The resistance unit can be cut out of the test by placing the test point on the screw or terminal (**R**) (Fig. 23).

When testing the condenser, terminal (**T**) and ground (**G3**) would be the circuit across the condenser.

A three-terminal ignition coil is shown in Figs. 24, 27. Many of the three-terminal coils were used with "pole-changing" switches, and "insulated" ignition systems (meaning that the primary circuit is fully insulated, or with two wires to the contact breaker).

The primary circuit (Fig. 27) would be from (+) of battery to 1 on switch, through "pole-changing switch" blade (**B**) which, if turned in one direction, would connect with 1 and 2 of the switch, thence to terminal 1 of the coil, through resistance unit (**R**), through the primary winding, to terminal 2, to movable interrupter-contact arm (**M**), through points (**PS**), back to terminal 3 on coil, thence to 4 on the pole-changing switch, through blade (**B1**) (now disconnected), connecting 4 and 3 together, out 3 to ground (**G1**), to ground terminal (**G2**) of battery (−), thus completing the primary circuit. This is termed an "insulated" system.

If the pole-changing switch was turned in the opposite direction, so that blade (**B**) would connect with 1 and 4, and blade (**B1**) with 3 and 2, the primary circuit would then first go to the stationary contact point (**S**) on the interrupter instead of to the movable arm (**M**). For instance, the primary circuit would then be from (+) of battery to 1 on the switch, through blade (**B**) to 4, to terminal 3 of the coil, to the stationary contact point (**S**), through the points, out movable arm (**M**), to 2 on the coil, through the primary winding, through resistance (**R**), to coil terminal 1, to switch terminal 2, through blade (**B1**) to 3, to ground (**G1**), to ground (**G2**) of battery.

Thus the flow of the primary direct current through contact points could be reversed so that it would flow first in one direction and then in another by moving the switch first one way and then the other. This is termed a "pole-changing switch" or "depolarizing switch," and a three-terminal coil is often used with it. See also Index under "Wiring diagram, Oakland 32," which clearly shows a pole-changing switch.

The purpose of a pole-changing or depolarizing switch is explained on page 203.

The pole-changing switch is not used very much at the present time, because tungsten metal is now used for points. It is very hard and does not have the electrolytic[1] effect to such an extent as the silver points which were formerly used. Note that the condenser is connected across the points with either direction of the flow of the current.

DRIVING THE INTERRUPTER AND DISTRIBUTOR

One modern method of driving the timer (interrupter, also called "contact breaker") and distributor, is from the generator shaft, as shown in Fig. 8.

The generator shaft is driven by gears or by a silent chain, encased. The timer shaft is driven from the generator shaft by a spiral gear, and is geared so that it will run the distributor and timer usually at one-half the speed of the crank shaft.

Quite often the timer and distributor shaft are operated from the cam shaft. In fact, there are various methods employed, but in most every instance it runs at cam-shaft speed (one-half the speed of the crank shaft).

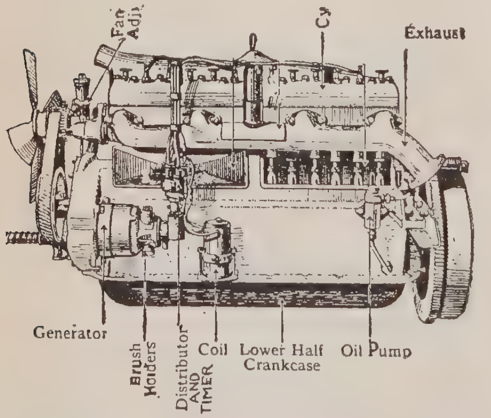

Fig. 8. Modern method of driving the timer and distributor through the generator shaft.

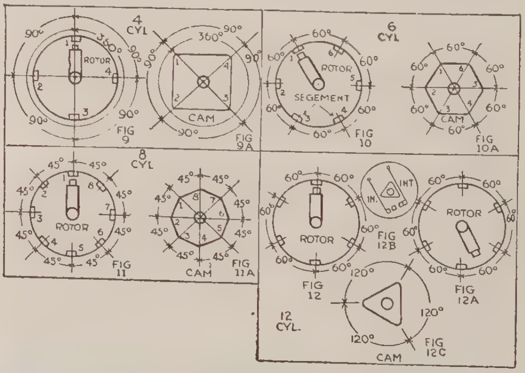
On the Packard double distributor, explained farther on, the cam operating the double set of interrupter contact breakers is driven at crank-shaft speed, but a three-lobe cam is used.

Relation of Speed of Distributor-Rotor, and Interrupter Cam to Crank Shaft of Engine

The crank shaft of the engine must make two revolutions (720°), to complete its four-cycle revolution.

The distributor rotor always revolves at cam-shaft speed, or half the crank-shaft speed.

The interrupter cam in all instances except one, as on the Packard twelve, revolves at cam-shaft speed, or half crank-shaft speed.



Four cylinder engine: When the engine crank shaft makes 2 revolutions—

The interrupter cam (4-lobe) makes 1 revolution and makes 4 interruptions of the primary low-tension current, 90° apart, or 180° of fly-wheel movement. (See Fig. 9.)

The distributor rotor makes 1 revolution and makes 4 high-tension contacts, 90° apart, or 4 sparks.

---

[1] Electrolytic (electrolysis) refers to the depositing of metal from one point to another, as in electro-plating.

Six-cylinder engine: When the engine crank shaft makes 2 revolutions—

The interrupter cam (6-lobe) makes 1 revolution and makes 6 low-tension interruptions, 60° apart, or 120° of fly-wheel movement. (See Fig. 10.)

The distributor rotor makes 1 revolution and makes 6 high-tension contacts, 60° apart, or 6 sparks.

Eight-cylinder engine of the "V" type: When the engine crank shaft makes 2 revolutions—

The interrupter cam (8-lobe) makes 1 revolution and makes 8 low-tension interruptions, 45° apart, or 90° of fly-wheel movement. (See Fig. 11.)

The distributor rotor makes 1 revolution and makes 8 high-tension contacts, 45° apart, or 6 sparks.

Twelve-cylinder engine of "V" type: When the engine crank shaft makes 2 revolutions, or 720°—

The interrupter cam (3-lobe) makes 2 revolutions (720°), or revolves at crank-shaft speed instead of cam-shaft speed; therefore it makes 6 interruptions of the low-tension primary circuit 60° apart. There being two contact-breaker arms instead of one, connected with two separate primary coils, then each breaker arm would make 6 interruptions, or 12 interruptions 30° apart, or 60° of fly-wheel rotation, during 2 revolutions of the 3-lobe cam. (See Fig. 12.)

Distributor rotor: Note that there are two distributors driven at half the speed of the crank shaft; therefore each rotor would make one revolution, or 360°, while the crank shaft made two revolutions. Distributor segments are 60° apart, therefore each distributor rotor would make six high-tension contacts during one revolution, or twelve sparks during one revolution with both distributors, during which time the crank shaft makes two revolutions.

With these explanations we have dealt with single distributors and single contact breakers, with the exception of the twelve-cylinder engine, as explained above.

Attention is called to the Delco double distributors and double interrupters, as explained under "Delco ignition coils, distributors and interrupters."

REMY IGNITION ON STUDEBAKER "LIGHT SIX"

As an example of a modern method of driving the generator and ignition system, the Studebaker "Light Six," model "EJ" engine is used.

Fig. 1. Cross-section. Fig. 1A. Right side view.

Figs. 1 and 1A. Studebaker Light-six method of driving ignition system.

The Remy distributor and closed-circuit interrupter are connected with a vertical shaft which is driven from a shaft called the "accessory shaft." The accessory shaft is driven by a silent chain (see page 51), which also drives a water-circulating pump and generator.

The speed of the distributor shaft is 1 revolution to 2 of the crank shaft of the engine, or at cam-shaft speed.

There are six high points or lobes on the interrupter cam, and six terminals on the distributor (Figs. 2 and 3); therefore, there are six sparks, one for each cylinder during two revolutions of the crank shaft.

The distributor and interrupter (Figs. 2 and 3) are advanced by a manual control connecting from the spark-control lever to the spark lever on the steering wheel. An automatic advance is also provided.

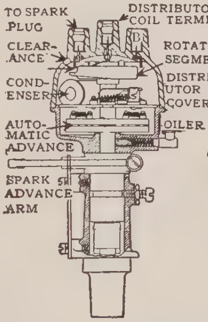

Fig. 2. Section of Remy distributor.

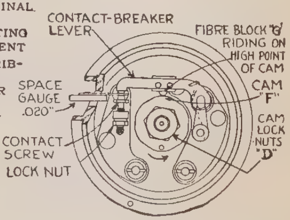

Fig. 3

The interrupter is of the closed-circuit type. See page 208 for construction of the Remy distributor and interrupter.

Adjustment of Remy Interrupter Points

To check the opening of the breaker points on the interrupter, remove the distributor cover, then turn the crank shaft over by hand-crank until the contact-breaker lever (Fig. 3) rides on one of the high points of the cam, then slip a thickness gauge through the space between the points. If the opening is greater than .025″, loosen the cam lock nuts and turn the contact screw until adjustment is not less than .020″ nor more than .025″. Be sure to tighten the lock nut.

Contact points should always be flat, and make good contact with each other. When they have a frosty appearance all over their surface, it indicates good contact. If they are not making good contact, the surfaces can be smoothed up with a fine file or with No. 00 sandpaper and can then be readjusted.

See also pages 221 and 224 under the subject of "contact-point surface and removal" and "dressing and testing platinum points."

By referring to the Index under "Wiring diagrams," the wiring diagram of the Studebaker Light-Six car will be found. This diagram clearly shows the ignition circuit.

REMY SEMI-AUTOMATIC IGNITION SYSTEM

This is a recent development of Remy ignition, and is similar in many respects to the Remy system used on the Studebaker "Light-Six."

In the design of the Remy semi-automatic distributor there is nothing radically different from the manual type that has served so well on the many Remy-equipped cars and trucks.

The condenser mounted on the breaker plate, a slight change in the **breaker lever,** and the addition of an automatic control mechanism as illustrated, are the only distinguishing features.

The type of advance used is known to the trade as semi-automatic, which means that part of the advance is performed automatically and part is taken care of manually. Under all ordinary driving conditions the advance mechanism adjusts the spark position to the engine requirements. The hand advance need be used only when a wide-open throttle at very low speed, or at maximum speed, is desired.

The automatic advance mechanism is simple. Three centrifugal weights advance the cam as the speed increases. The cam shaft carries a star-shaped punching against which rest the tangs on the weights, and as the weights fly outward, due to increase in speed, the cam is advanced.

From normal retard position the weights move easily and the spark starts to advance at very low speeds.

The primary circuit is from the battery (+) grounded battery terminal, to the grounded contact lever or arm, through the points, to the ignition-coil terminal marked "Timer," through the primary winding, through the resistance unit "IGN" on the switch, to the battery (−) terminal. Note that this is a two-terminal ignition coil, and the condenser is mounted on the breaker plate, placed across the points, one end being grounded. The cam which raises the breaker contact lever, or arm, has six high points; therefore the one shown in this illustration would be for a six-cylinder engine.

The secondary circuit is from the ignition coil of the secondary winding, to the distributor rotor, to the spark-plug terminals (note that the gap between rotor and terminals in the distributor cap leading to the spark plugs is 1/64"). Note that there are six terminal leads from the distributor cap to the spark plugs; therefore it would be for a six-cylinder engine.

INSTRUCTION No. 20

DELCO IGNITION: Coils; Distributors and Interrupters

The Delco distributor might be classified in three ways:

1. **Single distributor, with one set of timing contact** points on the interrupter, using one ignition coil.
2. **Single distributor, with two sets of timing contact** points on the interrupter (connected in parallel), using one ignition coil.
3. **Double distributor, with two sets of timing contacts,** using two ignition coils.

The following explanations will serve to make the foregoing classification clear.

Delco Ignition Coils

Four general types of non-vibrating, single-spark ignition coils have been used. They are:

1. **Round type with straw-colored shell.** This type does not incorporate either the resistance unit or the condenser.
2. **Round type with black shell.** This type does not incorporate the condenser, but the resistance unit is mounted on the outside of the coil shell.
3. **D-type with bakelite shell.** Certain of the coils carry the resistance unit mounted upon the end of the shell. This type does not incorporate the condenser.
4. **D-type with black shell.** This type incorporates the condenser within the shell and the resistance unit on the end of the shell.

Figs. 1 and 2 show the internal circuits in typical coils. Note in Fig. 1, that the resistance unit is mounted on the right end of the coil and in Fig. 2, it is on top at the right end.

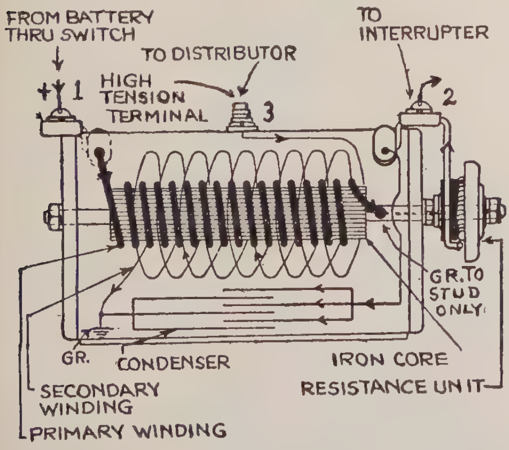

Fig. 1. Delco model "2158," ignition coil with condenser in coil.

In Fig. 1, note the condenser in the coil which is connected across the interrupter points, one end of the condenser being connected to terminal 2, and the other end grounded. The primary-circuit terminals are numbered 1 and 2; the secondary terminal is No. 3.

Fig. 1A illustrates a grounded ignition circuit using a condenser in the coil and a single distributor and interrupter.

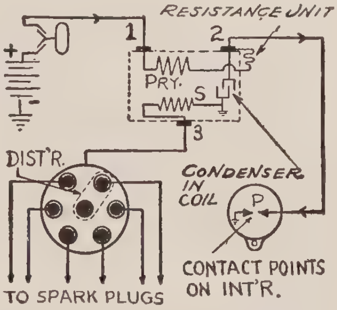

Fig. 1A. Circuit when using coil shown in Fig. 1.

The primary circuit (Fig. 1A) runs from (+) of battery, to ignition switch to terminal (1) of the coil, through primary winding, through "resistance unit," to coil terminal (2), to the insulated interrupter contact point, across contact points (**P**), to grounded interrupter contact, to grounded (−) terminal of the battery, thus completing the primary low-tension circuit.

The secondary circuit runs from the secondary terminal (3) on the coil to the center terminal of the distributor, through the rotor, to the spark-plug terminals of the distributor, to the spark plug, through the spark-plug gap, to the spark-plug shell grounded to the engine, through the ground of the engine and frame, to the grounded terminal of the secondary in-coil, thus completing the secondary high-tension circuit.

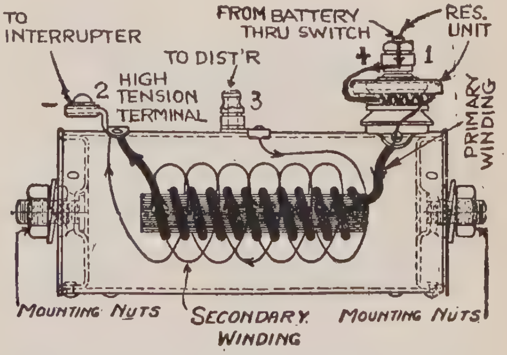

Fig. 2. Delco model "2159," ignition coil. Condenser is not in coil.

In Fig. 2, the condenser is not in this coil. It is located in the interrupter housing, either inside or outside, and is connected across the interrupter points (**P**). (This is the coil used on the Buick.)

The primary circuit (Fig. 2A) runs from (+) of battery, to the ignition switch, to the resistance unit (1), through the primary winding (**P**), to the terminal

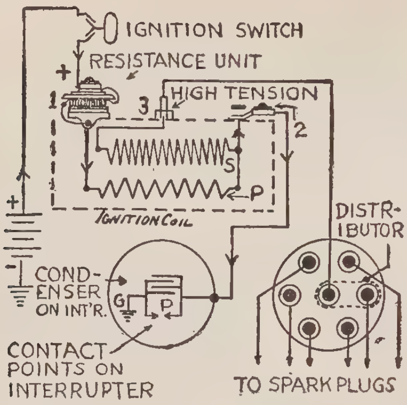

Fig. 2A. Circuit when using coil shown in Fig. 2.

(2), to the interrupter points (P), to ground, to (—) ground of battery, thus completing the primary low-tension circuit.

The secondary circuit: runs from the secondary terminal (3) to the center terminal of the distributor, to the spark plugs, to ground on engine and frame, to the battery ground (—), through battery (or generator, if generator is supplying current instead of battery), to the terminal (1) of the coil (+), through the primary winding (P), to the secondary connection to the primary winding at (S), thus completing the high-tension secondary circuit.

Delco Interrupter with a Single Contact-Breaker Using One Coil

The top view of a Delco closed-circuit interrupter with a single contact breaker is shown in Fig. 3. The cam in this instance, has 8 high points or lobes and revolves at cam-shaft speed; thus 8 interruptions, or 8 sparks occur during two revolutions of the crank shaft of the engine. One spark plug per cylinder is used.

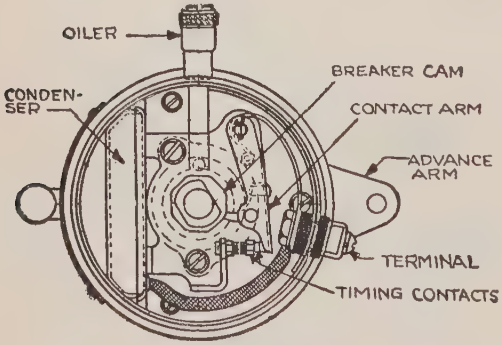

Fig. 3

Delco Interrupter with Two Contact-Breakers Connected in Parallel, Using One Coil

In Figs. 4, 5, 6, and 6A, note that the closed-circuit type interrupters have two interrupters or contact breakers operated by one cam.

One spark plug per cylinder is used and also one coil, but two contact points are connected in parallel, both of which open at one time. The primary ignition current which could otherwise flow through only one set of points is divided between the two sets, and the resultant wear upon the points is less and an additional factor of safety is provided. The Marmon, Cadillac, and Cole use this principle.

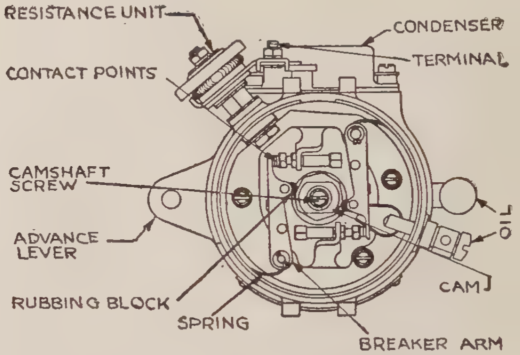

Fig. 4. Delco interrupter with two contact-breakers in parallel (top view).

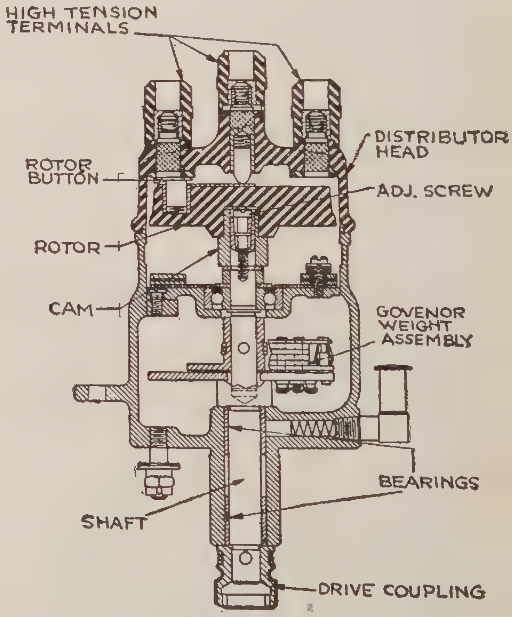

Fig. 5. Sectional side view of Delco ignition unit, a top view of which is shown in Fig. 4.

The distributor, interrupter, automatic spark advance mechanism and the ignition drive shaft are shown in Fig. 5. Manual advance of the spark, as shown in Fig. 5. Manual advance of the spark, controlled by a lever, as well as by an automatic advance, are provided for.

Delco-Cadillac Distributor and Timer

The Cadillac electric system consists of a Delco starting motor and generator in one unit, which is explained in the later discussion of electric systems. **The wiring** is a "single wire" or grounded return system. See Index under "Cadillac wiring diagram."

Ignition: The distributor and timer are carried on the fan-shaft housing, and are driven through a set of spiral gears attached to the fan shaft. The distributor consists of a cap or head of insulating

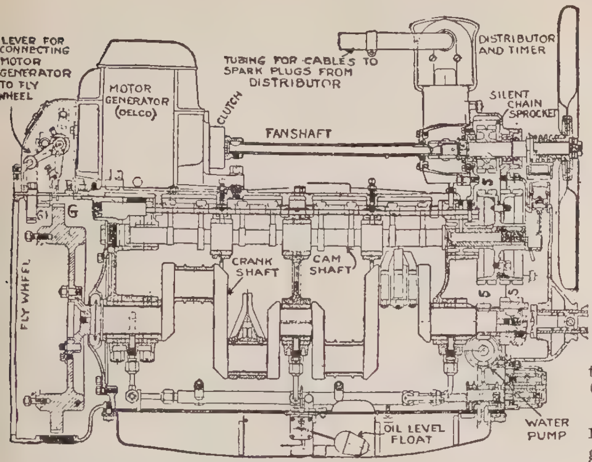

Fig. 5A—Location of the distributor and timer, and of the motor-generator on the Cadillac.

material, carrying one contact in the center with eight additional contacts placed at equal distances about the center and a rotor which maintains constant communication with the center contact.

The rotor carries a contact button which serves to close the secondary circuit to the spark plug in the proper cylinder.

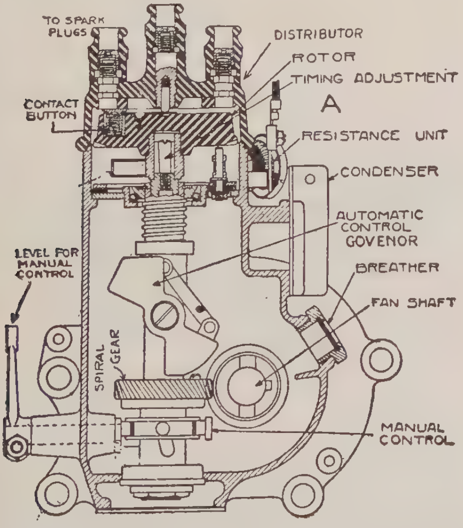

Fig. 6. The Delco distributor and timer. The Delco electric system as used on the Cadillac.

Beneath the distributor head and rotor is the timer. The timer cam is provided with a lock screw in the center of the shaft. (See Figs. 6 and 6A.)

A manual spark control is provided in addition to the automatic spark control. The manual spark control is for the purpose of securing the proper ignition control for variable conditions, such as starting, differences in gasoline, weather conditions, and amount of carbon in the engine. The automatic control is for the purpose of securing the proper ignition control necessary for the variation due to engine speed alone.

The timer, more properly termed an interrupter, is shown in Fig. 6A. It is of the closed-circuit type. Note that there are two contact-breaker, or interrupter points. The object for using two contact-breaker points, is to distribute over two sets of points the current which would otherwise pass through one. This greatly lessens wear and burning of the points.

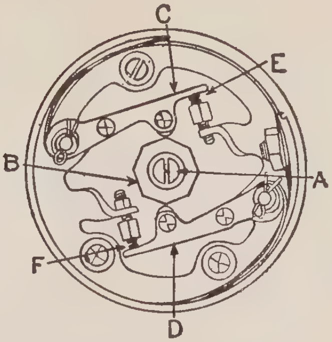

Fig. 6A. Delco-Cadillac timer (interrupter) with two contact-breakers. (A) is the adjusting screw; (B) cam; (C) and (D) contact-breaker arms; (E) and (F) breaker points.

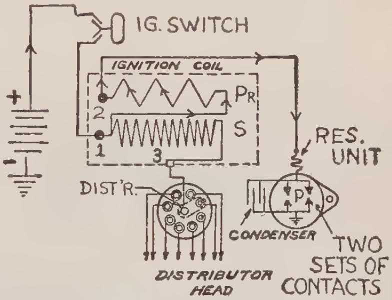

Fig. 6B. Illustration showing circuit where two sets of contact-breakers (connected in parallel) are used.

The primary circuit (Fig. 6B) runs from battery (+), to switch, to (1), through the primary winding (P), to (2), to the ignition resistance unit mounted on the interrupter housing, to the interrupter points (P) connected in parallel, to ground, to (—) ground of battery. Note that the condenser is shunted across the two contact points.

Note. Cadillac and Marmon have the positive (+) of the battery grounded.

The secondary circuit runs from terminal (3), to the distributor, to the spark plugs, to ground of engine, to (—) ground of battery, to (1) on coil.

Delco-Cadillac Distributor Connections

Distributor connections on the Cadillac—Delco ignition system are shown in Fig. 6C. The cables lead from connections on the distributor to the cylinders in the order which they fire.

Note that the brush (**B**) makes contact consecutively, but cables from the distributor are connected to the plugs in their respective firing order.

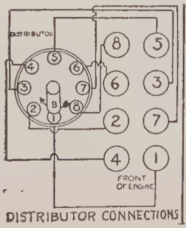

Fig. 6C

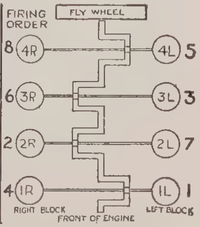

Fig. 6D

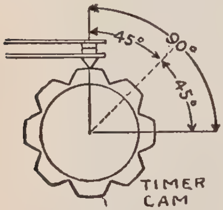
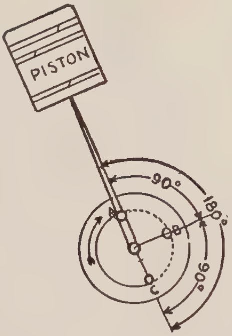
The firing order is shown in Fig. 6**D**. The cylinder marked (1L) fires first, then 2R, 3L, 1R, 4L, 3R, 2L, 4R. Follow the black figures on the side of the cylinders which show consecutively how the cylinders fire.





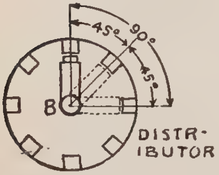


Fig. 7 (upper). Fig. 7B (right).
Fig. 7A (lower).

The relative movement of timer cam, distributor, rotor, and piston is shown in Figs. 7, 7**A**, 7**B**. The movement is shown in degrees. There is an impulse or firing spark at every 90° movement of the crank shaft, which is approximately one-half of a stroke of the piston, or one-quarter of a revolution of the crank.

When the crank shown in Fig. 7**B** travels 90° (**A** to **B**) the timer or distributor brush (**B**, Fig. 7**A**) being run at cam-shaft speed, or one-half crank-shaft speed, it then moves 45°, as does also the timer cam (Fig. 7).

When the crank makes two revolutions, or 720°, the timer cam and distributor brush (**B**) move 360° or one revolution. Therefore there are 8 sparks to two revolutions of the crank.

Delco-Cadillac Ignition Timing

The timer contact points are set as follows: Turn the engine over until the contact arms (**D**) and (**C**), Fig. 6**A** are directly on top of the lobes of the cam (**B**): (Note that there are eight lobes or high points on the cam.) Then adjust the contact points at (**E**) and (**F**) so that they stand .020″ (twenty-one-thousandths of an inch) apart. Both sets of contact points should be adjusted alike.

To time the ignition proceed as follows: Move the spark lever to the extreme left on the sector; open the compression release cocks on the cylinder blocks, and crank the engine by hand until the piston in No. 1 cylinder is on firing center. (No. 1 cylinder is the one nearest the radiator in the left-hand block of cylinders.)

Next remove the distributor cover, also the rotor, and loosen the lock screw (**A**) just enough to allow the cam (**B**) to be turned by hand after the rotor is fitted. (The lock screw should not be loosened enough to allow the cam to turn on the shaft when the engine is cranked by hand.)

Then replace the rotor and turn it by hand until the distributor brush in the rotor is directly under the terminal marked No. 1 on the distributor cover. Replace the distributor cover, and move the spark lever to the extreme right on the sector.

Then switch on the ignition; hold the high-tension wire to the spark plug in No. 1 cylinder about one-eighth of an inch away from the cylinder casting, and turn the engine slowly by hand in the direction in which it runs. Stop turning immediately a spark occurs between the wire and the casting. (It will be necessary to turn the engine nearly two complete revolutions before the spark occurs.)

If the cam (**B**) is properly set, a spark will occur when a point on the fly wheel 1 21/32″ (one and twenty-one thirty-seconds of an inch) in advance of the center line for No. 1 cylinder is directly under the pointer or "trammel" attached to the crank case of the engine. This point for each cylinder is marked on the fly wheel by the letters "IG/A."

If the spark occurs before this, rotate the cam (**B**) slightly in a counter-clockwise direction to correct the adjustment. If a spark occurs later than this, rotate the cam slightly in a clockwise direction.

After the adjustment has been properly made, lock the cam securely to the distributor shaft by the lock screw (**A**).

After locking the adjustment, it is a good plan to check the timing by fully retarding the spark lever; in other words, by moving it to the extreme left on the sector, holding the high tension wire to the spark plug, in No. 1 cylinder about one-eighth of an inch away from the cylinder casting, and again turning the engine slowly by hand in the direction in which it runs, stopping immediately when a spark occurs.

If the ignition is properly set, the spark will occur under these conditions when the center line on the fly wheel for No. 1 cylinder is directly under the pointer attached to the crank case, or has passed the pointer.

Caution: Do not set the ignition so that the spark occurs before center with the spark lever at the extreme left on the sector.

Resistance unit and ignition coil are explained in the discussion of the subject "Ignition."

Note. See Index under "Synchronizing two sets of interrupter points." Type 1 connection under this heading applies to the Cadillac.

Delco Double Distributors Using Two Distributors, Two Contact-Breakers, and Two Ignition Coils and Two Sets of Spark Plugs

Figs. 8 and 9 illustrate the Delco distributor used on the six-cylinder Pierce-Arrow "38–48" models. It is termed a "double ignition system" and consists of double distributors, double contact breakers (closed-circuit type) and a double set of spark plugs. Two coils are used. Automatic and hand (manual) advance of spark is provided. There are two distributor heads: one contains the two contact breakers and the other the condensers. There is a distributor head for each set of spark plugs. One single six-lobe cam, driven at cam-shaft speed, is used. Either the "single" or "double" ignition system may be used.

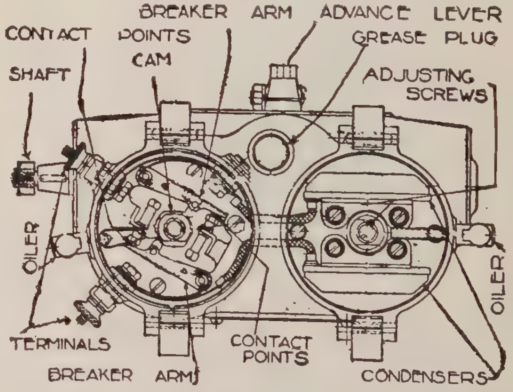

Fig. 8. Top view of Delco-Pierce-Arrow double distributors.

Two sparks occur at slightly different times in each cylinder; one coil furnishes high-voltage current to the plugs over the intake valves, while the other coil supplies the plugs over the exhaust valves. The Stutz uses a Delco distributor which is similar, except that interrupter points open simultaneously.

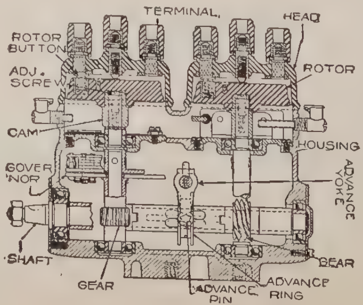

Fig. 9. Side view of Fig. 8.

Attention is called to the method of adjusting the relative time of separation of the timing contacts in the No. 5216 Pierce-Arrow double distributor. The left-hand set of contacts, viewed from the driving end of the distributor, and operating with the ignition of the plugs on the exhaust side of the engine, must be adjusted to separate 3° (flywheel) or 1½° (distributor) ahead of the other set of contacts. To make the adjustment accurately and easily, a method must be used very similar to that described on page 221 for the use of testing lamps. The firing order is 1, 5, 3, 6, 2, 4.

See Index for "Pierce-Arrow wiring diagram."

Delco-Packard (Twin-Six) Ignition

Figs. 10 and 11 are top and vertical sections of the Delco-Packard ignition distributors and interrupters of the closed-circuit type (Twin-six models "3-25" and "3-35").

The interrupter contact-breaker mechanism consists of a separate set of timing contacts for each low-tension circuit. These are operated by a single three-lobed cam mounted on the top of a vertical shaft which is driven at crank-shaft speed. Thus each low-tension circuit is broken three times during each revolution of the crank shaft.

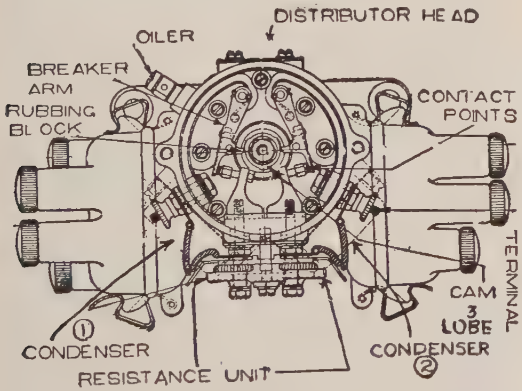

Fig. 10. Top view of Delco-Packard ("Twin-Six") distributor.

The distributor is equipped with the automatic spark advance. There are two coils used for engine ignition and one coil for fuelizer ignition.

A feature on the ignition unit used on the twelve-cylinder Packard models is the **auxiliary breaker mechanism** mounted on the top of the distributor and used in connection with a separate ignition coil to operate the spark plug in the "fuelizer." See Index for Packard "Fuelizer" and Packard "Wiring diagram." The wiring diagram will more clearly explain the principle.

It should be observed that the 5220 and 5238 distributors use a 15249 auxiliary breaker, while 5161 and 5220 distributors use a 14805 auxiliary breaker.

Note that in the system described above a three-lobe cam is used which revolves at crank-shaft speed, whereas with most all other systems it revolves at cam-shaft speed.

The fact that twelve interruptions, or sparks, can take place in the two six-cylinder blocks of cylinders during two revolutions of the single three-lobe cam is explained by the fact that there are two interrupter arms with separate contact points operating against opposite sides of a three-lobe cam. Note that the **cam is triangular** in form, with the sharp corners rounded off; thus the lobes are 120° apart. Therefore when one contact arm is raised at the highest point on one of the lobes of the cam (which is the wide-open position of the contact points), the interrupter arm on the opposite side of the cam will be exactly between the two lobes (which is the closed position of the contact points).

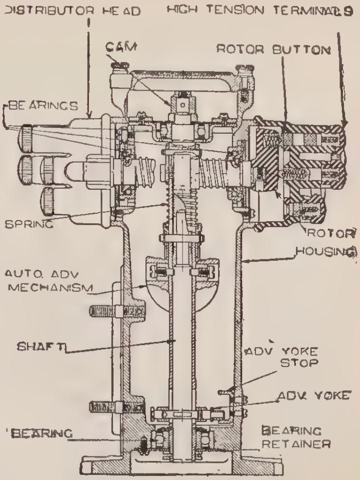

Fig. 11. Side sectional view of Delco-Packard ("Twin-Six") distributor.

Because there are three lobes 120° apart, three sparks would be produced per revolution of 360° for each set of contact points, or six sparks during one revolution for both interrupter contact points. Since the cam travels at the same speed as the crank shaft, then for two revolutions of the cam, there would be twelve sparks.

The high-tension distributor, like all distributors, revolves at cam-shaft speed, or one revolution to two revolutions of the crank shaft, and distributor terminals on the two distributor heads, each with six segments, leading to the twelve spark plugs, have the segments 60° apart.

Separate high-tension distributor heads are provided for each cylinder block. These are mounted on either side of the ignition apparatus housing and are operated by rotors on a cross-shaft driven from the vertical timer shaft.

The firing order in each block is: 1, 4, 2, 6, 3, 5. The impulses alternate between the two blocks. If we number the cylinders in succession, beginning with number one at the front of the right block, the firing order would be: 1R, 6L, 4R, 3L, 2R, 5L, 6R, 1L, 3R, 4L, 5R, 2L, the R and L designating the right and left cylinder blocks.

Arcing across the contact points when they are separating is minimized by the use of **separate condensers** for each set of breaker points, located in the rear side of the ignition timer and distributor housing. Indirectly these condensers also serve to intensify the high-tension current wave.

Resistance units in both low-tension circuits, and located on either side of the common ground return terminal on the timer housing, serve to keep the low-tension current down to the proper rate of flow at various car speeds. These also prevent excessive discharge from the battery when the ignition switch is left on and the engine is not running.

See Index for "Packard wiring diagram."

The Delco-Lincoln Ignition System

Figs. 12, 13, 14 show the **interrupter and distributor** used on the Lincoln. The vertical shaft viewed from the top turns counter-clockwise at one-half engine speed, and carries the manual spark advance mechanism, governor assembly controlling the automatic spark advance, the four-lobe breaker cam, and the rotor. The four-lobe cam produces eight sparks during one revolution of the cam, due to the two interrupters.

Each of the two sets of contacts are connected with the primary circuit of a separate ignition coil. In this manner the right-hand set of contacts (when viewed from the driver's seat) connected with the right-hand ignition coil, controls the ignition in the right bank of four cylinders. Likewise the left-hand set of contacts connected with the left-hand ignition coil controls the ignition in the left-hand bank of cylinders.

A rotor (Fig. 15), carried on upper end of distributor shaft, carries two steel rotor brushes, both electrically connected. One of them connects with the small carbon brush, which makes contact with the slip-ring in the distributor head. The other rotor brush connects with the center plunger contact in the distributor head.

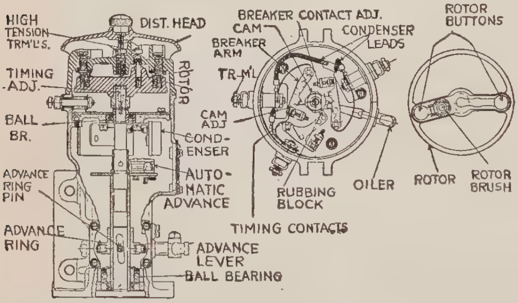

Fig. 12 Fig. 13

Figs. 12 and 13. Side and top view of Delco-Lincoln distributor.

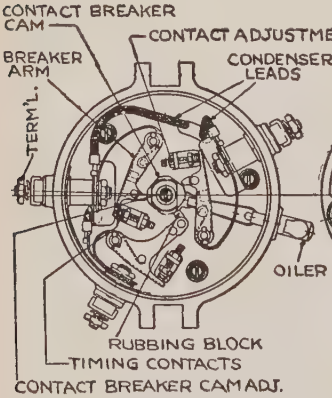

Fig. 14

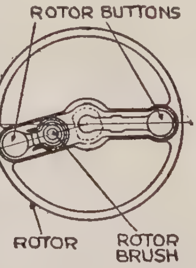

Fig. 15

Fig. 14. Clearer top view of Lincoln. On the interrupter, owing to the fact that the cylinders are 60° apart, they are not placed opposite to each other.

Leads from each of the eight equally spaced terminals around the distributor head should be connected to spark plugs in the cylinders which carry a corresponding number.

The high-tension lead from the right-hand ignition coil is connected to the center terminal (the long screw) of the distributor head. Current from this coil takes care of ignition in the right bank of cylinders Nos. 1, 3, 7, and 5, through the rotor brush connected with the center plunger contact in the head.

The left-hand bank of cylinders Nos. 6, 8, 4, and 2, receive ignition current from the left-hand ignition coil whose high-tension lead is connected to the terminal (the short screw) near the center of the distributor head. This current passes through the rotor brush connected with the carbon brush.

Care must be taken to see that the leads from both primary and secondary terminals of the ignition coils connect to their correct terminals on the distributor.

The distances between the contact points when opened by the cam are adjustable by means of the contact screws which carry the stationary contact points. They should be adjusted so that they are .020″ apart when the fiber rubbing block of the contact arm rests directly on top of the cam lobes. Due to the slight wear of the fiber block during the first 2,000 miles driving, it may be necessary to make one or two adjustments of the points, after which practically no attention is necessary other than to note occasionally that the adjustment conforms to specifications.

The thickness of the gauge on the distributor wrench provided in the tool equipment should be used in adjusting the points.

When a slight readjustment of the contact points will not affect the timing noticeably, it is recommended that the ignition timing be checked, and if necessary corrected after each adjustment of the contact points.

After assembly of the parts of a repaired Lincoln distributor it will be necessary correctly to adjust the two sets of timing contacts, so that they separate at intervals of exactly 30° and 60° of distributor-shaft travel.

These values correspond to 60° and 120° on the flywheel, which are the intervals of crank-shaft travel between cylinder firings.

To obtain the correct setting, first adjust each of the two sets of contacts to the correct maximum dimension of .020″. Then shift slightly the position of the contact-point mounting plate until a setting has been found which will cause the contacts to open exactly at 30° and 60° intervals. This plate may be shifted within small limits after loosening the three screws securing it to the distributor housing, and allowing the plate to pivot on the screw nearest the oiler.

In order to measure accurately the 30° and 60° intervals, the mechanic should connect a small lamp in series with each set of contacts similar to the test set in Fig. 20, page 221, to indicate the instant the points separate. An ordinary protractor, or similar measuring device calibrated in degrees and approximately 4″ in diameter, must be used to measure the number of degrees of interval between the separation of the contacts. Small scratches may then be made on the distributor housing opposite a previously made scratch or mark at any point on the edge of the rotor, indicating the actual intervals between the separation of the two sets of contacts. These angular distances may then be measured with the protractor, and if not correct, the contact mounting plate may again be slightly shifted.

If during the shifting of the plate, the adjustment of the contacts is appreciably changed, their adjustment should be corrected, after which a re-check should be made with the protractor and lamps of the intervals between the separation of the two sets of contacts. It would be advisable to check up the adjustment of the contacts once or twice during the first 2,000 miles driving, so that any necessary correction might be made.

Lubrication of the upper ball bearing is taken care of by placing in the oiler three or four drops of engine oil every 500 miles. The lower ball bearing of the distributor shaft and the advance ring of the manual-spark control mechanism receive their lubrication from the light cup grease carried in the lower part of the distributor housing. This section of the housing should be kept filled with light cup grease to a level just above the advance ring. Lubricant may be placed in the housing by removing the cover plate near the spark-advance lever on the forward side of the housing.

A very small amount of light grease or vaseline should be applied to the surface of the breaker cam each 500 miles. The rubber track containing the eight inserts or contacts should receive a very small amount of vaseline applied occasionally during the first 1,500 miles driving. The track will then become glazed, and no further lubrication will be required. It is then only necessary to wipe out the distributor head occasionally with a clean cloth. No lubricant is required on the slip ring in the distributor head, against which the carbon brush rests. The center plunger contact in the distributor should always make contact with the rotor, and the carbon brush in the rotor should always make contact against the slip ring.

A slight blackening of the surface of the distributor head inserts has no effect whatever upon the perfect performance of the ignition system.

Delco-Lafayette Distributor

Figs. 16 and 16A show the top and side cross-section views of **the interrupter and the distributor** used on the Lafayette model, which is similar to that shown in Fig. 4, page 214. The vertical shaft, turning at one-half engine speed, carries the manual advance mechanism, governor assembly controlling the automatic spark advance, the eight-lobe breaker cam, and the rotor.

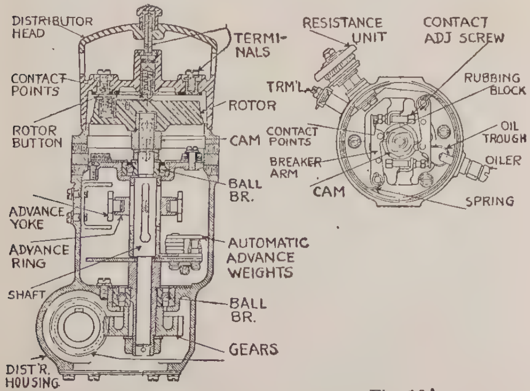

Fig. 16 Fig. 16A

Figs. 16 and 16A. Side and top view of Delco-Lafayette distributor.

Two sets of timing contacts are provided, the object being to distribute over two sets of points the current which would otherwise pass through one set. Both sets of points separate, and therefore are arranged to separate at the same instant.

See Index for "Wiring diagram."

Delco-Packard (Six-Cylinder) Distributor

Fig. 17 shows the general construction of the **interrupter and distributor** used on the six-cylinder **Packard** models.

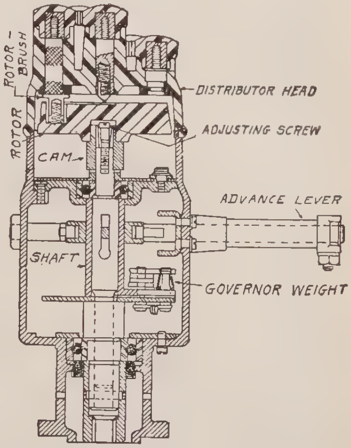

Fig. 17

Two sets of interrupter contacts are provided, each set being connected in series with a separate ignition coil. One of these coils provides ignition for the engine cylinders, while the other coil supplies ignition at the fuelizer spark plug. Electrical connections of this system are shown clearly in the circuit diagram. See Index for "Wiring diagram."

Delco-Buick Distributor

Figs. 18 and 19 show the top and sectional views of the Delco distributor and interrupter used on the 1921 **Buick models.** The design of the present **Buick distributor** is such that advance and retard of the ignition is accomplished through an **advance ring** (see Fig. 18) within the distributor instead of by an oscillating movement of the distributor head changing the angular position of the timing contacts with the distributor cam.

A condenser, mounted in former models inside the ignition coil, is now contained in a moisture-proof metal case within the distributor housing, next to the interrupter. Delco coil (1921) is Delco No. 2159 (Fig. 2, page 213).

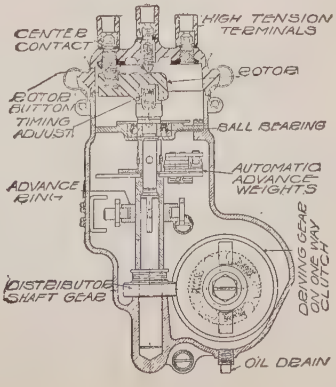

Fig. 18. Side view of Delco-Buick distributor.

The distributor consists of parts as shown in Fig. 18. The rotor revolves at cam-shaft speed, or one-half the speed of the crank shaft. The shaft is driven from the generator shaft which, through a one-way clutch, drives the generator (see Index for "Buick generator" and "Buick wiring diagram").

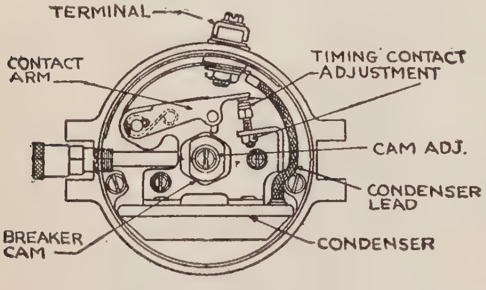

Fig. 19. Top view of Fig. 18.

Timing the Buick-Six Ignition

1. Place the spark lever on the steering wheel in the fully retarded position.
2. Turn the engine to the seven-degree mark (which is approximately one inch after dead center), with the No. 1 cylinder on the firing stroke.
3. Loosen the timing-adjustment screw in the center of the distributor shaft and contact-breaker cam. Turn the cam so that the rotor button will be in position under No. 1 high-tension terminal when the distributor head is properly located. Locate the contact-breaker cam carefully in this position so that when the backlash in the distributor gears is rocked forward the contact points will be opened, and when the backlash in the gears is rocked backward the contacts will just close. The distributor shaft turns clockwise when viewed from the top.
4. Tighten the adjustment screw securely and replace the rotor and distributor head. **The cylinders fire** in the following order: 1, 4, 2, 6, 3, 5.

The proper spark-plug gap should be thirty-thousandths of an inch (.030″). **The contact-breaker points** should separate .020″ when they are separated the maximum distance by the cam.

On account of the wearing to a seat of the fiber rubbing block on the contact arm, one or two adjustments may possibly be necessary during the first 2,000 miles of driving, after which practically no attention is necessary other than to note occasionally that the adjustment of the contacts conforms to specifications.

A **frosted appearance of the contacts** indicates that they are making **good contact** with one another, and should not be disturbed as long as proper operation is maintained. The contact points are made of tungsten. This metal is too hard to file. Should it be necessary to dress them, an oil stone should be used. Care should be taken that they seat properly against each other and are correctly adjusted after being replaced.

It is a good plan after adjusting the timing contacts to check the ignition timing. See instructions under "Timing the Ignition."

DELCO IGNITION TIMING

Adjusting Timing Contacts

See also the instruction on "Ignition Timing," which explains the advance and retard of the spark, etc.

The timing contacts should be adjusted so that when they are separated by the breaker cam they are apart by the following thickness: All Delco distributors for four and six-cylinder engines should have their contacts adjusted to .020″ to .0275″; all distributors used on eight-cylinder cars, except Cadillac, should be adjusted to .015″ to .0225″; Cadillac should be .015″ to .020″; Packard should be .020″ to .025″.

On those distributors, except the Packard and Pierce-Arrow, having two sets of timing contacts, the separation of the contacts, where there are two sets, should be as nearly simultaneous as possible. Both are intended to separate at the same time, and the maximum contact separation of each set of contacts should be held to the specifications. Should difficulty be encountered in obtaining the adjustment to synchronize the operation of the points, the contact-breaker plate on which the contacts are mounted may be shifted within certain limits after loosening the three screws holding it in place. These screws should be carefully tightened after the necessary adjustments have been made.

On account of wearing to a seat of the fiber rubbing block on the breaker arms, the points will require one or two adjustments during the first season's driving, after which practically no attention is required.

Interrupter contact points are made of pure tungsten metal, which is very hard and of long life. Should the contacts require cleaning or redressing, rub the points lightly over an oil stone—the tungsten metal is too hard to file. The contact arms may be removed by lifting them from the posts on which they are pivoted, after taking out the cotter-pins and loosening any clamping nuts holding the ends of the steel springs.

Timing the Delco Ignition

The breaker cam is secured to the distributor shaft with the cam adjustment screw, as in Fig. 4, page 214, in the majority of distributors; in others, by the timing adjustment screws. The adjusting screw permits the cam to be placed in any angular position for timing.

The manufacturer of the car should be consulted for the exact directions for timing the engine. However, the following directions will give an approximate timing which will prove satisfactory under ordinary conditions:

1. Place the spark lever on the steering wheel in a position one-third advanced.
2. Turn the engine by hand until the piston in No. 1 cylinder is just on top dead center on the compression stroke.
3. Loosen the timing adjustment screw in the center of the cam, and locate the proper lobe of the cam by turning the rotor until the rotor button comes under the high tension terminal of the distributor head connected to the No. 1 cylinder.
4. Locate this lobe of the cam so that when the back-lash in the distributor gears is rocked forward the timing contacts will be opened and when the back-lash is rocked backward the timing contacts will just close. The distributor shaft usually rotates in a clockwise direction when viewed from the top. Tighten the adjusting screw and replace the rotor and distributor head.

Note. The Lincoln distributor rotates counter-clockwise.

In the Stutz double distributor (similar to the Pierce-Arrow, Fig. 9, page 216), the distributor cam and collar, which carry the two rotors, are keyed in position, and are not adjustable. Timing is accomplished through an adjustable coupling through which the distributor is driven.

Adjusting Spark Plugs for Delco Ignition

The adjustment should be .030″. On spark plugs having more than one gap, all but one gap should be made wide, and closest gap adjusted to .030″.

An exceptionally wide adjustment may be the cause of missing at the higher speeds. **Too close an adjustment** will cause the ignition to be poor at very low speeds when idling.

Synchronizing Two Sets of Interrupter Contact Points (Delco)

Fig. 20 shows a simple device which is of material assistance in synchronizing the operation of two sets of timing contacts. This handy test set consists of a small block of wood upon which are mounted two small 6-volt lamps provided with the leads (**C**), (**D**), and (**E**). Terminals (**A**) and (**B**) are each made of a thin piece of fiber 1½″ by 1″, one side being covered by a thin piece of brass or copper to serve as a contact.

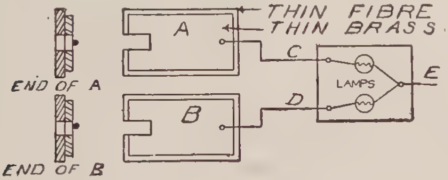

Fig. 20. Device for synchronizing interrupters.

Distributors with which this set is used are divided into two types: type 1 (Fig. 21) has two sets of timing contacts connected in parallel; in type 2 (Fig. 22) the double distributors have two sets of contacts, each of which is connected to a separate primary ignition circuit, as in the Pierce-Arrow and Stutz distributors.

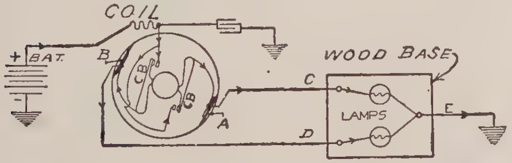

Fig. 21. Type 1 connection for synchronizing two interrupter contact-breakers (CB) connected in parallel.

When used with distributors in type 1 (Fig. 21), each of the terminals (**A**) and (**B**) are slipped between the contact-arm spring, and the distributor housing with the metal side of the terminal in contact with the spring. Connect lead (**E**) to "ground." Current is obtained from the storage battery on the car by placing the ignition switch lever in "on" position.

During this operation it will be well to place a piece of cardboard beneath one of the generator brushes on those generators not equipped with a cut-out relay, in order to prevent a flow of current through the generator windings.

In this type of distributor which is supplied with two sets of contacts the primary ignition current is divided between the two sets, which reduces the amount of burning and offers an additional factor of safety to the system.

The separation of each set of timing contacts will be indicated by the lamp in the circuit, and when both lamps go out at practically the same instant the contacts are properly synchronized.

When used with type 2 distributor (Fig. 22), the notches in the ends of the terminals (**A**) and (**B**) permit them to be readily connected to the two terminals on the distributor as shown.

In the Pierce-Arrow (page 216) and Stutz double distributors there are two sets of timing contacts. In these cases each set of contacts interrupt a separate primary ignition circuit, giving double ignition. One circuit supplies high-tension current to the plugs over the intake valves, while the other circuit takes care of plugs over exhaust valves.

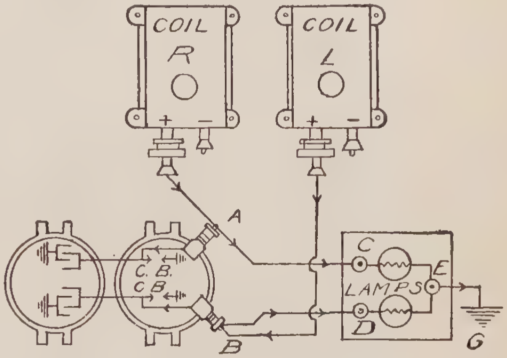

Fig. 22. Type 2 connections for synchronizing two interrupter contact-breakers used on double ignition.

By examining the connections as shown in Fig. 22, it will be noted that as each set of contact-breakers separate, the lamp in its circuit lights. When contact-breakers are closed, a short-circuit will be formed around lamps, causing them to go out.

In setting the Stutz contacts, both lamps should light at the same time; that is the timing contacts should be synchronized.

Pierce-Arrow interrupter contacts are not synchronized. By referring to the Pierce-Arrow wiring diagram, page 403, and to Fig. 8, page 216, it will be noted that one contact-point is for the ignition system on the exhaust side of the engine and the other is for the ignition system on the intake side.

The contact points for the exhaust side are set ahead of the intake, as mentioned below, the degrees referred to being flywheel degree movement.

Models 31 and 51: exhaust set to open 3° before inlet.
Models 32 and 33: exhaust set to open 3° to 7° before inlet.
Models X-5-W-2: exhaust set to open 0 to 3° before inlet.
Models R-10: exhaust set to open 0 to 3° before inlet.

For example, with models 32 and 33, the lamp connected in the circuit (Fig. 22) with the contact-points for the exhaust side should light 3 to 7 flywheel degrees before the one connected in the circuit with the contact-points for the intake side.

Contact-Point Surfaces and Removal

The contact-point surfaces often have a frosted appearance. This is not an indication of trouble, as is often believed, but shows that the contacts are making good contact with one another, and they should not be disturbed as long as proper operation is maintained. The contact points are made of tungsten. This metal is too hard to file. Should it be necessary to dress them an oilstone should be used. Care should be taken that they seat equally against each other after being replaced.

The contact arms may be removed by lifting them from the posts on which they are pivoted, after taking out the cotter-pins and loosening any clamping nuts holding the ends of the steel springs.

See Index for "Delco motor-generators and wiring diagrams."

INSTRUCTION No. 21

TESTS AND ADJUSTMENTS OF THE VIBRATOR TYPE OF HIGH TENSION COIL: Ford Ignition Coil

This instruction deals only with vibrator-type coil adjustments and tests. The next instruction will deal with the non-vibrator type.

Adjusting Vibrators of an Ignition Coil

The usual method of adjusting a coil trembler or vibrator is the rather rule-of-thumb method of screwing down the trembler screw till there is a sharp musical "buzz" obtained, and, as near as it is possible to determine, to adjust the screws so as to obtain the same note from each trembler.

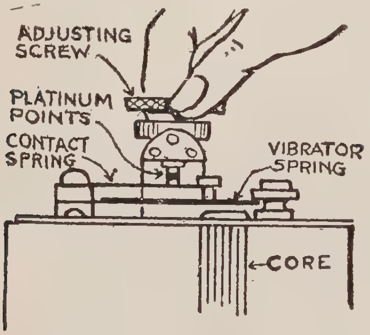

Fig. 1

Current consumption of the coil depends largely on how close the vibrator contacts are set. Very often it happens that a good deal of current is wasted in having too close contact, and at the same time the platinum points on both the vibrator and the adjusting screw are soon "pitted" and worn out from the excessive sparking.

There is a further serious disadvantage, inasmuch as the firing point cannot be synchronized for each cylinder, the closely-set trembler firing the charge earlier than the lightly-set one, and thus it happens that an engine rarely gives off the full amount of power. Perfect synchronization is required in obtaining full power. This explains why some engines often give more power on the magneto. The fault lies in bad setting of the coil and sticking vibrators.

Instructions for Adjusting the Ford Vibrator Coil (K.W. Ignition Co.'s Make)

There are four vibrator-type coil units (Fig. 2) contained in the Ford coil box.

The primary winding starts at the bottom of the coil unit, which consists of a metal disk which makes contact with a spring inside of coil box and which is connected with electric current, either from the battery, the generator, or the magneto (see Index under "Ford wiring diagram").

The primary current passes through the primary winding, through vibrator blade (**VS**), through points (**P**), to the contact spring, to the primary contact to the timer, to the contact on the timer or commutator.

The secondary winding is shown in Fig. 2. See also Index, for "Ford wiring diagram."

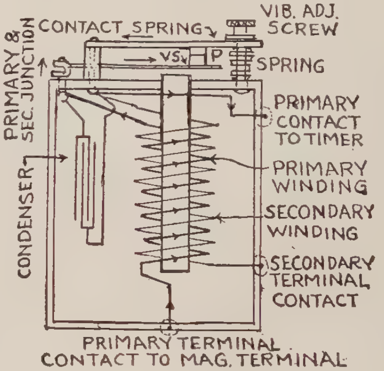

Fig. 2. Ford vibrator coil unit (K.W.)

Adjustment of vibrator: The K.W. coil unit shown in the illustration is designed to operate on a current consumption in the primary winding of 1 1/10 to 1 2/10 amperes at a voltage of 6 to 8 volts.

When the vibrator tension on a coil is increased, or more vibrations are produced in a given time by screwing down on the vibrator adjusting screw, the secondary voltage is increased and the primary will draw more current.

Therefore the proper adjustment of this adjusting screw for certain current values is necessary in order to prevent the building up of too high a voltage, which is liable to puncture the insulation of the secondary winding.

A Ford coil unit (K.W., Fig. 2), when tested on a 6-volt circuit with a low-reading ammeter in series with the primary circuit, should register 1 1/10 to 1 2/10 amperes.

When the vibrator spring is pressed down against the iron core, the air-gap clearance between points (**P**) should be 1/32″ apart. It is very essential that this vibrator spring have the proper tension, inasmuch as on this depends the amount of current that the primary winding consumes, as well as the effectiveness of operation.

The tension, or number of vibrations, can be adjusted by the vibrator adjusting screw. First, however, in order to adjust properly, the vibrator spring itself should be tested for proper tension as follows:

Remove the top bridge. If "tungsten" contact points are used, the vibrator spring should stand exactly ¼″ above the iron core. If K.W. "sparkite" springs and contact points are used, the spring tension is less, owing to the low-surface resistance of this metal; therefore the vibrator spring should be 5/32″ above the iron core.

It is important that the vibrator-spring tension be correct, as just stated, before attempting to adjust the tension of the vibrator spring with the adjustment screw.

The condenser is located in each coil unit, and is connected or shunted across the vibrator contact points.

Hard starting, due to vibrator adjustment: If there is **too much tension** on the vibrator springs, the weak current generated by the magneto at cranking speeds will not be sufficient to cause the vibrators to buzz, and it will be difficult to start the engine. **Too little tension** will not let the vibrators respond quickly, and the engine will run unevenly.

A defective coil unit can be detected by noticing if the vibrator buzzes without producing a spark at the plug. Then the suspected unit can be exchanged with another unit to make sure that the trouble is actually in the coil unit. A defective or punctured condenser is indicated by a heavy spark at the vibrators and a weak spark at the spark plug.

If the engine has a tendency to miss when driving over rough roads, this may be due to the coil units not fitting tightly in the coil box. The bouncing of the car makes the coil units touch the metal cover of the box and causes misfiring. Coil units in the Ford coil box depend upon spring tension for contact.

Sometimes, misfiring is due to the wooden lining of the metal coil box being damp and allowing the electric current to leak across from one terminal to another.

The spark plug: On the Ford and some magnetos where there is a volume of spark, a spark plug recommended by the manufacturer should be used, as the points usually have metal of slightly high resistance to prevent pitting and burning of points, due to the excess of current supply. **The spark-plug gaps** are 1/32″ apart on Ford plugs.

Vibrator Coil Cause of Missing

In rare instances one of the coil sections will become short-circuited or the insulation may become punctured on the secondary winding. This is commonly caused by using too many batteries or too high a voltage. In this case the plug would not spark at all, therefore it would be advisable to try changing positions of the coil units in the box. If the plug sparks properly on one of the other coil sections, then you may know that that particular coil unit is defective. Therefore, inspect the platinum points on the vibrators and contact points, as they may be partially burned away or badly pitted. If this coil section still fails to give a spark, then it is evident it is burnt out inside.

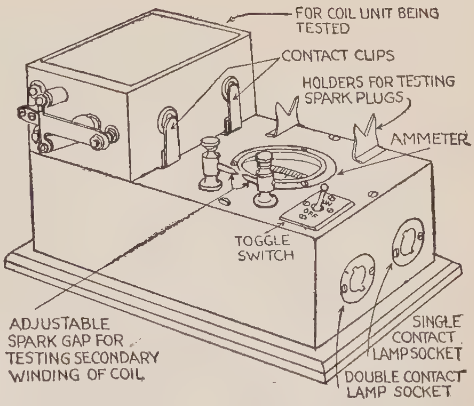
In some instances a coil may have its insulation short-circuited for only half its length of winding and would give a spark. If a short circuit was near the beginning of the winding, it would not spark at all.

Testing the Coil

If a multiple-cylinder engine, test each unit separately until it is determined which coil is missing. After assuring yourself the missing is not caused by a spark plug, weak batteries, carburetion, or other causes, then test the coil itself.

Vibrator Coil Tester

A very serviceable device for testing Ford coil units, single and double contact lamps, as well as spark plugs, is the B.W. Tester[1] illustrated above.



FOR COIL UNIT BEING TESTED
CONTACT CLIPS
HOLDERS FOR TESTING SPARK PLUGS
AMMETER
TOGGLE SWITCH
ADJUSTABLE SPARK GAP FOR TESTING SECONDARY WINDING OF COIL
SINGLE CONTACT LAMP SOCKET
DOUBLE CONTACT LAMP SOCKET

Fig. 3. The "B W" tester. Designed for testing Ford coil units, spark plugs, and lamp bulbs.

To test a Ford coil: The coil to be tested is slipped into place so that the contact springs touch the proper contacts. A 6-volt battery is attached by means of cord and test clips. The ammeter on the Tester has zero (0) center, and it is proper for it to read in either direction. The adjustable spark gap should now be set with one-quarter inch (¼″) gap. This may be measured by gauging the gap with one-quarter inch (¼″) drill or rod. This gap is much greater than the gap in the spark plug, due to the fact that a spark takes place in the open air, while in the case of the spark plug, the sparking takes place in a highly compressed charge in the cylinder which requires the spark gap to be considerably smaller.

The switch is now closed, and the ammeter should give a fairly steady reading of about 1½ amperes. While this current is flowing, a continuous flow of sparks should follow across the spark gap. If the flow of sparks is not constant, this indicates that the vibrator contacts of the coil have probably become pitted; they should be removed and smoothed with a fine file. The adjusting screws on the coil should be turned one way and another until the stream of sparks appears the hottest.

If at this point of adjustment the current is lower than 1.2 amperes, then the vibrator spring on the coil is weak and should be strengthened as follows: Remove the cross-piece that carries the adjustable contact. Now note the distance that the vibrator spring stands away from the coil head. Increase this distance slightly by bending the vibrator spring away from the coil head; then replace the adjusting cross-head, and the current will have increased as well as the stream of sparks. If the current is higher than 1.8 amperes, then the vibrator spring is too strong and stands away too far from the head of the coil. In this case the vibrator springs should be bent inward.

If the ammeter pointer flies over to the end of the scale, then this indicates that the vibrator contacts are stuck together. If in this case they are worn out and cannot be smoothed with a file, they should be replaced.

If it is impossible to get a reading of 1½ amperes and a continuous hot spark across ¼″ spark gap, after making all the adjustments named above, the coil is no longer serviceable and should be replaced.

To test a spark plug with the tester shown above: Connect the Tester to a source of power, as instructed above. Place a Ford coil into the coil guides in the same manner as in testing the coil. Now open the spark gap to at least ½″, then place the spark plug into the rack provided on the Tester and close the switch. Where it is possible, it is a good idea to open the spark gap of the spark plug to about ¼″, so as to get the same condition in the open as with the small gap in the highly compressed cylinder.

If the spark plug is only foul from carbon deposit on the porcelain, the carbon will be immediately burned off. If there is a cracked procelain, the spark will short-circuit through this crack and no spark will flow at the spark-plug gap, and the plug is no longer serviceable.

To test lamp bulbs: Both the single and double-contact sockets provided for testing lamps are directly connected to the transformer, and all that is necessary to test lamps is to connect to source of power as instructed above and push the lamp into the proper socket.

---

Causes of Spark Plug Missing

The usual cause of missing of explosion is that the spark plug becomes fouled by carbon, or soot is deposited on the porcelain insulation, causing the plug to become short-circuited. It is generally caused by using a poor grade of oil or loose piston rings, which permits the oil to pass too freely into the head of the cylinder.

Other causes are sticking vibrator points, a defective commutator, or a weak battery.

When mis-firing occurs, particularly when running at high speeds, it would be advisable to inspect the commutator, as the fiber may be worn so that the roller touches only the high spots, or it may be that the roller has worn out of round and consequently forms imperfect contact on all of the points.

At slow speeds, mis-firing is apt to be the result of improperly seated valves or air-leak in the carburetor or cylinder-head gaskets.

A weakness in compression may be detected by lifting the starting crank slowly the length of its stroke for each cylinder in turn. In rare instances an exhaust valve may become warped by the engine becoming overheated, in which case the valve seat will have to be reground or the valve replaced.

When starting to test for the trouble, first determine if the missing occurs when running slow or when running fast, or if at all times. Also be sure the carburetion is right.

Testing for Miss with Vibrators

We will assume the engine is a four-cylinder engine.

To ascertain which, if any, of the four plugs are fouled with oil, short-circuit with carbon, or inoperative from some other cause, open the throttle two or three notches to speed up the engine; now hold your two fingers on two outside vibrators so that they cannot buzz. The evenness of the exhaust will show that the other two are working correctly and that the trouble is not there; or an uneven exhaust will indicate that it is between the two that are free.

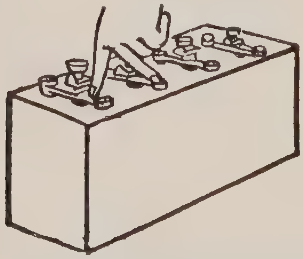

Fig. 4. Testing for missing with vibrators on the coil.

If the two cylinders fire evenly, change the fingers to the two inside vibrators and again listen to the exhaust. Having ascertained in which pair the trouble is, hold down three fingers at a time until you find the one which does not fire.

Cylinder No. 1, we will say, is the front cylinder, and they number in rotation 1, 2, 3, 4. No. 1 coil unit would be the one farthest from the steering post (left-side drive), and they number 2, 3, 4 to the left.

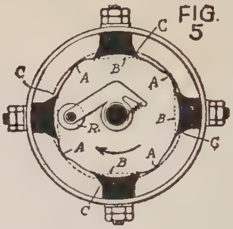

FIG. 5

Causes of commutator troubles (Fig. 5): (1) worn metal segments (C) often cause missing by not making good con act. (2) The commutator may also become loose on the shaft and get out of time. (3) Spring weak. (4) Loose connections at binding posts. (5) Depressions worn on face of fiber on which the roller (**R**) travels, resulting in the roller jumping (at high speeds) almost over the metal contacts (**C**). The roller (**R**) and pin of the revolving part will also probably be found in bad shape. To repair, turn down in a lathe or replace with a new one. (6) Grease will coat the insulated fiber ring (**C**) from one segment to another, and cause a short circuit. Too much oil will also cause a glazed surface over the segments (**B**), and good contact cannot be made between roller (**R**) and these metal segments.

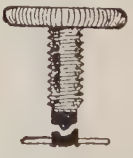
Dressing Platinum Points

Every time the contact separates, a minute quantity of platinum is transferred from one contact to the other. If the current is reversed by means of a reversing switch, the lost platinum will be transferred back to some extent. This is called depolarizing. Therefore, when using "direct" current for vibrator-coil ignition, it is a good idea occasionally to change the connection on the battery. The current flowing in one continuous direction causes this pitting of points. Where "alternating" current is used, as with a magneto, the points do not pit as much, because the current is changing its direction of flow.

On the Ford, the magneto generates "alternating" current. Therefore the pitting of points is not so bad, but when the car is run continuously at high speed, naturally the magneto generates a higher voltage, hence pitted platinum points.

Testing Platinum Contact Points

Imitation platinum will also cause "pitting." You can test to see if genuine platinum has been used by putting nitric acid on it. If it eats into the metal, it is not genuine platinum. A jeweler's stone can also be used for this test. Ask any jeweler.



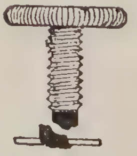


Fig. 6 (left). Shows pitting, and is the state to which a properly set contact-point finally arrives.

Fig. 7 (right) is the result of a badly set contact which is worn unevenly. The platinum would have to be filed away right down to the steel, and the spark would then soon eat the rivet hole and cause serious mis-firing.

Dressing Ignition Contact Points

To dress the platinum points, remember that the main requirements are to remove only as small an amount of the valuable metal as possible and to trim the surface dead level and smooth. In making the final adjustment of the screw, do not set the platinums closer than necessary to give a good, steady buzz of the vibrator.

For dressing the points (also magneto points), suitable small jeweler's files are sold at accessory shops. These are very thin and finely cut files.

If the surfaces are merely blackened, insert a strip of 00 emery paper between the two points, and pull the paper through them a few times.

An oil stone is excellent for dressing points, especially Tungsten points, which are too hard to file. An example of dressing the tungsten contact points on an oil stone is shown in Fig. 8.

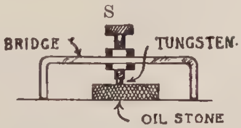

Fig. 8. The coil point screw (S) is clamped, by means of two nuts, to the center of the metal strip. The strip is moved forward and backward over the oilstone, thus securing a true surface on the tungsten point, which makes it last much longer without grinding.

Platinum and Tungsten Contact Points

Procure **genuine platinum points** when purchasing new screws or vibrator springs, if possible. Platinum-iridium and Tungsten metal points are both used. Imitation points will "pit" and burn together and cause missing.

Platinum-iridium alloy, which consists of 80 per cent platinum and 20 per cent iridium, should be used on all magneto contact-breaker points. Pure platinum would hammer under action of the interrupter, therefore iridium, which is harder, is used with it.

Tungsten points are quite often used on coil and battery systems because of the extreme hardness and infusibility of this metal, but its disadvantages for magneto use are oxidation of points when heavy currents are carried. The oxidation results in a high resistance oxide which makes it difficult to start, and the arcing makes it very difficult to distinguish when a condenser is defective. When platinum-iridium contacts are used, extreme arcing is always an indication of a defective condenser. Tungsten points therefore require a greater condenser capacity to overcome arcing than platinum does.

Platinum-iridium is best for all contact points, but, as stated, tungsten can be used on coil and battery systems. See also Index for "Platinum points for magneto contact breakers."

The foregoing applies to contact points on vibrator coil screws and springs.

Spark Plug Gap Suggestions

Do not set spark plug gaps over 1/32″ apart. A longer gap will likely cause a mis-fire.

When testing the spark, by removing the wire from the plug, do not separate the terminal wire from the plug or engine frame more than 3/8″, as it will strain the coil and break down the insulation.

INSTRUCTION No. 22

TESTING IGNITION COILS OF NON-VIBRATOR TYPE: Condenser Tests; Resistance-Unit Tests

As an example of the procedure for testing an ignition coil of the non-vibrator type, the North East Ignition system as used on the Dodge car will be used.[1]

See Index for "Dodge wiring diagram" for the internal circuit of this system, and study it carefully.

LOCATING IGNITION TROUBLE: N. E. IGNITION SYSTEM (MODEL "O")

1. Whenever it is determined that trouble has been located in the ignition mechanism or in the coil windings, and that it is not in the spark plug or loose connections, or due to a run-down battery, then turn off the ignition switch and remove the distributor head in order to expose the interior of the breaker box. Crank the engine slowly until it is seen that the breaker cams come together.

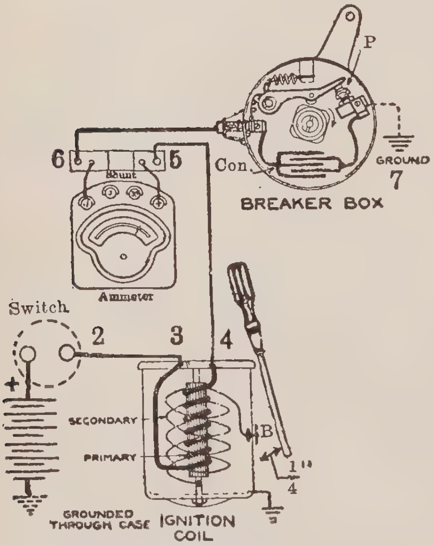

Fig. 1. Testing the North East ignition coil as used on the Dodge.

2. Disconnect the wire at the contact breaker leading from the switch to the contact breaker, and insert a low-reading ammeter in the circuit, as shown in Fig. 1. (The ammeter shown is the model "280" Weston.)

Note. The use of a screwdriver is not resorted to in this test. Fig. 1 is used to illustrate several different tests.

3. Turn on the ignition switch and note the amount of current through the primary circuit. With a battery voltage of 12 volts, the normal amount of current consumed by the coil with the engine idle and breaker contacts (**P**) closed, is approximately 2.5 amperes. This will determine if the primary circuit of the coil is in proper shape.

Note. It is best to use first the 30-amp. shunt, if a Weston model 280 instrument is used, because, if there is a short circuit it will read far more than 2.5 and burn out the meter. If a low reading is thus obtained, then connect the 3-ampere shunt and use the lower reading scale, which is more accurate for low readings.

To Test the Secondary Winding

a) **A ground** in the secondary from the secondary winding to the coil box cannot be tested with an ordinary test lead, because the inner end of the secondary coil is normally grounded to the core. A ground from the coil to the core can usually be indicated by burning of the insulation appearing on the outside of the coil where the spark has punctured it.

b) The simplest method of **testing for a short circuit of the secondary winding** is to substitute another coil temporarily for the suspected one, and to compare their behavior under similar operating conditions.

c) **To test for an open circuit in the secondary winding:** Remove the high-tension terminal bushing (**B**) (Fig. 1) on the side of the coil, and then run the distributor unit at a moderate speed with ignition switch on, while a screwdriver is held against the housing with its tip about ¼" from the high-tension contact button (**B**) on the ignition coil. If no spark jumps, the winding is probably open-circuited. Before accepting this as final, however, be sure the primary coil winding is in proper shape, because the induced current comes from the primary coil.

If the primary winding test shows abnormal ammeter readings, either more or less when the meter is inserted between switch, coil, and breaker box, as in Fig. 1, or if there is an open circuit, then other portions of the circuit should be tested as follows:

1. **Test the wiring from coil to switch** by placing one lamp test point on 2, and one on 3, then from switch to ammeter (2 to 5), and ammeter to breaker (6 to 7), to see if these are open circuits, grounds, short circuits, or loose connections. Also examine the switch and coil connections. The 110 or 220-volt direct-current test lamp and leads (Fig. 3 can be used for this, but be sure no current is passed through the ammeter and that the ignition switch is open.

2. **Test the battery:** If the battery shows 2.6 volts across each cell, it is fully charged. If it shows 1.8 volts or less per cell, it is discharged. However, voltmeter readings are not accurate, for if a battery is sulphated, unreliable high-voltage readings will result when tested while on charge. Therefore a battery should be tested on discharge also. See Index for "Testing a storage battery on discharge."

3. **Examine switch, ammeter,** and also the **storage battery connections** for loose or poor connections or grounds. Quite often poor or loose connections on

---

[1] Through the courtesy of N.E. Electric Co.

the battery or switch will cause lack of proper current supply, as a loose connection not only causes missing, but offers resistance and cuts down the current supply.

To Test the Condenser[1]

The condenser in the N.E. Dodge, Model "O" interrupter is in the contact breaker housing, and connects across the points of the contact breaker. One point of the contact breaker in this system, is grounded, and so also is one end of the condenser (see Fig. 2). The purpose of the condenser is explained on page 191. On some ignition systems the condenser is placed on the coil.

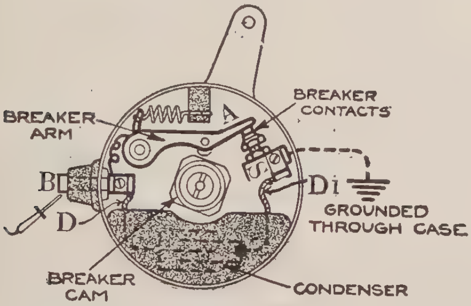

Fig. 2. Testing condenser on N. E. (Dodge) model "O" interrupter or contact-breaker.

To test condenser for a ground: Disconnect condenser leads (**D, D1**) from the contact breaker mechanism (Fig. 2). Hold one test lead (110 or 220-volt direct-current lamp and leads) against the condenser case, and touch the two condenser leads (**D, D1**), one at a time with the other lead. The test lamp will light if there is a ground; if the condenser is in proper shape, the lamp will not light.

To test condenser for a short circuit: Separate breaker contact points. Place a test lead on each of the condenser terminals (D, D1). If the condenser is short-circuited the lamp will light; if nothing is wrong, it will not light.

To test condenser for an open circuit: This test should be made with a test lamp from alternating current. Separate the contact breaker points. Hold one test lead on one terminal (D) of the condenser and touch the other condenser terminal (D1) lightly with the other test point. If the condenser is in proper condition, a slight spark will occur every time the test lead is applied. If the condenser is open-circuited, no spark at all will occur. In either case the test lamp will not light, because even with a normal condenser, the current permitted to flow through the test lamp is so small that no visible effect will be produced.

To Test Contact Breaker

To test contact breaker for a ground: Disconnect the wire to the contact breaker binding post at (B), (Fig. 2). Separate the contact points. Touch one test lead to the shell of the contact-breaker box and the other to breaker arm (**A**). The lamp should not light if everything is correct. If the breaker is grounded it will light. The condenser should be tested first, as a short-circuited condenser would cause the lamp to light, since it would be in the circuit.

Note. If the contact breaker has two binding posts and has an insulated return instead of a grounded return, the test should be made with breaker points closed in order to include the stationary contact point (S), as well as the rest of the breaker mechanism.

To test contact breaker for short circuit: Disconnect wire at (B) (Fig. 2) to contact breaker. Separate points. Place one test lead on the terminal (B), and the other on the stationary contact (S). If the lamp lights there is a short circuit. Be sure the condenser is in good order, for the reasons given in the test immediately preceding. If the lamp does not light it is without defect.

To test contact breaker for open circuit: Make the same test, except that the contact points should be closed instead of being separated. If the test lamp fails to light when the breaker contact points are closed, an open circuit is indicated.

To Test Primary Winding

To test primary winding of ignition coil for ground: Remove the coil-housing cover and disconnect the coil leads from the terminal block on the cover (Fig. 3). Hold one test lead against rod (6) in the center of the coil and touch the lead to the primary winding terminal (3), then (4). The test lamp will light if there is a ground.

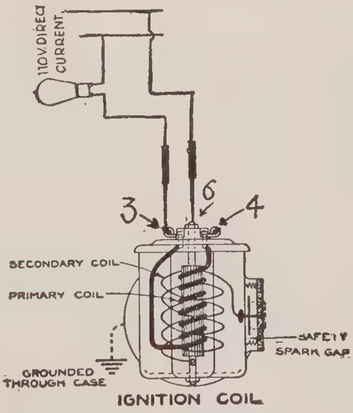

Fig. 3. Testing primary winding of ignition coil.

To test primary winding for an open circuit: Place one test lead on (3) and the other on (4). If the lamp does not light there is an open circuit.

To test primary winding for a short circuit: See paragraphs 2 and 3 under "Locating Ignition Trouble." If the ammeter reads more than 2.5 with switch closed, points together, and engine idle, it indicates a short circuit either in the primary winding or elsewhere in the circuit.

Operating Test: Bench Running Test of N.E. Ignition System (Model "O")

The N.E. ignition test[1] is made on a special test bench (Fig. 4) with apparatus designed for the purpose.

---

[1] A method where many coils are tested is to have an interrupter connected with a drive system of some sort. See Fig. 12, page 230.

[1] Through the courtesy and with the permission of the North East Electric Co., Rochester, N.Y.

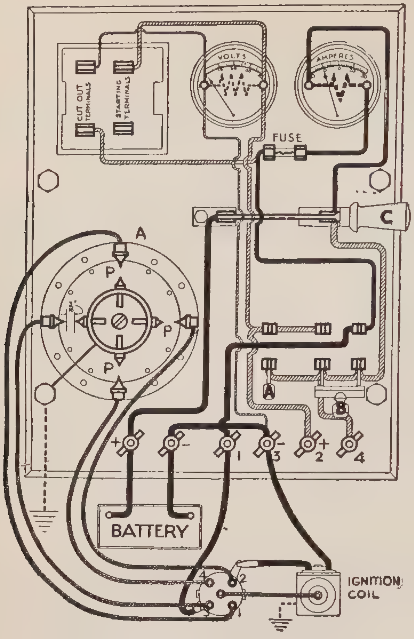

Fig. 4. N. E. ignition test-board for testing the ignition system, generator, and cut-out.

The ignition unit is placed on the test-bench and connected to a motor which drives the ignition unit under conditions as nearly like those encountered in service as practical, and is carried out with a range of speeds equal to that of the engine. The test-board shown in Fig. 4 is the N.E. testing outfit for testing the ignition system, generator, cut-out, etc.

The ignition unit, consisting of distributor, interrupter, and coil, all in one unit (see Index for "Dodge ignition unit"), is connected with a motor which drives it at various speeds as stated above. The distributor is connected with an adjustable spark device (Fig. 4), with the points (**P**) adjusted to ¼" gap. The unit is first driven at 1,200 r.p.m., and switch (**C**) is closed. High-tension sparks are at once produced at points (**P**). The speed is varied from 1,200 to 2,000 r.p.m. A low-reading ammeter is inserted in the primary circuit as shown.

At 500 r.p.m. with a 12-volt fully charged battery, the consumption should be nearly 1 ampere; at 1,200 r.p.m. approximately 0.8 ampere; and at 2,000 r.p.m., 0.6 ampere.

The black wires show the primary circuit of the coil connected with battery, switch, and ammeter. For instance, the primary circuit is from battery to (+) terminal, to switch, to ammeter, to fuse, to terminal of switchboard 1, to contact breaker, through points, to primary coil, from other end of coil primary to (−) terminal (3) on switchboard, to (−) terminal of battery.

The secondary circuit of the coil is from the secondary terminal of the coil to the center of the distributor, thence from terminals on distributor to points (**P**) on spark tester (**A**), through points to ground, to ground of coil.

A coil on a test should jump ¼" in the open air without missing. If it will not jump this gap continuously, then it is certain not to jump the spark-plug gap inside the engine which is under compression and thus shows greater resistance.

For timing the N.E. ignition system on the Dodge, see Index under "Dodge ignition timing."

REMY NON-VIBRATING COIL AND CONDENSER CONNECTIONS

The condenser is always connected or "shunted" across the interrupter points (**P**) of all high-tension coil primary circuits and magnetos. It can be placed **on the coil,** as shown in Fig. 5, or **on the interrupter,** as in Fig. 6.

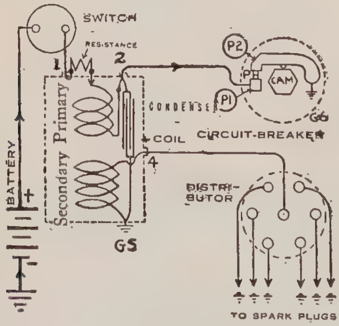

Fig. 5. Remy grounded ignition system using a non-vibrating cylindrical type, two-terminal coil with condenser in coil. Note that the condenser is across the contact-breaker points (P).

The primary circuit (Fig. 5): From (+) of battery, to switch, to coil terminal 1, through resistance unit, through primary winding to coil terminal 2, to interrupter stationary contact (P1), through movable contact (P2), to ground, to (−) ground of battery.

Note that the condenser in the coil is connected across interrupter points (P).

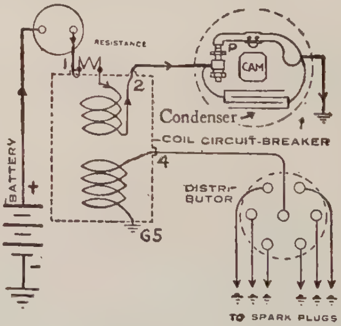

Fig. 6. The same ignition principle as shown in Fig. 5, but with the condenser in the interrupter housing. The condenser is shunted across the contact-breaker points (P), as in Fig. 5.

The primary circuit (Fig. 6): From (+) of battery, to switch, to 1, through resistance unit, through primary winding to 2, through points (P) on interrupter, to ground, to (−) ground of battery.

Note that the condenser in the interrupter housing is connected across the interrupter points (P).

In order to explain the importance of connecting the proper wires to a coil where a condenser is in the coil, the diagram (Fig. 7) is used to show how the condenser can be cut out of action to a great extent, thus reducing the efficiency of the coil and causing sparking at the interrupter points.

Primary circuit (Fig. 7) (connected wrong): From (+) battery to 2, through primary winding, through resistance unit, through points (P), to ground, to (−) ground of battery.

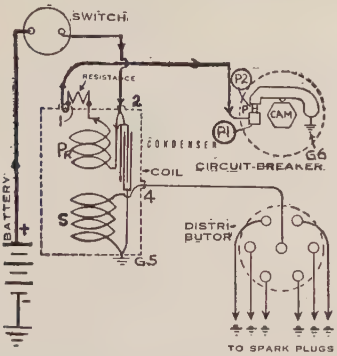

Fig. 7. The same ignition system as in Fig. 5 with leads to and from the ignition coil **connected wrong**, thus disconnecting the condenser from across the contact-breaker points where it is required.

Note that the condenser is not directly across the interrupter points (P); the primary winding and resistance unit are between one end of condenser (2) and (P1) of interrupter. The proper connection is shown in Fig. 5. Coils are usually marked (B) for battery, and (T) for timer. Thus the terminal from the battery leading to the switch and from the switch, should connect with (B) or (1) on the coil. See page 209, explaining Remy 2 and 3 terminal coils; see also page 213, for Delco coils.

Remy Condenser Instructions and Tests

Condenser trouble will usually be distinguished by severe arcing at breaker contacts.

Test for shorted condenser: Disconnect the condenser, or, if condenser is inside of coil, disconnect coil. Connect terminals leading to the condenser, across 110 volts A.C. or D.C. with a lamp in series. If lamp lights, the condenser is short-circuited or broken down between layers. Test points from lamps are indicated as (T) (T1) (Figs. 8, 9).

On systems using grounded ignition, that is, grounded primary winding in ignition coils (Fig. 8), connect test point (T) to post (2), to which the lead from the breaker is attached, marked "Timer," and to base of coil with test point (T1), for this test.

Note. If primary winding has become grounded in this type of coil, the lamp in this test will be lighted the same as if the condenser is shorted. However, if the breaker points are badly and are burned, it can be assumed to be condenser trouble.

On systems using insulated ignition (primary winding not grounded), (Fig. 9), connect test point (T) to center post (2), marked "timer-switch" and connect (T1) to outside post (3) which has not the resistance unit connected to it.

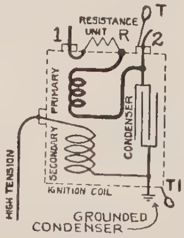

Fig. 8

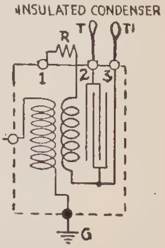

Fig. 9

Fig. 8. Remy ignition coil (two-terminal type) with condenser grounded.

Fig. 9. Remy ignition coil (three-terminal type) with both terminals of condenser insulated.

Open condenser: An open condenser may be one which is disconnected inside of the box or coil tube, or one which has opened up between layers so that its capacity is very low. With an open condenser or one which has no capacity from any cause, very severe arcing will occur at contacts as stated above.

Capacity test: In case 110 volts D. C. is available, a capacity test can be made by connecting across the condenser with the test lamp in series, then disconnect the test lamp and bring the condenser terminals together. If a good spark is obtained, the condenser is all right. A. C. current is not as dependable for this test as D.C. current, although with proper care fair results can be obtained. In using A.C. current a good spark will not be obtained every time the condenser leads are touched together, but only occasionally.

Ignition coil test: In all battery ignition systems a good spark should be obtained at maximum engine speed. For testing a coil in the open through ordinary spark-gap points, which are well cleaned, a good coil will jump a gap of not less than 5/16″ when the coil is connected up in the regular way at 3,600 or less sparks per minute with breaker points opening at a point between .020″ and .025″. Test coil for at least one hour until well heated up, according to the instructions given above, before mounting on the car. A coil which cuts out or misses under these conditions should be taken out of service.

DELCO INSTRUCTIONS RELATIVE TO TESTS OF RESISTANCE UNIT AND CONDENSER

Delco ignition coils, interrupters, and distributors, as well as adjusting Delco timing contacts are explained on pages 213–221. In the present discussion we deal with the Delco ignition resistance unit and condenser tests.

Resistance Unit Tests

Resistance units sometimes break down or burn into, with the result that there is no spark at all, or a very weak one.

Connect the coil so that the resistance is cut out and note if the spark is improved. See pages 213, 214, showing resistance on coils.

A resistance unit, if short-circuited, will permit excessive current to pass through the contact-points, and this will cause them to be burned or pitted excessively, although the ignition may appear to be very good and without a miss.

If the resistance unit is connected properly, it will heat up; if it does not heat up it will indicate that the resistance unit is not in the circuit. See page 198, explaining the purpose of a resistance unit. Also refer to page 231, relative to the resistance unit becoming thin, owing to heat, thus weakening the spark.

Condenser

If the condenser is not in good condition, the contacts will burn and pit rapidly, owing to the excessive arcing when they are separated, but the ignition will be rather bad if, indeed, it will operate the engine at all, so that the burning of the contacts, due to a bad condenser, can, as a rule, be distinguished from burned contacts due to a high voltage or to a short-circuited resistance unit.

A good test for the condenser, by which to show whether it is in good condition or not, is to connect it up in accordance with the circuit diagram shown in Fig. 10. For this test a 110 or 220-volt source of direct current is necessary, a lamp of the same nominal voltage as the circuit, and the wiring shown. The lamp is connected in series with the line and the condenser across the line.

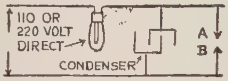

Fig. 10

If the terminals (A) and (B) are connected together, a very faint spark, which has a snapping sound similar to the sound made when leads from a storage battery are attached, should occur. If the condenser be disconnected from the circuit, a much different arcing will be observed, somewhat longer and yellower, and without the distinct snapping sound mentioned previously.

If a condenser, known to be good, is tested in this manner once, it will enable the observer to distinguish very readily between the sparks at the points (A) and (B) obtained with a good condenser and a bad condenser, as a bad condenser will give the same quality of spark as if no condenser at all were in the circuit. This test is a mere qualitative test, but this is about the only satisfactory test which can be found which does not require expensive apparatus.

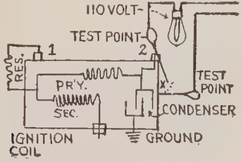

Fig. 11

If a condenser is in coil, it can be tested in the same manner as shown in Fig. 10, by placing the test points (Fig. 11) so that the same effect can be had. One end of the condenser is usually grounded.

Condenser and Coil Test Suggestions

Possibly the most common test is to disconnect the doubtful condenser and substitute one that is known to be correct. The results obtained when using the good condenser will show up the action of the original condenser.

For instance, if an excessive amount of sparking is at the contact points, it is probably due to a defective condenser. Therefore if a good condenser is connected right across and over the condenser to be tested, and if the sparking stops, then you may know the trouble is with the old condenser.

Where there are many coils and condensers to test, it is a good idea to rig up a contact breaker on the bench (Fig. 12), so that it can be driven at various speeds, and then to have a good condenser across its points which can be connected and disconnected by a switch (SW). Then when a coil is tested it can be connected with the contact breaker. If it has a condenser in the coil, disconnect the condenser on the contact breaker; then watch if it sparks at points (P). If it does, cut in the good condenser.

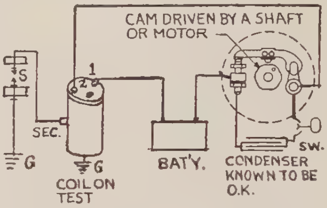

Fig. 12

Also **watch the spark at secondary test points** (S). It should spark for at least ¼″ to 5/16″ without missing for, say, 50 or 60 sparks. Be sure the coil is well warmed up when making the test.

If the condenser of the system being tested is in the contact breaker, it can be tested without removing, by connecting a good condenser so that it will be across the points of the contact breaker and noting results.

Home-Made Tester for a High-Tension, Non-Vibrating Coil and Condenser

This device (Fig. 13) consists of a sheet copper plate about 6″ wide, by 8″ long, by ⅛″ thick to serve as a base.

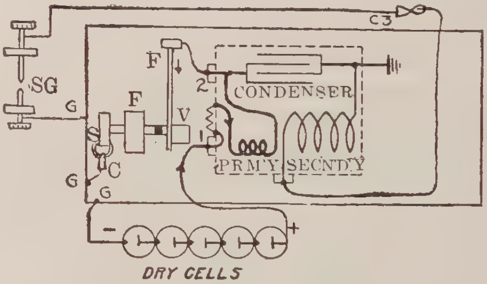

Fig. 13

A magnetic vibrator (V), similar to a vibrator on a high-tension vibrator coil, is mounted on the plate with fiber blocks (F), as shown.

The purpose of the device is to produce a vibrating action on the end of a coil, thus producing the same effect as a vibrator coil. By this method the strength or intensity and the constant steady spark of the secondary can be tested.

When testing a coil (Fig. 13), it does not make much difference which end is used; furthermore, the magnetic effect is so great that the vibrator will vibrate directly on the metal shell. It is best, however, to have the vibrator knob (V) vibrate against the end of the coil if possible. Either end could be used.

Fig. 13 illustrates a **Remy two-terminal coil** with a condenser in the coil. With coils where the condenser is in the contact breaker, they should be tested separately with a 110-volt test light, as previously explained.

The primary circuit through the coil is from (+) of battery to (1), through primary winding to (2), through vibrator blade (V), through points, to vibrator screw, through clamp (C), to ground of plate (G), to ground on plate, to (−) of battery. The condenser on the test outfit is across the points of the vibrator. By adjusting the vibrator screw (S) the vibrator blade (V) will vibrate, causing a spark at secondary spark gap (SG).

The secondary circuit is from the secondary winding to a clamp (C3), thence to a spark gap tester (SG), which can be made of two finely pointed brass rods through a fiber support. The gap of the points should be adjusted to ¼″ or 5/16″.

Condenser Test

When making the condenser tests, the object is to see if there is excessive sparking at the vibrator points. If so, it is probably due to a defective condenser and it should then be tested separately with test points as described in page 227.

A good plan is to **have another condenser known to be in good** condition. If there is excessive sparking, place the terminals of the good condenser across the vibrator points, by placing one terminal at (2) and one on screw (S). If the sparking then ceases, it is clear that the condenser in the coil is defective. A Delco No. 13057 (Packard) condenser which has two leads would be a suitable condenser for use in this manner. See Index under "Testing a magneto condenser," which shows a similar method of using a device as herein described.

The quality of the spark should be closely observed when testing the condenser. If the spark at the tester gap (SG) is fiery, showing glints of purple or purplish-red flame, the coil is normal. If the spark is thin, thread-like, and whitish or very light blue, and there is a snappy spark at the breaker points, the indication is that the condenser is punctured. This can then be checked by placing an extra condenser, known to be in good condition, as described above. If the coil will deliver a good spark when connected to a known normal condenser and will not give a spark when the condenser is disconnected, the proof is conclusive that the coil condenser is defective.

A great deal of stress is laid on the condenser test. This is advisable for the reason that condenser failure causes about 90 per cent of coil failures; therefore, when testing coils the condenser is always suspected. While open and short circuits in the coil windings do sometimes occur, they are comparatively rare and need hardly be considered.

Coil Test

Operate coil and see if it will produce a spark continuously at gap (SG) for at least one hundred steady sparks without missing with gap $\frac{5}{16}$″. If there is a safety gap on the coil being tested, the gap (SG) should be slightly less than the gap of the safety gap on the coil.

A high-tension coil when in operation at normal speed should draw about 2 amperes.

Resistance Unit Test

In testing a coil such as the Delco or Remy with a resistance unit in it, test with the resistance in circuit and with the resistance out of circuit. This can be done by making connection on the opposite side of it from 1 (Fig. 13) thus cutting it out.

This may be the cause of a weak spark, because the resistance burns out at times, and, if not burned into, may be thin (owing to heat), and thus reduce the quantity of current going through it, consequently weakening the spark. By cutting it in and out of circuit, the intensity of the spark at gap (SG) can be observed.

Many coils are equipped with resistance units. If current cannot be passed to the coil through the regular terminals, it may be suspected that the resistance unit is burned out. This can be determined by touching a test wire to the central nut which holds the unit in position. This has the effect of cutting the unit out completely and sending the current directly to the primary windings. If current does not flow, the indication is that there is a break between the resistance-unit screw and the end of the coil winding inside the cartridge.

If a coil is defective, in that the secondary spark is weak or misses, or if the condenser permits excessive sparking at contact points, thus causing a weak spark, then the chances are that it would cost more to repair the coil than it would be worth.

In some instances the condenser ground comes loose in the coil where it is soldered. This can be remedied by soldering.

Ignition resistance units can easily be fitted if burned out, or condensers can be replaced when in contact breakers, but if the coil is defective otherwise, do not attempt to repair it. Send it to A. L. Dyke, Elect. Dept., St. Louis, Mo., or to the manufacturer, and obtain a new one.[1]

Parts: Contact-breaker arms and screws, ignition resistance units, condensers, etc., can be carried in stock for different ignition systems most in use in any particular vicinity. Such parts can be secured of the manufacturer or of A. L. Dyke, Elect. Dept., St. Louis, Mo.

The United Motor Service, Detroit, Michigan, supplies parts for Remy and Delco apparatus, and issues a catalog of parts.

Clamps for connecting wires, such as shown in the illustration, are very handy for all testing purposes. They can be obtained of A. L. Dyke, Elect. Dept., St. Louis, Mo. The size is No. 8, trade No. 90239, price 30 cents each.

Spark-Plug and Lamp-Bulb Portable Testing Outfit and Test Board

A spark plug and lamp testing portable outfit illustrated in Fig. 14, is handy for carrying from one part of the shop to another, for testing on different cars. Several dry cells are placed in a long, narrow

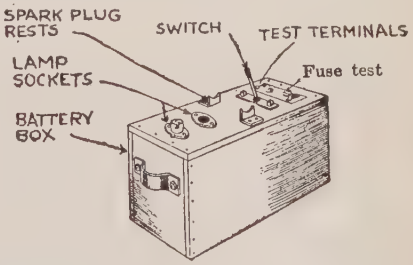

Fig. 14. Spark plug and lamp testing portable outfit.

---

[1] To find the make of ignition system used on different makes of cars, see Index under "Specifications of Leading Cars."

box, and connected through a switch to the testing terminals. The switch throws the two types of lamp sockets (single and double contact) into the circuit, and the push button connects the batteries through the spark coil to the plug-testing rests. This unit is compact enough to be taken directly to the job.

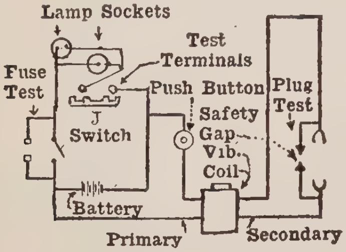

Fig. 15. Wiring of a test board for testing bulbs, fuses, spark plugs, and horns. This can also be used as a guide in connecting the portable outfit shown above.

A test board, which can easily be constructed, for testing spark plugs, coils, lamp bulbs, fuses and circuits, is shown in Fig. 15. Quite often a lamp does not burn. It may be due to the lamp being burned out, or to an open circuit in the wiring. In order first to determine if it is due to the lamp bulb, it can be quickly tested. If it is in proper condition, then the trouble is in the wiring. This also applies to the fuse. When the test terminals are not being used to test a circuit, connect jumper (J) across them to permit testing of lamps and fuses.

Testing an Electric Horn

The electric horn can be tested by placing an ammeter with the 30-ampere shunt in the circuit, as shown in Fig. 16. Then adjust to take the least possible current. The average horn draws from 3 to 8 amperes, according to its size; see Index under "Electric horns." The ammeter can also be used to test the horn for short circuit or open circuit.

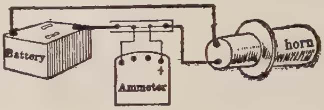

Fig. 16

Test Lamps and Test Points

This subject is treated farther on. See Index.

Manufacturers of Ignition Devices

Splitdorf: Splitdorf Electrical Co., 98 Warren St., Newark, N.J.

INSTRUCTION No. 23

SPARK PLUGS: The Missing Spark; Spark Intensifier

Spark Plugs

The purpose of spark plugs is explained on page 188. There is usually one spark plug for each cylinder.

Location of spark plug in cylinder: The spark plug can be placed in the cylinder as follows: over the center of the piston, over the exhaust valve, or over the inlet valve. The first position is not the best, as it is found that it too easily becomes fouled. If screwed above the exhaust, it will likely miss fire; this is on account of the dead gases surrounding it. The correct position is **over the inlet valves,** as it will be kept cool by the inrush of fresh gas, and it is in an atmosphere perfectly suited for explosion directly the spark appears, as this is the more perfectly scavenged part of the cylinder, i.e., in the direct path of the fresh gas.

The plug is usually placed over the inlet valve on "T" or "L"-head cylinders. In the overhead valve type, the plug is placed in the top center or in the side of the cylinder. It is exposed to the full heat of the explosion when overhead, directly in the center of the bore; consequently in a high-compression engine, a well-made plug, gas-tight and free of electrical leaks, must be used.

Double ignition: On the Stutz and Pierce-Arrow engines, there are two spark plugs in each cylinder, which is an advantage, in that a very hot spark is produced which ignites all of the gas more quickly, thus saving in gasoline consumption. One spark plug is placed on the exhaust side of the cylinder and the other spark plug on the inlet side. See Index for "Pierce-Arrow ignition and wiring diagram."

As previously stated, where one spark plug per cylinder is used, the usual location is in the neighborhood of the inlet valve, as it should be surrounded by fresh gas that enters during the inlet stroke. If it is located on the exhaust side, dead gas will collect about the plug electrodes and cause missing, and also heat.

It is also desirable to have the plug where the water jacket surrounds it, as in Fig. 4, to avoid overheating, else the plug electrodes are liable to be overheated and become incandescent and to cause pre-ignition.

Fig. 1

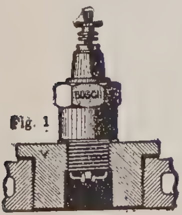

Fig. 2

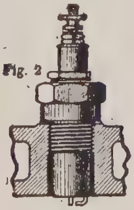

Fig. 1. Valve cap too thick; out of the path of the gas.

Fig. 2. Recess around the plug shell retains heat.

A poor location is shown in Fig. 1. When set in a thick valve cap (V) with short threads, dead gas accumulates in the recess and causes missing at slow speeds. Fig. 2 shows another poor method. The recess accumulates heat, and metal extension is liable to result in a plug becoming red hot and warping electrodes, altering the size of the gap.

Fig. 3

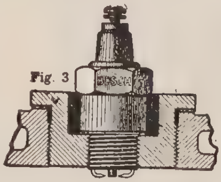

Fig. 4

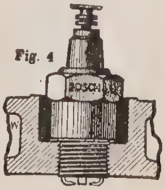

Fig. 5

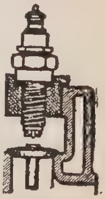

Fig. 3. Correct position of plug in valve cap.

Fig. 4. Correct position of plug when set in water jacket.

Fig. 5. Plug reach too long.

A good location is where spark-plug points or electrodes just reach the combustion chamber, where cool fresh gas will come in contact with them and flame will spread with maximum rapidity, as in Figs. 3 and 4.

When the plug extends too far in the combustion chamber, there is danger of the valve head striking it (Fig. 5).

For spark-plug lengths, see page 235.

Spark-Plug Construction

Construction: There are two types in general use: the "separable" type plug, where the insulation or core can be removed, as shown in Fig. 6, and the "integral," or one-piece plug, shown in Figs. 10 and 11.

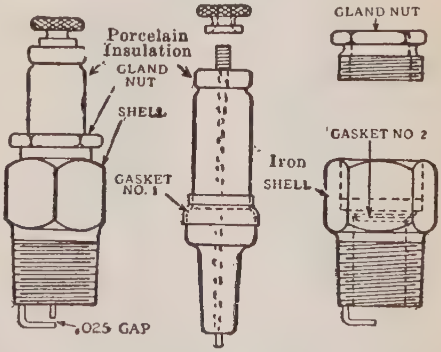

Fig. 6. Parts of a porcelain insulated spark plug—separable type.

The parts of the plug are: the iron shell or body which screws into the cylinder (see Fig. 6); the insulation which is held in the shell by the bushing or a gland nut; the electrode which passes through the insulation. Washers or gaskets are used as a gas-tight packing (Fig. 6).

The insulation is sometimes made of mica (Fig. 7), but owing to the construction, which is usually with washers, it leaks or permits current to pass to the electrode, especially when oily. The insulation in general use is porcelain, and this, unless of the best grade (not porous) will also leak, thereby weakening the spark. It is difficult to secure spark plugs which will not absorb oil and cause leakage.

Fig. 7. Parts of a mica insulated spark plug—separable type.

Spark plugs for aeronautic use: Mica is used extensively on plugs for aeronautic engines (Figs. 8 and 9). They are used but a brief time, and new ones are substituted.

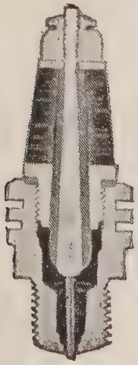

Fig. 8

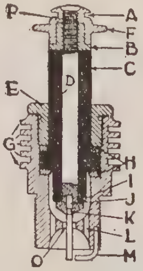

Fig. 9

The aeronautic type of spark plug is designed for great heat and high compression. The spark plug shown in Figs. 8 and 9 is made of mica and is very costly to construct. Note the heat radiation flanges on the shell; also the baffle plate (O) which tends to keep oil from the mica; stem (P) made of brass or copper for heat conductivity; electrode (J) is swedged at bottom of stem (K). The core is of mica washer sections (I), with a mica insulation tube at (D). The usual gap opening is .015″ to .018″. They are subjected to a pressure of 90 to 110 lbs. The life of a plug of this type is 25 to 100 hours.

The parts of the Splitdorf mica aeronautical spark plug (Fig. 8) are as follows: brass terminal, mica washers, lateral wound mica, steel center rod, 98 per cent pure nickel electrode point, carbon steel from brass terminal to electrode, and carbon steel shell.

The AC Titan, one-piece porcelain spark plug is used on the Liberty 12-cylinder engine. There are two spark plugs per cylinder to the Liberty 12 engine.

Separable Spark Plugs

Separable spark plugs are those in which a gland nut or bushing holds the porcelain or mica in place, as shown in Figs. 6 and 7. Plugs of this type have a tendency to leak and cause missing, especially at low speeds and hard pulls, or on high-compression engines. The integral plug appears to gain a point in its favor here.

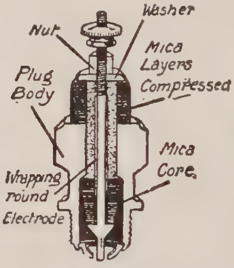

Fig. 10

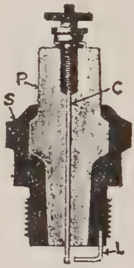

Fig. 11

Fig. 10. Integral type of spark plug with mica insulation. This plug is not separable.

Fig. 11. Integral type of spark plug with porcelain (P) or composition insulation. This plug is not separable.

The electrode (C) should be made of manganese nickel alloy. If not properly made it will expand under intense heat and break the porcelain. Spark-plug electrodes, or wires are approximately .050″ or .060″ diameter. Best results are obtained with .050″.

Cement is placed around the electrode. As it dries, it becomes porous, and porosity means electrical leaks.

Thus, it will be clear that "leakage of gas" and "leakage of electricity" are the troubles to be overcome in spark-plug construction. Leakage of gas causes "leakage of compression," and leakage of electricity causes a "weak spark."

Poor throttling, poor pick-up, missing on hard pulls and high speeds, are frequently caused by using a poor grade of plug. Of course there are other conditions which will cause this, such as carbonized insulators, or too close or too wide a gap at the plug points, or improper carburetion adjustment, but assuming that these troubles are corrected, the

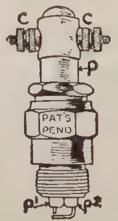

Fig. 12. Double spark plug—shell is not grounded. P1 and P2 are separate porcelain insulators.

leakage of gas and electricity are two of the fundamental troubles seldom noticed.

Therefore, the highest priced plug is often the cheapest. Likewise, a poor grade of ignition coil, when hot, will lose its efficiency.

Spark-Plug Sizes and Threads

Different threads and different lengths of spark plugs are used, illustrated in Fig. 13.

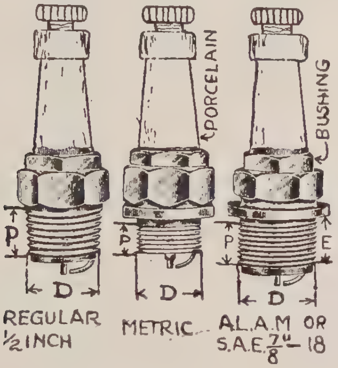

Fig. 13. Regular length of ½″, metric, and ⅞″ spark plugs.

Spark plugs are made with three standard threads (see Fig. 13): the ½″ pipe thread; metric; and ⅞″–18 S.A.E.

The half-inch size is a thread which is a standard ½″ iron pipe size, and has a slight taper.

The seven-eighths inch 18-size is the size which was adopted as a standard by the Society of Automotive Engineers for automobile use. It was formerly known as the A.L.A.M. The thread is ⅞″ in diameter, with 18 threads to the inch. It is used on a majority of the cars today.

The metric size is smaller than either of the others. Its diameter is 18 millimeters, or approximately 11/16″. This is the size of thread for spark plugs, adopted by the Society of Automotive Engineers for aeronautic engines. It is also used on some makes of automobiles and motorcycles. It is used extensively abroad.

S. A. E. Spark-Plug Shell Sizes

Figs. 14 and 15 show the two S.A.E. spark-plug shells. It will be noticed that the diameter of the hexagon part of shells differs. The "small hex." measures ⅞″ across the flat, and has a round gasket flange. The "large hex." measures 1⅛″.

S.A.E. spark plugs are all ⅞″–18, meaning that the outside diameter is ⅞″, and that there are 18 threads to the inch.

Gaskets used with the S.A.E. spark plugs of ⅞″ size measure ⅞″ inside diameter and 1⅛″ outside diameter. The "S.A.E. Reg." measures 13/16″ from shoulder to firing point, and the "S.A.E. Long" measures 1 1/16″.

The ⅞″ S.A.E. plug requires a special tap cutting of 18 threads, whereas the standard ⅞″ thread is 14 threads to the inch.

Fig. 14 Fig. 15

Spark-Plug Lengths

The length of a spark plug depends upon the engine. If the valve cap is deeply recessed as in Fig. 16, a **long body** plug is required, otherwise the wrench could not reach the hex. If it is not recessed, a **long thread** is required. If, however, the valve-cap plug should not screw well down into the combustion chamber, an extension of the spark plug is required, for it is important that the points of the plug extend to the combustion chamber.

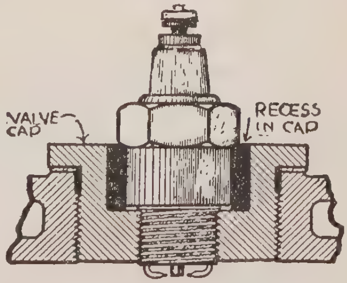

Fig. 16. Note the long body for raising the hexagon part of the plug above the recess in the valve cap so that a wrench can be applied. Different kinds of valve caps require different lengths of plugs. This plug is of the integral type.

Note that the plug points must not extend too far (see Fig. 5). This extension depends upon the distance the plug is to extend; therefore they are made with ½″ and 1″ extension. Figs. 17 to 19 will make this clear.

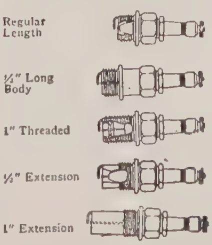

Fig. 17

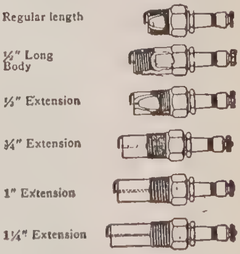

Fig. 18

Fig. 17. ⅞″–18 (threads per inch) S. A. E. thread spark plugs with different length of body or shell.

Fig. 18. ½″ pipe-thread spark plugs showing the different lengths of body.

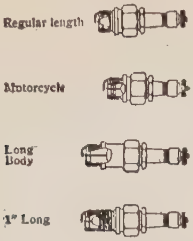

Fig. 19. The metric thread (18 m.m.) spark plug which is also made with different body lengths as shown.

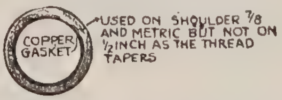
Spark-Plug Sizes and Lengths Used on Leading Cars

Practically all cars, with the exception of the following, use the ⅞″ size spark plug with 18 threads per inch and of the "regular" type, as shown in Fig. 17.

Essex, A: metric, regular, Fig. 19.
Ford, T: ½″ pipe size; regular, Fig. 18.
Jordan, M: ⅞″–18, extension, Fig. 17.
Locomobile, M–48: ⅞″–18, special.
Nash: ⅞″–18, extension, Fig. 17.
Nelson: metric, regular, Fig. 19.
Olympian, 45: ⅞″–18, extension, Fig. 17.
Overland, 4: ½″ pipe size, extension, Fig. 18.
Porter, 46: metric, regular, Fig. 19.
Scripps-Booth, B–39: ⅞″–18, extension, Fig. 17.
Stephens, 80: ⅞″–18, extension, Fig. 17.
Studebaker: ½″ pipe size, regular, Fig. 18.
Willys-Knight, 20: ⅞″–18, special.

Gaskets for Spark Plugs

Copper, asbestos-lined gaskets are used between bushing and shell on all "separable" plugs, to make them leak-proof. They are also used on ⅞″ and metric plugs between the shell and where they screw into the cylinder—but not on the ½″ plug, because it has a taper thread and no shoulder on the shell.

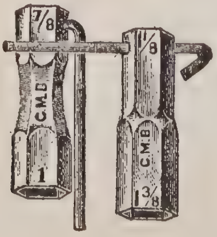


COPPER GASKET
USED ON SHOULDER ⅞ AND METRIC BUT NOT ON ½ INCH AS THE THREAD TAPERS

Fig. 20. Spark plug copper gaskets. Measurements of gaskets are as follows: S. A. E.: ⅞″ (inside di. ⅞″; outside di. 1⅛″); Half-inch: (inside di. 27/32″; outside di. 1 3/32″); Metric: (inside di. 23/32″; outside di. 63/64″).

Spark-Plug Wrench

No. 1. The ⅞″ end of this wrench fits all standard spark plugs, such as the Spitfire, Reliance, Rajah, Red Head, and many others; the 1″ end fits the Sootless, Reliance; the ⅞″ fits the Herz, Bosch, and others.



No. 1 No. 2

Fig. 21. Spark-plug socket wrenches.

No. 2. The 1⅛″ end fits all standard spark plugs of the large "hex." type, such as the Champion, De Luxe, and others. See also Index under "Spark-plug wrenches."

Spark-Plug Gap

The gap is the distance between the points on the plug shell and electrode. It is important that this distance be exact.

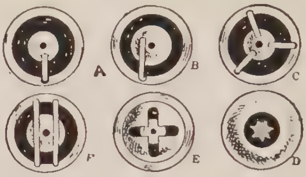


Fig. 22. Different kinds of plug points or gaps.

A spark plug used with magneto ignition should not have too wide a gap, because, when the engine is running slow, the current is weaker.

Relation of spark-plug gap to engine compression: Assume that we have a four-cylinder magneto, the "safety gap" of which is set at ⅜″, corresponding to 8,000 volts, which also corresponds to the voltage required to fire a spark plug having a gap .025″ under a pressure of 65 lbs. If this magneto was required to fire an engine where there was a higher compression of 85 to 90 lbs., even if the mixture represented slightly lower resistance, it would probably fail to fire and, instead, would jump across at the safety gap. However, a slight reduction of the distance between the spark-plug points would lower the effective pressure, so that it would operate in the proper manner. On the other hand, if the engine had low compression, the spark-plug points should be opened up, but if too wide, this would immediately place a greater strain on the spark-plug insulation and if the plug carbonized badly it would be likely to flash over.

Spark-plug gap and compression: For high-compression engines (75 to 80 lbs.) set gap .020″; for medium-compression engines (65 lbs.) set gap .025″; for low-compression engines (55 lbs.) set gap .030″. See Index for "Compression."

It does not always hold true, however, that spark-plug gaps should be set according to compression, because on some engines of high compression the gap is not made less, but the coil is wound for a stronger current to take care of the extra high resistance.

Greater resistance at spark-plug gaps in high-compression engines is due to the fact that air offers less resistance than does gas under pressure. A spark plug in the open air will jump a greater distance than when under pressure. The higher the pressure, the greater the resistance at the gap.

The space between the spark points must be considered an insulator, and it must be remembered that the compressed charge in the cylinder through which the spark is required to jump is a better insulator than uncompressed air.

A spark that will jump the point or gap of a spark plug when the plug is out of the cylinder may not have strength enough to jump when the plug is screwed in the cylinder and under compression. So the spark must be especially strong, and should be able to punch a hole through a visiting card held between the points.

It is essential that the battery be kept charged so that it will deliver its proper voltage with a "single-spark" system—as it is quick and must have pressure enough behind the coil to cause a hot spark.

If points are too close, it will be impossible to run slowly, for the actual area of the flame will be too small.

If the gap is too wide, misfiring (on a high-compression engine) is likely to take place, especially when one tries to accelerate suddenly, after going slow. The effect of opening the throttle and admitting a full charge is to increase compression, and it is a well-known law that resistance increases with pressure.

The coil will operate up to 1/32", but bear in mind that the greater this distance, the more strain on the coil and the "leaner" the spark.

Therefore the gap depends upon: (1) the kind of ignition system; (2) the amount of compression of the engine.

Where a vibrator coil is used, the usual distance is about 1/32". With a "single-spark" system, however, such as the Atwater-Kent, where the spark is very quick, the gap must be very small, about .025". In fact, this is the average distance.

On 4, 6, and 12-cylinder engines, the spark-plug gap is .025" and on 8-cylinder engines .020". The spark-plug gap where a Bosch NU4 magneto is used is .016".

To experiment, try setting the plug point on, say, one cylinder until it misses on a hard pull up hill with throttle closed or as much closed as it will pull up the hill comfortably. Then slightly close the gap and try the hill again, and continue experimenting in this way until the missing stops. When the correct distance is found, then set the other plugs accordingly.

Where spark plugs are used on magneto ignition, and also on the Ford, the metal electrode of the plug is carefully figured out as to its resistance capacity, as a very heavy voluminous spark requires an electrode of somewhat higher resistance metal, to prevent burning and pitting. **Therefore always use a spark plug that is recommended by the manufacturer.**

To Clean Spark Plug

To clean a spark plug: Unscrew the bushing which holds the porcelain in the shell, remove the porcelain (or mica) and soak the shell and porcelain in kerosene or gasoline. Clean all carbon off each. **Don't scrape porcelain,** as it will roughen the glazed part and cause it to retain carbon, and will also cause "porosity," which causes electrical leaks. If the oil is burned on the porcelain, muriatic acid will remove it. In placing the porcelain back into the shell, be sure that the copper washer is placed back and that the bushing screwed tight so as to prevent leaking. Alcohol is also used for cleaning spark plugs.

SPARK INTENSIFIER

This device consists of an insulated base and screws for adjusting (Fig. 23).

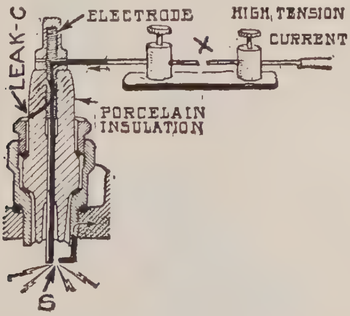

Fig. 23. Spark intensifier.

The purpose is to provide a gap (**X**) in series with the high-tension circuit for the spark to jump before it reaches the plug. It is claimed that this will intensify or raise the voltage of the high-tension circuit to such an extent that it will jump across a carbonized plug in spite of its fouled condition.

The extra gap throws an additional load on the coil. Naturally, if it is not well made, the high voltage will be very likely to break down the insulation. Furthermore, a fat voluminous spark is hotter and will ignite the gas quicker than a thin, lean spark. Although the intensified spark will jump across the fouled part of a plug, the spark is thin, and it is best to use good clean plugs. It is a question whether or not the intensifier will add anything to the efficiency or performance of a clean-running engine; if so, the gap at the spark-plug points might be widened. This, of course, would be impractical as the gap under compression offers more resistance to a jump than in the open air; but at that, if the gap in the cylinder was widened in proportion, this cylinder would likely miss fire.

One theory is that the intensifier is beneficial where a plug has a tendency to collect drops of oil on the points, and that by increasing the intensity the spark will jump through the oil. There is one thing certain, and that is that any electric current is going to follow the path of least resistance.

The action is this: In order to cause the spark to jump the gap (S) at the spark plug in the cylinder, 5,000 or more volts are required. Suppose, however, that the spark plug has an accumulation of carbon from the porcelain insulation to the plug shell, or a crack in the porcelain which fills up with carbon, oil, and dirt, as at (C) to the electrode (Fig. 23). Although this path is longer than the spark-plug gap, it is not under compression and thus it offers less resistance than does the gap (S), or, in other words, it requires less voltage to go over the carbonized path. There is then a leak of voltage at the carbonized path which prevents 5,000 volts reaching the plug-gap (S). This explains the reason for its missing.

If the intensifier gap (**X**) is provided, this temporarily acts as a dam to the flow of current, and, like flowing water, it will pile up against the dam and thus establish a greater force when released. After the breakdown of the dam, the current comes with such a rush that it cannot all pass through the carbon path, and as its voltage is now sufficient, it will also jump the spark-plug gap.

THE MISSING SPARK

If the engine misses explosion, the trouble may be due to carburetion being at fault (see "Digest of troubles" and "Carburetion"). If the trouble is not with carburetion[1], then the chances are the spark plug is missing through being fouled. The spark plug causes more trouble in this respect than any other part of the ignition system.

The cause of spark-plug sooting and pre-ignition: A poor grade of oil or too much oil will turn to carbon (soot), and will deposit on the end and inside of the spark plug, and "short-circuit" the plug, so that the spark will not occur at the point, consequently causing missing of explosion.

Poor oil or too much oil will also leave carbon or soot deposit on the end of the piston and inside of the combustion chamber. This deposit hardens, and sharp points of it will project. This projection will become white hot, causing the gas to ignite before it is time. This is called premature or "pre-ignition."

Spark-plug troubles are therefore usually as follows: short circuit from carbon, cracked porcelains, electrodes burned away, spark plugs not pressure tight, moisture condensing on insulator.

There are several general causes for ignition missing, or for a failure to ignite the gas, as follows:

1. **Lack of current** from the battery.
2. **Loose connections.**
3. **Burned out or thin resistance unit** occasioned by excessive heating, thus permitting only a small amount of current to pass through.
4. **Improperly set interrupter** points.
5. **Defective condenser,** causing sparking at the interrupter points and weakening the spark.
6. **Defective primary winding.**
7. **Spark-plug crack** on that part of the plug which is not in the cylinder under compression. This crack fills up with oil and dirt, and while the crack is longer than the spark-plug gap, it is not under compression. The result is, usually, missing at low speeds and hard pulls, but hitting on high speeds.

   The reason for this is because at low speeds and on hard pulls the throttle is wide open and the low piston speed greatly increases the degree of compression. Compression offers greater resistance; therefore the spark takes the easiest path, through the carbon.

   At high speeds, the cylinders do not have time to fill up with gas and, the piston speed being greater, the degree of compression is not so great in comparison; thus there is sufficient voltage to jump the gap.
8. **Carbonized spark plugs,** of course, will cause missing at low or high speeds.
9. **Burned points,** due to excessive current. For instance, the Ford spark plug, unless of the proper quality of metal in the electrode, will burn the points badly due to the excess of current. This coil should be adjusted according to instructions on page 222, and only high-grade Ford plugs should be used.
10. **Moisture on the outside of the porcelain** at high voltages will cause the current to leak over the surface of the shell as in Fig. 24 (10).

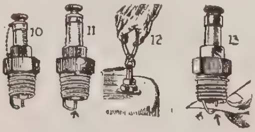

Fig. 24. Spark-plug troubles.

11. **Points may have come together** as in Fig. 24 (11), when they were screwed into the cylinder.
12. **Wire may be loose** on the terminal (Fig. 24) (12).

To adjust the gap, use a thickness gauge or paper (Fig. 24) (13). Adjust to $\frac{1}{32}$″ for vibrator coil ignition; to .025″ for non-vibrator coil ignition, and to about $\frac{1}{64}$″ or .015 to .020″ for magneto ignition.

To Find Cause of Missing

First, check the ignition circuit, and also find the cylinder which is missing by loosening the spark-plug wire from one plug at the time and holding it about 3/16″ away from the spark-plug shell (Fig. 25). With the engine running slow, the sparks should be counted for at least 50 without missing. It is safe then to assume that the ignition is doing its part.

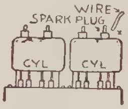

Fig. 25. Testing the ignition system by observing the steadiness and intensity of the spark.

If there is missing and the spark is not hitting regularly, then clean the interrupter points and see if they are properly adjusted; look for loose connections; see if the current from the battery is of proper strength; try another coil, if results are not obtained otherwise.

Second, check the spark plugs. It is useless to check these until you first know that your ignition system is in perfect order. If good sparks have been obtained on the first test, then proceed to test each spark plug with the engine running and the ignition switch "on," as follows:

Place the point of a screwdriver (Fig. 26) on top of the plug terminal, and hold the metal part of the screwdriver on the metal part of the engine, thus killing the spark in this cylinder.

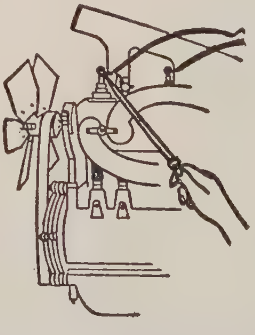

Fig. 26. Testing to locate the spark plug which is missing, after determining that the missing must be attributable to the spark plug. (Be sure to use a wooden handle screwdriver, and do not stand on damp ground, thus avoiding a shock.)

If there is now no noticeable difference in the running of the engine when the spark plug is cut out in this manner, it is evident that this plug has not been firing even before it was killed or shorted by the screwdriver. Thus the missing plug is located.

---

[1] Carburetion troubles are dealt with elsewhere. Missing is quite common when first starting the engine with cold, unvaporized gasoline. Therefore be sure that the trouble is not due to carburetion.

It is possible that a **sticking valve** or other engine trouble may cause missing. Remove the spark plug from a cylinder which you know is not missing and exchange it with the plug in a cylinder which is missing. If the missing continues, then you know it is not in the plug.

On eight-cylinder and twelve-cylinder engines it is difficult to locate missing. A good plan is to detach all the spark-plug wires from one side, or block, and lay the wires on the engine (in order not to overload the coil). Also open the relief valves, so that one side only will run on power. Thus it is easier for the test as outlined above.

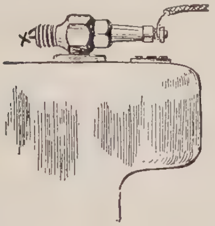

Fig. 27

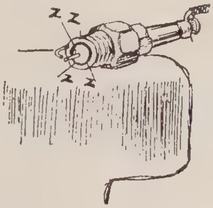

Fig. 28

To test a spark plug to see if it is carbonized: Place the spark plug on the cylinder with wire connected and switch on (Fig. 27). Crank the engine slowly. If the spark occurs at the gap (**X**) the plug is in order. If it sparks up inside of the shell, between the porcelain and shell at (**Z**) (Fig. 28), it is fouled and misses. It must then be taken apart and the carbon must be removed.

Remember the plugs may spark in the open air, but when under compression will fail to spark, because the resistance is greater. Therefore be sure the spark-plug gap is correct.

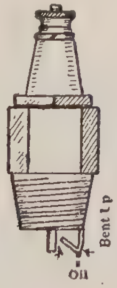

Fig. 29

Too much oil in the combustion chamber may have a tendency to cause missing due to the current passing through the oil. A good plan, if the plug points are of the type shown in Fig. 29, is to bend the outside point, as shown, which may cause the oil to collect at the bend instead of the gap

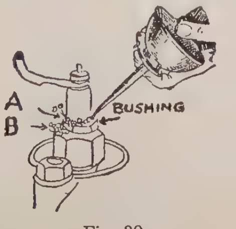

Fig. 30

To test for a spark-plug leak around the porcelain at the top (**A**) of bushing or below (**B**) where the bushing is screwed into the shell of plug (Fig. 30): squirt gasoline at these points, while the engine is running and note if bubbles appear. If so, there is a leak, and if tightening of the bushing does not remedy the trouble, then put in a new gasket.

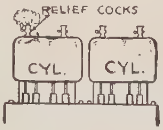

Fig. 31

A method often used to see if a **cylinder is firing** is to open the relief cocks, one at a time (Fig. 31). Watch for the flame shooting out of each opening and listen for the sharp reports of the explosions. The cylinder without flame, out of which issues only hiss, but no sharp report, is the one at fault.

This test, however, is not reliable, because, when the relief cock is open, air is drawn into the cylinder which mixes with the carburetion mixture and thus changes the proportions of the mixture.

The Airco Ignition Tester[1]

The tester consists of an insulating hard rubber shell into which is packed a sensitized glass tube of Neon. When the metal cap, which permanently seals one end of the tester, is brought into contact with a high-tension electric current, the Neon becomes luminous and emits flashes of orange-red light, visible through the indicator opening in the side of the case.

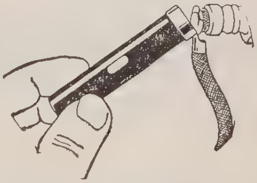

Fig. 32. The Airco tester as applied to the end of a spark plug. Flashes occur in the white gap if there is current. If placed on an insulated wire conducting a high tension, current flashes will occur.

The active element in the Airco ignition tester is a gas which the Air Reduction Company extracts from the air through a process of mechanical and chemical operation. This particular gas which is known as "Neon" has the peculiar property of becoming luminous when brought into contact with electricity. (See Index under "Neon gas.")

Neon, as applied to the Airco ignition tester, is contained in a small glass tube, the ends of which have been plated similar to the manner in which a mirror is silvered. The entire tube is then packed inside of a hard-rubber shell, and a quantity of steel wool is used to make the contact between the metal cap of the hard-rubber tube and the silvered end of the glass tube containing the Neon. By placing this device to the end of the spark-plug terminals, or even on the insulated wire itself, if there is a high-tension current passing in the wire, the gauge becomes luminous or emits flashes.

The following indications point to trouble:

No flashes: Spark plug completely fouled or shorted, or no current to the plug.

Flashes continuing for an unusual distance as the gauge is withdrawn from the plug: Broken plug—probably broken porcelain.

Very intense flashes: Spark gap too wide.

Overlapping flashes (not clean-cut with each piston stroke)**:** Leaks between feed wires or fouled distributor.

Dim or irregular flashes: Plug partly fouled, or feed wire leaking excessively. Examine plug.

INSTRUCTION No. 24

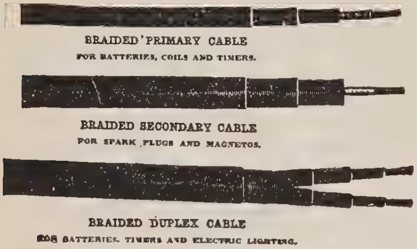
WIRE FOR IGNITION SYSTEMS

There are three kinds of ignition wire for general use with the ignition system of a car, as follows:

Primary wire or cable, made of several strands of fine wire in order to make it flexible and insulated, oil and moisture proof. This wire is usually used between the battery, coil, and timer for all low-tension work, and must be of sufficient size to carry the current. Usually No. 14 or No. 16 size is used.

Secondary cable is also made flexible and the insulation on the wire is much heavier. This is used to conduct the high-tension current from the coil or magneto to the spark plugs. It should be kept free from all metals, as much as possible. Size is usually No. 16 or No. 14.

Duplex cable is also flexible, but generally two to four wires are run in one insulation, being separated, of course, from each other by insulations. This wire is generally used for lighting and low-tension work.



BRAIDED PRIMARY CABLE
FOR BATTERIES, COILS AND TIMERS.
BRAIDED SECONDARY CABLE
FOR SPARK PLUGS AND MAGNETOS.
BRAIDED DUPLEX CABLE
FOR BATTERIES, TIMERS AND ELECTRIC LIGHTING.

Fig. 1. Ignition wires.

Metal conduit: A good plan in wiring a car, where several wires are run together, is to enclose the wires in a metal conduit. See Index under "Wire for wiring a car."

The wires running from coil, or magneto distributor to the spark plug, carry the high-tension current and are called "secondary cables." This current escapes more readily than from the wires running from the battery to the timer or coil. The wires running to the plugs are called "high tension" wires because the tension or voltage is high and current will often jump through the insulation and short-circuit (cutting out spark plug) to any metal part it happens to be in contact with. For this reason these wires must be carefully protected and very heavily insulated.

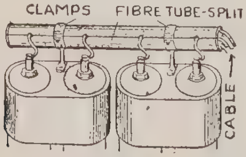


Fig. 2

Fig. 2 shows one method of distributing the secondary or high-tension cables on multi-cylinder engines. A divided fiber tube supported on brackets encloses the cables and permits of easy inspection or renewal if required. Any number of leads or cables can be distributed. The eight plug leads required for dual ignition on a four-cylinder engine can be accommodated in a two-inch fiber tube.

The primary wires running from the battery to the timer or to the interrupter on the magneto are "low tension." They do not need to have as heavy insulation, but the connections should be well made and clean because the pressure is so low that the current will not pass over dirty or loose connections, and a loss of current will result. All connections ought to be soldered and taped.

Do not use lamp-cord wire under any circumstances as it will give unsatisfactory results and cause missing if damp. Wire for the electric horn is usually No. 18.

Size of Wire Used for Winding a Coil and Magneto

Primary winding is No. 19 to 24 B. & S. gauge copper insulated wire. **Secondary winding** is No. 34 to 38 B. & S. gauge silk-covered insulation.

There is usually a ratio of about 60 to 1. For instance, if the primary consisted of 200 turns, the secondary would have 12,000 turns.

The winding of a Bosch DU4 magneto armature usually consists of three layers of No. 20 or No. 22 wire, to form the primary winding, and of 70 to 72 layers of No. 36 silk-covered wire to form the secondary winding. The reader, however, never has occasion to bother with wire on a coil or magneto armature as this is the work of a specialist.

Making Connections and Ignition Wiring Troubles

A grounded connection should be filed or scraped bright before attaching the wire, and the connection when made should be covered with vaseline or paraffine. A copper washer should be placed under the head of the screw, to hold the wire firmly in position, and tightly drawn up.

All connections must be bright and clean, for a dirty connection will add resistance. Binding posts, screws, and the ends of the wire must be scraped clean before the wire is attached. This is very important on low-voltage wiring.

When joining two wires or attaching terminals (Figs. 3, 4 and 5), solder and then tape.

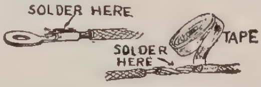

Fig. 3 Fig. 4

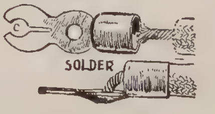

Fig. 5

Figs. 3, 4, and 5 show how to make a connection with wire and terminal; solder and tape all connections.

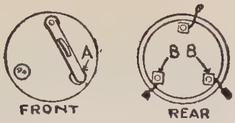

Fig. 6

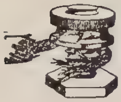

Fig. 7

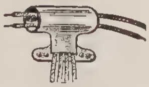

Fig. 8

Fig. 6. Loose switch terminals will cause missing as will also loose binding posts (Fig. 7).

Fig. 8. A good method of protecting primary (battery) wires when they run along the frame.

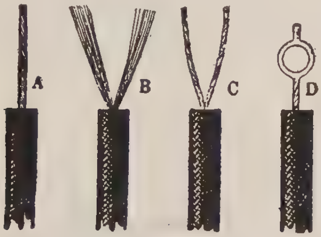

Fig. 9. Four steps in making loop end: (A) insulation removed; (B) separating the strands; (C) twisting wires into two leads; and, (D) the looped end dipped in solder. (*Motor Age.*)

No possible cause for leakage of the current should exist; a single strand of fine wire projecting from a flexible cable will be enough to cause a short circuit if it should touch metal.

Missing of ignition where dry cells are used (Fig. 10) may be due to weak batteries. To test, use an amperemeter. Test each cell separately by placing the terminal of the meter on the terminal of the battery. Each battery ought to show 15 to 25 amperes. If less than 8 amperes are shown, replace. If one should test, say, 10 amperes, and another 20, then the good battery will be brought to the level of the poor battery. Remove it and put in a fresh one. See Index for "Testing a storage battery."

An emergency dry-cell connection is shown in Fig. 11. Usually two sets of dry cells are provided when ignition is on dry cells alone. Only one set at a time is used, however. If both sets should run down, a multiple connection of the two sets can be made, as shown, which will suffice to enable the car to reach home. Dry cells are now seldom used.

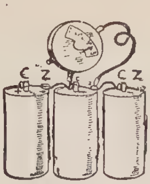

Fig. 10

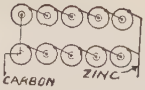

Fig. 11

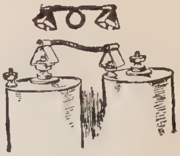

Fig. 12

Quite often missing will occur from loose connections at the battery terminals (Fig. 3). See that they are always tight. On some connections, the wire may be broken or not soldered well to the terminal. A good connector for dry cells, called the "Bull Dog," is shown in Fig. 12. For storage batteries, see Index.

On many cars one wire is grounded (Fig. 13). It is therefore essential that the grounded connection be well cleaned and then tightened. A copper terminal should be soldered to the wire, the surface cleaned, and drawn tight with a bolt.

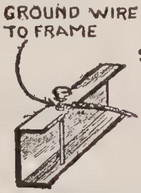

Fig. 13

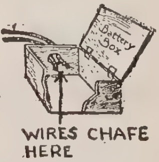

Fig. 14

When metal battery boxes are used (Fig. 14), and dry cells are placed in them, dampness will short-circuit the batteries through the paper insulation around them. Therefore keep the box dry inside, and watch the wire where it passes through the metal box.

Fig. 15

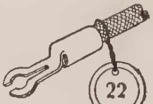

Fig. 16

When removing the wires (Figs. 15, 16), mark them by painting the ends with cheap water colors, or tag them, thus saving a lot of time when replacing.

INSTRUCTION No. 25

LOW-TENSION MAGNETO: Principle of Magneto Ignition

In the preceding instructions, we dealt with the low-tension coil, using only a primary winding, and the high-tension ignition coil using a primary and secondary winding.

In this instruction we shall deal with the low-tension magneto, a mechanical generator of a low-tension alternating current.

The difference between a low-tension magneto and a high-tension magneto is that, on the low-tension magneto armature core there is but **one winding,** called a primary winding, whereas on the high-tension magneto armature there are **two windings,** a primary winding and a secondary winding.

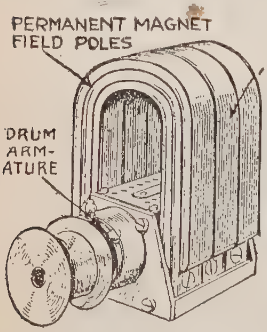

Fig. 1. Magneto.

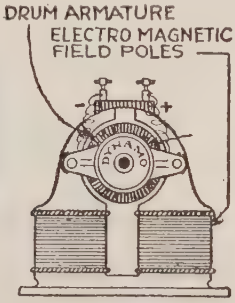

Fig. 2. Dynamo.

Mechanical devices, such as **a magneto** and **a dynamo** (Figs. 1 and 2), are termed **mechanical generators of electricity.** The armature, which revolves between the pole pieces, is driven by the engine, and alternating current is generated.

Alternating current is suitable only for ignition, and all magnetos generate alternating current.

Where a generator (dynamo) **is required** to charge a storage battery, it is necessary that **the current should be "direct,"** that is, flowing in one direction continuously, from positive (+), to negative (−).

Therefore, while, as stated above, all generators or dynamos or magnetos generate alternating current, on a generator used for charging a storage battery, the **alternating current is transformed,** or commutated, into a "direct" current by means of a commutator and brushes. Thus while alternating current is generated inside, direct current is delivered outside, or from the brushes. Generators of direct current supply current for coil ignition and lights, and also charge a storage battery. This subject is explained under "Generator principle," farther on.

The magneto generates alternating current inside and delivers alternating current outside, and, as previously stated, is suitable only for ignition. It will not charge a storage battery because the electric current it generates flows first in one direction and then in another direction, and thus "alternates" its flow.

Construction

The principle of a low-tension magneto is similar in many respects to that of a low-tension coil. In a magneto, the armature on which the primary wire is wound is called upon to produce its own electric supply, whereas in a primary or low-tension coil, the electric supply is from another source.

Field magnets: Permanent magnets (1a), called the "field magnets," are provided as shown in Fig. **1A.** The **pole pieces** (11a) provide a magnetic field for the shuttle-type armature (Fig. **4A**) to revolve in. End plates with ball bearings are attached to screw holes in pole pieces (**11a, Fig. 1A**). There is very little clearance between the armature and the poles, and therefore accurate fitting is necessary.

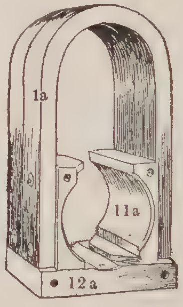

Fig. **1A.** Permanent magnets (**1a**); pole pieces (**11a**); base of brass or aluminum (**12a**).

There are usually two, four, or six magnets placed over the pole pieces; all north poles on one side and all south poles on the other side. The base (12a) is usually made of brass or aluminum, as neither will become magnetized.

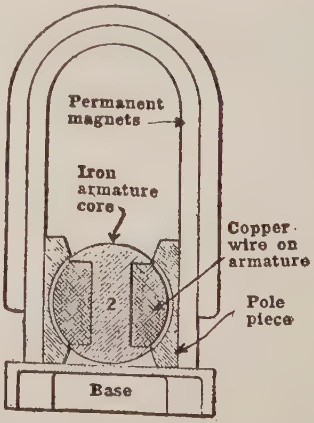

Fig. **1B.** View of a low-tension magneto with the end-plate off and the armature shown in section. (1) permanent magnets (magnetized at all times); (2) the armature, revolved by a gear connected with the engine shaft. Note that a single winding of insulated copper wire is wound on the armature.

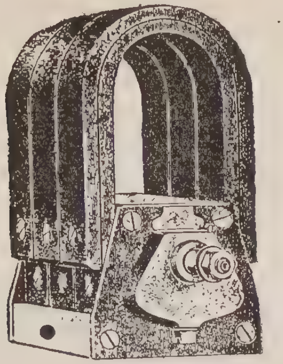

Fig. 1C. The low-tension magneto complete. View shows the drive end of the armature, which is driven at a fixed speed from the crank shaft of the engine, by gear or chains. The direction of rotation of all generators is considered at the drive end.

The armature of a direct-current generator (Fig. 3) is called a "drum-wound armature." It differs from a magneto armature in that the coils wound over the armature core are connected in such a manner with the commutator segments that the current delivered from brushes resting on the commutator segments is direct.

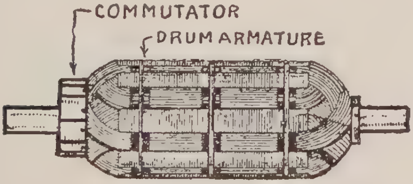

Fig. 3. Armature of a direct-current generator.

This drum-type armature could be made to revolve between permanent magnets, and current would be generated, but it is not practical, because the voltage must be a steady voltage. And since the voltage increases with speed, the armature of a direct-current generator is made to revolve between poles which are wound with wire, called "electro-magnets." This subject is dealt with under "Direct current generators," farther on.

Permanent magnets are of the horseshoe type and are permanently magnetized. They are called the "field" magnets.

Electro-field-magnets are wound with copper wire and are electrically magnetized. They remain magnetized only when the armature revolves between the field-magnet poles. This type of dynamo or generator generates a steady "direct" current, usually of 6 or 8 volts, and will light electric lamps and recharge a storage battery and supply current for ignition. It is usually run in connection with a starting and lighting system, and, in smaller models, is used for ignition on stationary and marine engines to a considerable extent.

The armature of a magneto, which delivers alternating current, is called a "shuttle-type armature." It revolves between the poles of "permanent field magnets."

The parts of an armature are as follows: Bronze heads (**B, B1**) are screwed to the armature core (**C, C1**) (Fig. 4). Shafts (**A, A1**) are driven and riveted to the bronze heads. Wire is wrapped around space (**C, C1**), called the core.

It will be seen that the core is not a solid casting; rather it is a pair of castings between which is clamped a group of soft iron stampings (**D**), having the form shown in the detail sketch. The object of thus "laminating the core," as it is called, is to retard the circulation of "eddy currents" in the core due to induction. The same forces of induction which are at play in the windings operate also in the iron core itself, and if unchecked, would both consume power and heat the armature unduly. As the voltage of these currents is very low, even the slight obstruction of the laminations is sufficient to retard them.

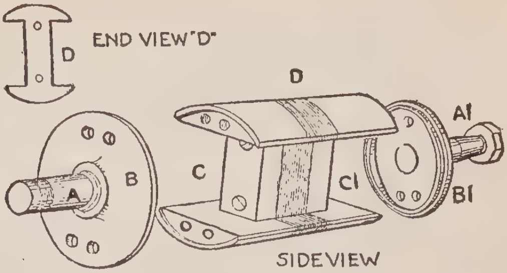

Fig. 4. Magneto armature core and end plates. The winding is placed on the core C and C1.

The laminated section of the armature is shown at (**D**). "Laminated" means that instead of the castings (**C**) being solid, there are several layers of flat sheet iron placed together, between the cores (**C**), as shown at (**D**).

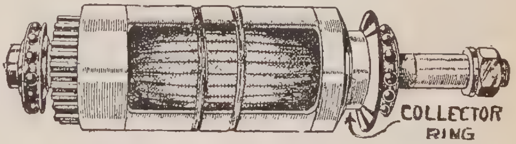

Fig. 4A. Shuttle type of armature with one winding (low-tension).

The completed magneto shuttle-type armature is shown in Fig. 4A. Note the "collector ring," from which the current is taken by a brush resting on the flat surface of this ring.

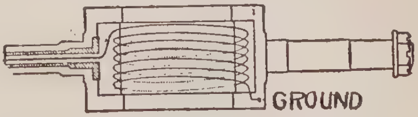

Fig. 4B. Primary winding on armature core. Note that one end is grounded to the core and the other end is insulated.

The single primary winding is shown in Figs. 4B and 4C. One end (**A**) conducts the current from the armature to the collector ring and the other end is grounded (**G**).

A sectional view (Fig. 4C) shows one method of conducting the low-tension current from the armature, where a collector ring is not used. The principle, however, is similar.

One end of the primary winding, which is heavy, coarse wire, is grounded to the armature core at (**G**). The other end (**A**), is insulated and passes through the hollow end of the armature shaft and makes contact with a point (**D**).

As the armature revolves, the spring (**S**), which is mounted on an insulated block (**IB**), conducts the current through a wire connected with it, to the terminal. "Collector rings," are more often used.

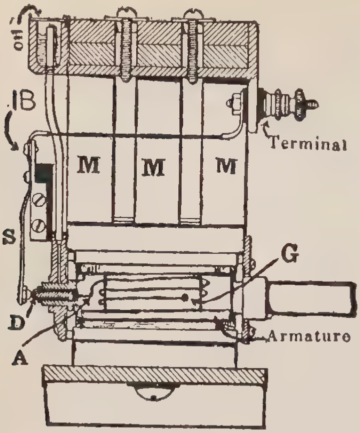

Fig. 4C

From the terminal the current is carried to the "igniter," as in Fig. 5. This is a "make-and-break" low-tension ignition system similar to the system described on page 185.

It will be noted, however, that a separate low-tension coil is not necessary in this instance, as the winding on the armature takes its place.

If the low-tension magneto is used in connection with a separate high-tension coil, then this wire (A) (Fig. 4C) from the armature would go to the primary winding of the coil.

Two methods of utilizing the low-tension magneto are therefore used, as follows:

1. In connection with a low-tension "make-and-break" ignition system.
2. In connection with a high-tension coil.

Low-Tension Magneto Supplying Current for a "Make-and-Break Ignition System

On page 185, this system is explained. The magneto, however, was not explained.

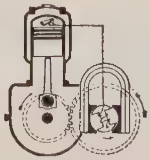

Fig. 5. Low-tension magneto supplying current for a low-tension "make-and-break" ignition system.

It is well to bear in mind that a low-tension magneto used in connection with the low-tension "make-and-break" system, shown in Fig. 12, page 185, **does not require a low-tension coil,** because the action of intensifying the current, is obtained by the snapping of the "igniter" points, by action of a cam, and the winding on the armature of the low-tension magneto takes the place of the low-tension coil. See also explanation, page 186.

Low-Tension Magneto and High-Tension Coil

The low-tension magneto can be used in connection with a high-tension coil and produce a "jump-spark" or high-tension spark at points of a spark plug in the cylinder, by using the low-tension magneto to produce the current, and a separate high-tension coil (without vibrator) to intensify the low-tension current to a high pressure, so that it will jump the gap of the spark plug.

We should need for this system **a high-tension coil, a distributor** on the magneto to distribute the high-tension current to the spark plugs (if a multiple-cylinder engine, which, in this instance, we will say, is a four-cycle, four-cylinder), and **an interrupter** to break the low-tension current at the proper time.

The coil: The double-wound high-tension coil, but without a vibrator, can be used. The interrupter will take the place of the vibrator. Therefore we should have a single spark instead of a succession of sparks. When the contact points separate, as explained under "Interrupter," the low-tension magneto current is intensified, and "induced" current is set up in the secondary winding. This coil can be placed separate from the magneto.

The distributor: This "induced" or high-tension current is then distributed to the spark plugs in correct firing order by the distributor rotor and brush, as shown in Figs. 6 and 6A. The distributor is driven at one-half the speed of the armature.

The interrupter[1] (see Fig. 6A) is mounted on the front end of the magneto armature shaft. The housing on which the interrupter parts are mounted can be shifted, by means of a rod (**SL**) (Fig. 6**A**). This rod connects with the spark lever on the steering wheel.

Therefore the time for the spark to occur can be made early ("advanced"), or late ("retarded"). The usual range of advance on a magneto is from 22° to 35°.

Attached to the housing, and moving with it, is the interrupter arm (**A**) and the terminal (**B**).

On the end of the interrupter arm (**A**) is a platinum point (**P**). There is also another platinum point (**P**) on terminal (**B**).

Platinum is used because there is more or less sparking occurring at the points and, platinum being hard, it stands the spark with less pitting than other metals.

The condenser is in the coil and takes up excess sparking to a great extent. This condenser can be placed in the coil box or on the magneto.

The cam (**C**) is attached to the front end of the armature and revolves with it.

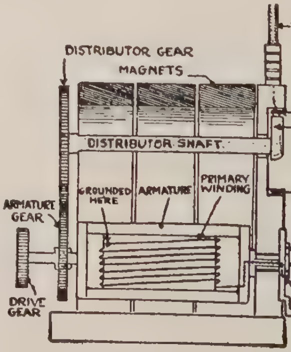

Fig. 6

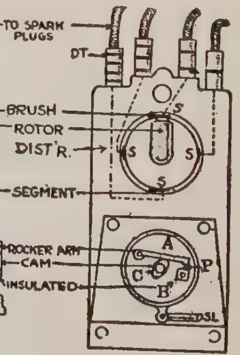

Fig. 6A

Fig. 6. Note how the distributor shaft is driven by the gear on the armature.

Fig. 6A. Front view of distributor and interrupter.

---

[1] There are many different constructions of the interrupter. This one is shown in order to simplify the explanation.

When the nose of the cam raises the interrupter arm (A), the current is interrupted in the primary winding, causing the high-tension current to be set up in the secondary winding of the coil.

The cam has two lobes. It will therefore raise the interrupter arm twice during one revolution, or four times during two revolutions of the armature. The armature would then run at the same speed as the engine crank shaft. As the cam (C) is attached to the armature, it must revolve with it.

The cam is set on the armature, so that the nose will raise the interrupter just as the armature is in a vertical position.

If the cam raises the interrupter arm (A) when the armature is in a vertical position and the interrupter housing is at full retard position, this will then allow for advancing of the spark full 35° or less, according to the range of the magneto.

The primary circuit on the armature of the low-tension magneto consists of a winding of coarse wire. One end is grounded to the armature core (see Fig. 6), and the other end is carried to the insulated terminal (B, Fig. 6A).

The armature revolves, therefore the end of the armature primary winding, from which the low-tension current is taken, is carried through the end of the armature shaft (insulated).

The current is then carried through the primary winding of the coil, to the insulated terminal (B), through the interrupter points (P) (which open when the armature is in maximum position), to arm (A) which is grounded, thence to the other end of the magneto primary winding, which is grounded to the armature core (Fig. 6). This completes the primary circuit of the magneto and high-tension coil. See Figs. 38 and 39 for two different methods of connecting a low-tension magneto with a high-tension coil.

The secondary circuit is clearly shown in Figs. 38 and 39, page 252.

The magneto armature must be driven at a fixed speed because the interrupter and the position of the armature govern the time of the spark. Therefore the magneto is either driven by a chain or by a gear from the cam shaft, but not by a belt. This subject is treated farther on.

Also bear in mind that **the magneto is a closed-circuit system,** and interruption of the closed circuit by the interrupter points being separated by the cam occurs when the spark takes place.

Note the arrangement of the interrupter on page 258. It is a different construction from that shown in Fig. 6A. The interrupter on page 258 is more modern. The one in Fig. 6A is simplified.

Remarks Relative to Distributor on a Low-Tension Magneto Operating a High-Tension Coil

The purpose of the "high-tension" distributor is to distribute the high-tension current to the spark plugs. The distributor brush in the end of the rotor should make contact with one of the spark-plug leads just as the interrupter points (P) are breaking. See the discussion farther on, explaining connections to the distributor.

The distributor is usually attached to the magneto—when operated with a magneto, either of the low or high-tension type.

The distributor is usually made of hard rubber insulation material with metal segments (S). The rotor with a brush revolves by means of a gear wheel twice the size of the gear wheel on the armature (Fig. 6).

The armature for a four-cylinder magneto would revolve at engine crank-shaft speed and make four sparks during the two revolutions of the crank shaft.

The distributor, however, would revolve once and the rotor brush would make four contacts during two revolutions of the crank shaft, or one revolution of the distributor rotor. Hence the reason for the larger gear on the distributor.

On a six-cylinder engine the armature revolves 1½ times to one revolution of the crank shaft, but the distributor is geared to turn at half the speed of the crank shaft, or one complete revolution to two revolutions of the engine crank shaft.

There are two kinds of contact arrangements on a distributor: the "gap-type," and the "brush-type." The gap type does not make a wiping contact, but a slight gap clearance is allowed between the distributor rotor and segment (S). The brush type makes a wiping contact.

It must be remembered that while we are referring to the magneto distributor of the true "high-tension type magneto"—to show the parts of a "high-tension distributor"—the distributor used with the low-tension magneto and separate coil differs only in that on a true high-tension magneto there are two windings on the armature which take the place of the separate coil.

Dual System; Low-Tension Magneto, Coil, and Battery

A dual system of ignition is where a set of batteries are provided to start on. After starting the engine, the magneto is used as a source of electric supply instead of the batteries.

Types of Magneto Armatures

Magneto armatures may be classified as of two types. Although this instruction deals with low-tension magnetos, it will be necessary to allude to the armature of the high-tension magneto in order to make the explanation clear.

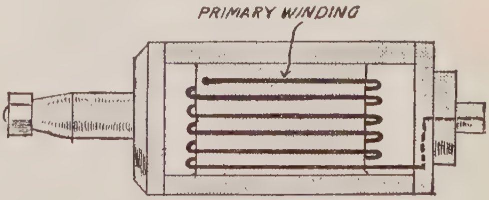

Fig. 7. Primary armature.

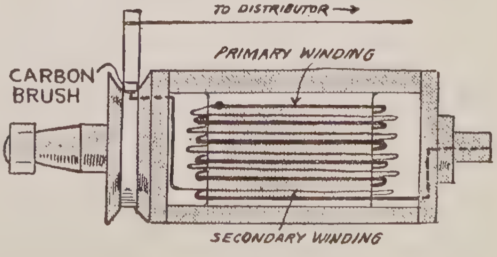

Fig. 8. Compound armature.

Magneto armatures are known as of the "shuttle" type because they are shaped like a shuttle. They are further classified as the "armature" type and the "inductor" type.

The "armature" type is where wire is wrapped around the armature core and the armature and wire revolve between the permanent magnet field poles. The armature type can be a single primary-wound armature used on a low-tension magneto, as in Fig. 7, termed a "primary-armature type." If there are two windings on the armature, a primary and secondary, as in Fig. 8, which is used on a high-tension magneto, then it is termed a "compound-armature type."

The "inductor" type of armature differs from the "armature type," principally in that the wire does not revolve. The inductor type of armature can be a low-tension magneto or a high-tension magneto, and differs from the armature type magneto only as mentioned above.

K. W. Inductor-Type Magneto

The K. W. Ignition Co. makes a low-tension and a high-tension inductor-type magneto. The Remy Electric Co. formerly made a low-tension inductor type of magneto used with a high-tension coil, as explained on page 247.

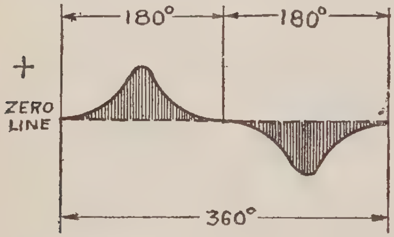

Fig. 9. Note that the shuttle type of armature produces two impulses or waves, of maximum strength per revolution (360°).

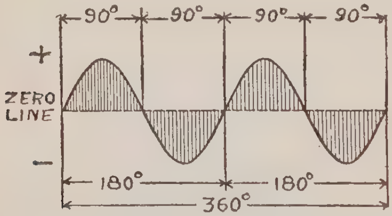

Fig. 10. Note that the K.W. "inductor" type of armature produces four impulses or waves, of maximum strength per revolution. (The line is zero, or no current.) Also note that the direction of the flow of current is changed twice in Fig. 9, and four times in Fig. 10, during a revolution.

The K. W. inductor type magneto is a leading magneto of the inductor type. Construction: magnets, permanent type; pole-pieces placed above armature 90° apart; rotors set 90° apart. There are two rotors with four ends as shown in Fig. 11, which illustrates the arrangement of the rotors on the armature shaft. This gives the same effect as if two shuttle armatures were placed cross wise—which would be four impulses per revolution (Fig. 10) instead of two in the shuttle type (Fig. 9). If we continued adding rotors we should soon have the alternations so close together that we could light an electric lamp—in fact, the K. W. low-tension magneto at high speeds will accomplish this.

The coil winding between the rotors of the K.W. magneto (Fig. 11) is stationary and the rotors revolve. With a single primary winding on this coil core it is a low-tension magneto. With two windings, it would be a high-tension magneto.

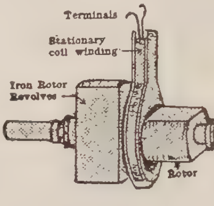

Fig. 11

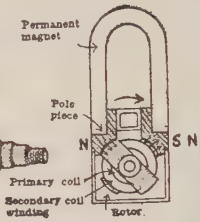

Fig. 11A

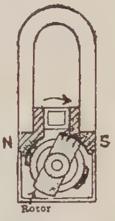

Fig. 11B

Fig. 11 shows the "inductor-type armature." Note that the winding is stationary.

Fig. 11A, shows the lines-of-force passing down through the rotor wing from N pole, then centrally through the core over which the coil is placed, up the rotor to S pole.

Fig. 11B shows rotors moved in position where the lines-of-force are now passing in the reverse direction, which causes a complete reversal of polarity through the coil winding. This is maximum position, where contact points (P) should separate.

Interrupter points are used on the K. W. inductor-type magneto when of a high-tension double-wound type.

The K. W. Low-Tension Inductor Type Magneto and Master-Vibrator

The K. W. inductor type of low-tension magneto, used with a master-vibrator, is shown in Fig. 12. Dry cells are used as a source of supply for starting when the switch lever is on the left, or (B) side. The magneto is used when the switch is on the (M) side. Note that the vibrators on the dash coil are short-circuited, as seen in the top left illustration, and are not used on the multiple dash coil to the right, as the one vibrator on the master-vibrator coil does the vibrating for the four coils.

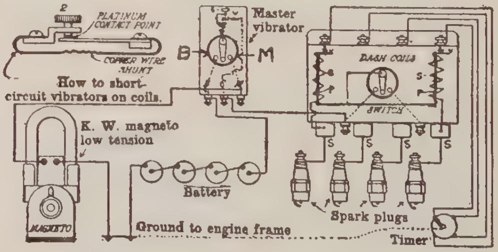

Fig. 12. K. W. low-tension inductor-type magneto connected with a high-tension coil-ignition system using a K.W. master vibrator coil.

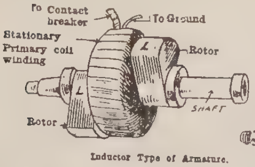
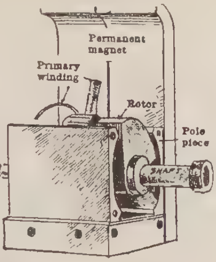
With this low-tension inductor-type magneto an interrupter is not used, because the vibrators on the coil take the place of an interrupter on the magneto. This type is not timed. Note that the commutator or timer is timed instead, as on a vibrator-coil system.

The Remy Low-Tension Inductor Type Magneto (Model R D)

The principle is similar to the K. W. (Fig. 11) except that the Remy rotor is a half-rotor, whereas on the K. W., both ends of the rotor are utilized.

The Remy produces two impulses per revolution and the K. W. four impulses per revolution.





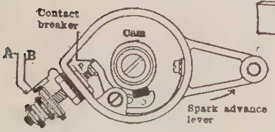


Fig. 13 (upper)
Fig. 15 (lower)

Fig. 14

Fig. 13. Remy rotors (L) which revolve and the stationary single primary winding.

Fig. 14. Remy inductor or rotor in maximum position.

Fig. 15. Remy contact-breaker or interrupter. The points (P) should have a clean surface. Dirt and grease should not be allowed to accumulate.

A distributor is mounted on the low-tension magneto which distributes the high-tension current from the high-tension ignition coil to the spark plugs.

If the engine misses with spark retarded at slow speed, adjust the contact screw (B) (Fig. 15) out a few notches.

If the engine misses with spark advanced at high speed, adjust the contact screw in a few notches.

On this magneto ignition system adjust the spark-plug points .025″.

The contact-breaker is used on this magneto just the same as on a shuttle-type magneto armature, to interrupt the flow of current in the primary winding.

To set the rotors: The rotors are placed in just the same position as on the shuttle-type armature when they are originally set, at which time the interrupter points open.

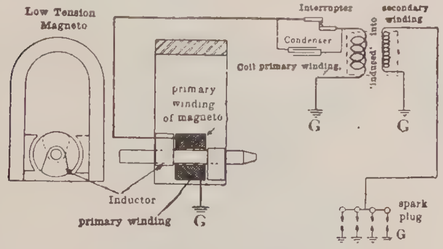

Fig. 16. Illustration showing how a high-tension coil is used in connection with Remy low-tension magneto. (G, ground.)

Note that the condenser is in the coil.

Examples of Remy Low-Tension Inductor-Type Magneto Systems

A dual system (Fig. 17) consists of a Remy model R.D. low-tension "inductor"-type magneto used in connection with a high-tension coil. Note that the condenser is placed in the coil, but is shunted across the interrupter points.

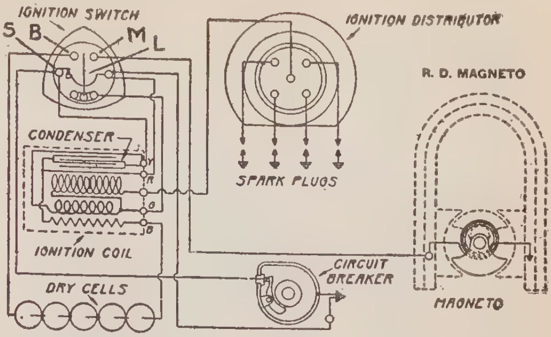

Fig. 17. Dual ignition system using a low-tension magneto of the "inductor" type in connection with a high-tension coil, with condenser in the coil. Note that the dry cells supply current for coil when on (B) side of switch, as when starting.

Dry cells are used to supply current to start with, by pressing a switch button (S) with switch lever (L) on battery side (B) of the switch, which closes the circuit between dry cells, primary winding of coil, and interrupter points. Thus when the engine is being cranked, the dry cells supply the current instead of the magneto.

The distributor and interrupter are mounted on the inductor-type low-tension magneto. The high-tension ignition coil is separate, as is also the switch.

After the engine is started, the switch lever (L) is placed on the magneto (M) side of the switch, the dry cells are cut out, and the magneto supplies current. The magneto interrupter is timed, so that the interruption of sparks occurs at the right time.

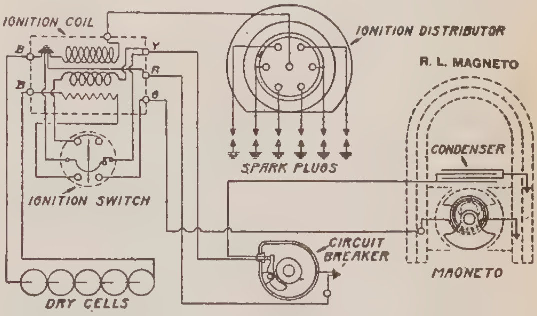

Fig. 18. Similar to Fig. 17 except that the condenser is on the magneto.

Fig. 18 is similar to Fig. 17, except that the condenser is mounted on the magneto, being across the interrupter points as usual. The magneto model is R.L., and is an inductor type similar to the model R.D. in Fig. 17.

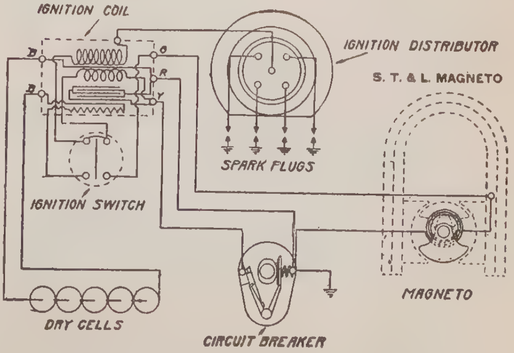

Fig. 19. See text on next page for explanation.

The system shown in Fig. 19 in many respects is similar to model R.D., except that the push button is not used and the interrupter is arranged differently. This type of low-tension inductor magneto is the S.T. & L. Dry cells are used for starting.

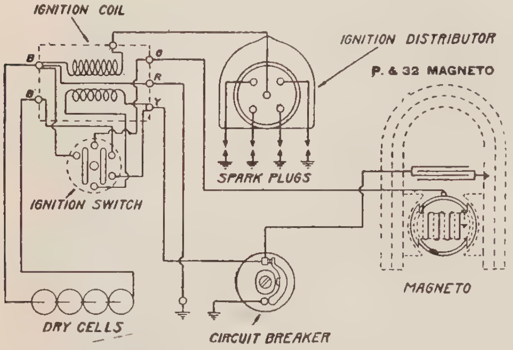

Fig. 20. Dual ignition system using a low-tension magneto of the "primary armature type."

In Fig. 20, this system (Remy P and 32 magneto) differs from that just described, in that the magneto armature is a "primary-armature type" low-tension magneto, instead of an "inductor" type. The push button is not used, and the switch is arranged differently.

All of the foregoing are examples of dual high-tension ignition systems, using a low-tension magneto of the inductor type (except Fig. 20) as a source of electric supply.

Note. The letters **Y, R, B, G,** refer to the color of wire on these systems. To time the Remy RD and RL low-tension magnetos: Place No. 1 piston on top of compression stroke. Press in on timing button (Fig. 17) which is at the top of the distributor and turn the shaft of the magneto (with coupling loose) until the plunger back of the timing button drops into the recess on the distributor gear. Then couple the magneto to its drive member. It is not necessary to set the interrupter in this instance, as the interrupter is in correct position with this operation, and No. 1 distributor segment is in contact with No. 1 distributor terminal, which is marked.

Ford Inductor-Type Low-Tension Magneto

Another form of low-tension alternating-current magneto of the inductor type is the Ford magneto.

This magneto might be termed a high-frequency magneto, meaning that there are 16 impulses per revolution. For instance, on the "shuttle-armature type" magneto there are 2 impulses per revolution. On the K.W. inductor magneto (Fig. 11, page 246), there are 4 impulses per revolution.

The term "impulse" refers to the points where the generated current is the strongest and is where the interrupter, as on the shuttle-type armature magneto, interrupts or opens the primary circuit just as the armature is leaving the pole pieces. Thus the spark or "impulse" occurs.

The term "frequency" refers to one-half the number of times the current changes its direction of flow in the winding per revolution (see "cycle" and "frequency" explanation, Fig. 7A, page 192). For instance, on an "armature or shuttle-type" magneto the direction of current in the primary winding on the armature changes its direction twice during one revolution (see Fig. 9, page 246). On the K. W. (Figs. 11 and 10, page 246), there are 4 changes during one revolution, because there are 4 ends to the rotors.

On the Ford magneto there are 16 changes per revolution, because there are 16 stationary coils attached to a plate or support inside of the flywheel housing. These coils consist of a thin strip of copper wrapped around a small soft iron core (C). The consecutive coils are wound in opposite directions on each coil core and are connected in series.

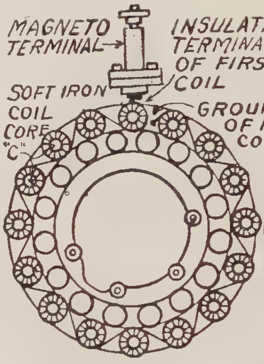

Fig. 21

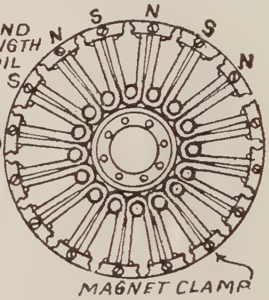

Fig. 22

Fig. 21. The sixteen stationary coils of the Ford low-tension inductor type of magneto mounted on the coil plate.

Fig. 22. The sixteen permanent magnets which are attached to the flywheel and revolve in front of the core of the coils. Like poles of the magnets are placed together.

The terminal of the first coil connects with the magneto terminal, which conducts current to the four primary windings on the four-unit vibrator-type coil. The end of the sixteenth coil is grounded.

There are 16 permanent magnets, but instead of being placed over the pole pieces and the armature being made to revolve between them, as in the "armature-type" magneto, the magnets are attached to the fly wheel by means of non-magnetic studs and are made to revolve within 1/32″ in front of the coil cores (C) (Fig. 23).

Note. Fig. 23 shows magnets separated, as if separate horseshoe magnets, as an explanation as to how they revolve in front of the coil cores. The magnets are placed close together, as shown in Fig. 22.

The N poles of the magnets are placed together; so are likewise the S poles. Thus we have N and S polarity alternately around the magnets, as shown in Fig. 22.

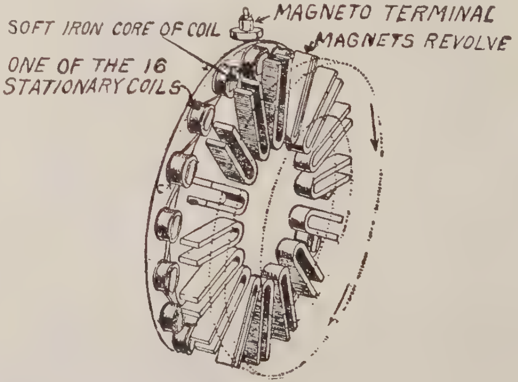

Fig. 23. Illustrating how the permanent magnets revolve in front of the coil cores. The magnets are within 1/32″ of the coil core.

When the N pole ends of the magnets are in front of one of the coil cores (C), the magnetic lines-of-force flow from N pole to the magnet, through the coil core (C), through the plate to which it is attached, through the core (C) of the coil next to it, to the pole end of the magnet, thus completing a magnetic circuit from N to S pole end of the magnet, and setting up a generated electromotive force in the coil winding, causing current to flow out of the coil windings into the magneto terminal (Fig. 21).

When the flywheel moves one-sixteenth of a revolution, the flow of current is reversed. Thus there are sixteen alternations or changes of flow of current during one revolution of the sixteen magnets, or sixteen "impulses" per revolution, because there are sixteen coils and sixteen inductors or magnets.

In other words, each revolution of the flywheel, to which the magnets are attached, means one revolution of the crank shaft. There are 16 positions of the magneto when the current output is at its maximum, and each of these positions is called **the peak** of the current wave. There are, also, 16 positions during which no current is flowing at all. Each of these is called **the neutral** position, and each is half-way between two peaks. Therefore, at every sixteenth of a revolution of the magneto a position is reached when no current is being generated. These are termed "dead points."

Each alternate peak is of an opposite polarity, that is, there are 8 positions in each revolution when the current flowing from the magneto winding to the spark coil is positive, and between these positions are 8 other positions when the current is negative. In other words, the frequency is 8 cycles per revolution.

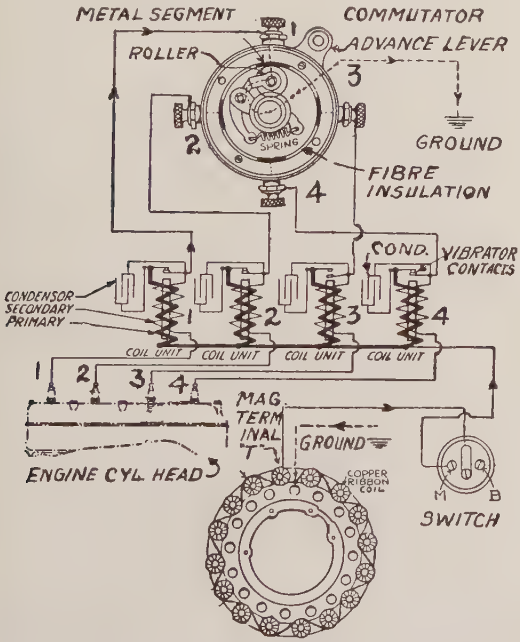

Fig. 24. Illustrating the circuit from the magneto terminal (T) to the switch, to the primary winding of one of the four high-tension coils, to segment (No. 1 in this example) of the commutator, to ground, to the grounded end of the sixteenth magneto coil. Note. There is a mistake in the drawing. The coil vibrator of No. 1 coil should be shown open instead of No. 3.

The Ford coil circuit and connections are shown in Fig. 24. See also Index for "Ford wiring diagram" and "Relation of speed of magneto to voltage generated."

The Ford inductor-type magneto, owing to its high frequency, will light lamps and supply current for a vibrator-type coil, but the voltage varies considerably. Thus the lamps will vary in brilliancy in relation to the speed of the engine. Owing to these variations of voltage, the ignition coil should be adjusted carefully, as explained on page 222, or else the spark-plug points will burn as well as the points on the vibrator blade of the coil.

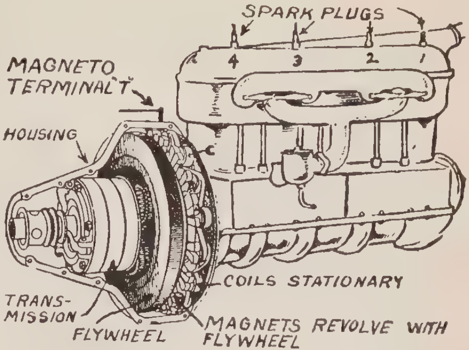

Fig. 25. Illustrating the location of the Ford magneto on the engine.

Low-Tension Magneto, "Armature Type"

The low-tension magneto like the low-tension coil, does not supply a very high voltage and would not jump a straight open gap like a spark-plug gap, but the voltage is raised sufficiently in the single coarse wire primary winding to produce a flash or spark when its circuit is very quickly opened.

The low-tension magneto can be used with a "make-and-break" igniter (Fig. 13, page 185), or with a "wipe-spark" igniter (Fig. 18, page 187).

The low-tension magneto can also be used in connection with a high-tension coil, but it would not be termed a high-tension magneto, even though the high-tension coil and the distributor were mounted on it; which is often the case. It would, however, be termed a high-tension ignition system.

The low-tension magneto is now seldom used, but is explained, because it is necessary to understand the principle of it before taking up the subject of the high-tension magneto.

The parts of an "armature type" low-tension magneto are: (1) magnets to produce the magnetic lines-of-force; (2) pole pieces of soft iron (see Fig. 1A, page 242); (3) a primary winding on a soft iron armature core which revolves, being driven at a fixed speed by the engine; (4) a contact-breaker (also called an interrupter) and a cam.

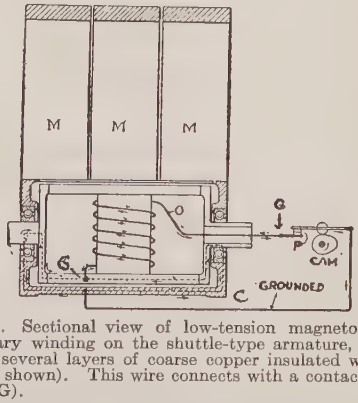

Fig. 26. Sectional view of low-tension magneto. (O) is the primary winding on the shuttle-type armature, of which there are several layers of coarse copper insulated wire (only one layer shown). This wire connects with a contact-breaker (P) and (G).

This contact-breaker would be in the form of an igniter (see page 185) and would be inside of the cylinder, if the "make-and-break" system of ignition is used.

If the system consisted of a low-tension magneto and high-tension coil, then the contact-breaker (G and P) above would be mounted on the end of the armature shaft and the circuit would be opened at the correct time, producing a spark, by a cam on the end of the armature shaft.

The circuit of a magneto system is a closed circuit; that is, the primary winding is closed and the circuit is opened by the cam only at the correct time, which is just as the armature passes the vertical position. At this time the greatest energy exists in the circuit, the position being termed the "maximum" position.

In other words, the spark is produced by the change from closed circuit to open circuit when the contact-breaker is opened by the cam. This break is made very quickly, and in order to get the hottest spark at the points of the spark plugs or igniter, the opening should occur when the armature is in "maximum" position. If the opening occurs earlier or later than maximum, then the intensity of the spark is weaker.

The primary winding on an "armature-type" magneto, consists of about 200 turns of No. 19 to 24 B. & S. gauge copper insulated wire.

HOW THE "ARMATURE-TYPE" MAGNETO GENERATES ELECTRIC CURRENT

A permanent magnet is made of hard steel and retains its magnetism. Its magnetic influence extends from one pole to the other, which is called the magnetic field, as shown in Fig. 27.[1]

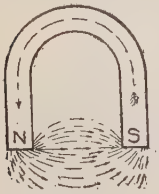

Fig. 27

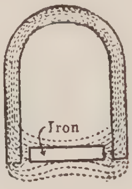

Fig. 28

The magnetic lines of force always flow N into S outside of the magnets or between the poles, and from S to N through the magnetic field poles. See Fig. 27.

If a bar of iron be placed between the poles (N and S), or in the magnetic field (Fig. 28), the magnetic lines of force will travel freely through the iron. It offers an easier path, because the air gap between poles offers 280 times the resistance that iron does. The magnetic lines will also be greatly increased, as the iron will collect a lot of stray lines of force and concentrate them.

Therefore a soft iron armature core (shuttle type) (Fig. 4A, page 243), with wire wrapped on it, is placed between pole pieces and made to revolve by being driven, usually by a gear from the cam shaft. The space between armature and pole pieces is very slight. The pole pieces (see Fig. 1A, page 242) are soft iron attached to the hard-steel permanent magnets. The armature is the "shuttle" type.

How Electromotive Force Is Induced into Wires of Armature

Whenever a loop of wire forming a closed circuit is placed in a magnetic field, an e.m.f. will be induced in the wire whenever the strength of the magnetic field changes.

Or, if a wire is moved up or down quickly in the magnetic field, so that the wire will cut across the magnetic lines-of-force or magnetic flux[1] at right angles (Fig. 29), an e.m.f. will be generated in the wire, and if the wire is in the form of a closed loop, the electromotive force thus generated will force the electricity in the wire to move. Why the electricity is in the wire we do not know, but we do know that the generated e.m.f. will cause it to move, or flow.

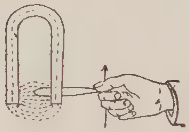

Fig. 29

The e.m.f. is induced in the wire by the lines being stretched by the movement of the wire, like rubber bands, then snapping at the weakest point—the S pole—then wrapping or whirling around the wire, thus generating e.m.f. in the wire. The intensity and number of lines-of-force around the wire will depend upon the strength of the magnetic field and the rate of speed with which the wires cut the lines-of-force. The direction in which the e.m.f. will force the electricity or current to move in the wire will depend upon the direction in which the wire itself is moved.

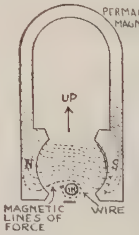

Fig. 30

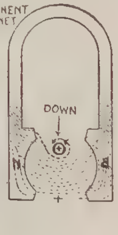

Fig. 31

If the wire is moved up (as in Fig. 30), the magnetic lines-of-force whirl around the wire in a clockwise direction and current will flow **into** the wire.

If the wire is moved down (as in Fig. 31), the lines-of-force will whirl counter-clockwise, and current will flow **out of** the wire.

If we have two wires (as in Fig. 32), revolving in the direction of the arrow point, the wire on the left would then cut the lines **up** as it revolved, and current would flow **into** the wire. The wire on the

---

[1] A "permanent magnet" will retain its magnetism a long time if a keeper is kept on the ends of the poles. The armature on a magneto, when in a horizontal position, acts as a keeper.

An "electro-magnet" is a magnet consisting of an iron core around which wire is wrapped. When direct current is passed through the wire, the iron core becomes a magnet—if current is flowing in one direction. Soft iron cores are used, as it quickly loses its magnetism when current ceases flowing.

[1] "Magnetic flux" is the total number of lines-of-force flowing through a magnetic circuit.

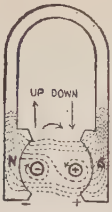

Fig. 32

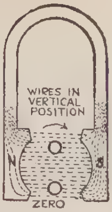

Fig. 33

right would move **down** and cut the lines down, and consequently the current would flow out. Thus we should have a complete circuit of current flowing, if the wires were in the form of a closed loop.

When the wires reached a vertical position (as in Fig. 33), there would be no e.m.f. generated in the wires and the e.m.f. would be zero value, because the wires would not be cutting **across**, or at right angles to the path of the lines-of-force.

This position of wires in Fig. 33 would be represented by the position of the armature of the magneto in Fig. 34. Note that all the lines-of-force would flow through the armature core, and the wires on the armature would not be cutting the lines-of-force at all; thus the e.m.f. is "zero" value.

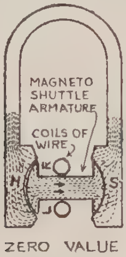

Fig. 34

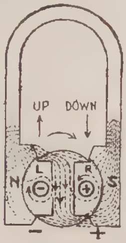

Fig. 35

Fig. 32 represents the position of the wires when the armature is in the position shown in Fig. 35. In this position the wires on the armature would be cutting the greatest number of lines-of-force, if, of course, the wires were moving rapidly with the armature. Thus the e.m.f. would be at its highest value at this position, which is called the "maximum position." It is the point at which interruption of the primary circuit should take place, if it were not for a factor called "armature reaction."

Owing to the fact, however, that the circuit is a closed circuit in which the current is flowing, there is an "armature reaction" which produces a hindering effect (explained farther on), and consequently the maximum position of the armature is reached a few degrees later, or just as the armature cheek breaks from the pole tip.

Before we proceed any farther, however, there are laws governing the generated e.m.f. which must be considered as follows:

The momentary induced e.m.f. is greatest when the wire is moved so as to cut the magnetic lines of force at right angles. Applying this principle to the coil of wire on the magneto, the coil would be cutting the greatest number of lines of force when in position shown in Fig. 35—or when it is moving at right angles so as to **cut** the lines of force.

The electric current in the wire depends upon the e.m.f. (electromotive force) causing it to flow; therefore e.m.f. is generated in wire when it is made to cut the lines-of-force, and a current flows when its circuit is complete, due to the generated e.m.f. The faster the coils cut the lines-of-force, the greater will be the e.m.f. generated.

The generated e.m.f. depends upon the speed of cutting the lines-of-force, that is, the number of lines cut per second. Therefore the greater the number of lines and the greater the number of wires there are, the greater will be the e.m.f. Therefore several layers and many turns of wire are wrapped on the armature core called the primary winding.

Referring now to Figs. 33 and 34, it will be seen that the coil is not cutting any of the lines-of-force—the lines are passing freely through the armature core from N to S; therefore e.m.f. (voltage) strength is at zero.

In the position shown in Figs. 32 and 35 the coils of the wires of the primary winding are cutting the greatest number of lines-of-force at right angles to the flow of lines-of-force. Some few lines are flowing through the ends of the armature core, but most of the lines are being cut by the wires on the armature. Therefore this position would appear to be the logical position at which the spark should occur, since it is the position where the **generated e.m.f.** in the wires is greatest.

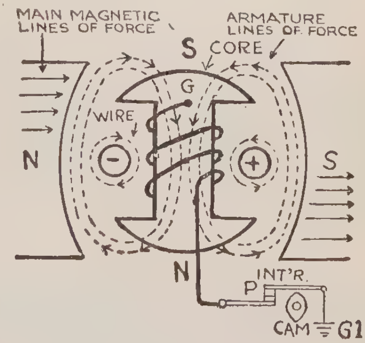

Fig. 36. Armature reaction.

There is, however, another factor which has not yet been considered, and that is, that when this generated e.m.f. is produced in the wires on the armature, by the wires cutting the main magnetic lines-of-force flowing from N to S poles of the magnets, this heavy current in the wires on a closed circuit has the effect of making an electro-magnet out of the iron core (Fig. 36). This is the same condition as was explained on page 182, where current from a battery flowing through a coil of wire around an iron core caused magnetic lines-of-force to whirl around the entire coil and thus form an electro-magnet with an N and S polarity.

Due to the generated e.m.f. in the primary wires on the armature, which is a closed circuit, the same effect is being produced, that is, independent magnetic lines-of-force are set up around the armature core which has made a S pole and N pole of the armature core (Fig. 36), with the result that these independent armature lines-of-force cause the main magnetic lines-of-force to follow their own path. This action is termed **"armature reaction."**

Note. The position of the armature in Fig. 36 is represented in Fig. 35. In the latter, the main magnetic lines-of-force are passing in at the **top** of the armature core and coming out at the **bottom.** This is due to the fact that the "main magnetic lines-of-force" are flowing "**with** the armature lines-of-force." See arrow points of both, in Fig. 36.

We have now built up a very strong magnetic field which extends all around the wire on the armature, and the principle is now similar to the coil action, explained on pages 182, 184. Now, the point is, if we could demagnetize the core of the armature, so that the lines-of-force which have been built up around the armature (Fig. 36) could collapse rapidly (as with the coil on pages 182, 184), then, as the lines-of-force collapsed, they would cut the wires at a very rapid rate of speed, if the core was fully demagnetized, or magnetized in an opposite direction. The result would be another independent induced (or self-induced) e.m.f. in the wires of a higher voltage, causing the current to flow in the wires in the same direction as it did before the circuit was opened.

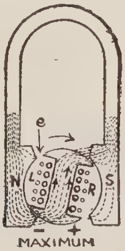

Fig. 37

The demagnetization of the core is accomplished by two different factors. If the circuit is opened at the interrupter points (**P**) (Fig. 36), just as the armature breaks from the pole piece (**e**), (Fig. 37), the magnetic lines-of-force which were flowing through the armature core in the direction shown in Figs. 35 and 36, will now flow in the opposite direction, coming in at the bottom instead of the top, as in Fig. 37, thus assisting in the demagnetization of the armature core.

These two actions combined cause the lines-of-force to collapse more rapidly on open circuit. Thus a fairly high induced voltage is built up in the wires, which, being generated on open circuit, will have no other outlet[1] except at the open points of the interrupter. Thus the voltage jumps the interrupter-point gaps in a manner similar to the action of the low-tension coil (Fig. 11, page 184). There being only a limited number of turns of rather coarse wires in the primary winding, however, the voltage will not be very great, but great enough to jump the interrupter point gap.

If the low-tension magneto is used with a "make-and-break" igniter (Fig. 12, page 185), (or a "wipe-spark" igniter), the spark is desirable at the break, because it would be in the cylinder where it is required.[2]

Low-Tension Magneto and High-Tension Coil in Series

If the low-tension magneto is used in "series" with a high-tension coil (Fig. 38), the spark is desired at the spark-plug point. It will then be necessary to have a condenser to absorb the current passing through the primary winding (**PRY**) of the coil from the magneto at the time of the break at interrupter or contact-breaker points and also to assist in demagnetizing the core of the high-tension coil, so that the lines-of-force built up around the coil core will collapse quickly and induce a high voltage in the secondary winding (**SECY**) of the high-tension coil. Thus a very high voltage will be produced at spark-plug points (Fig. 38).

Low-Tension Magneto and High-Tension Coil Shunted

If the low-tension magneto is connected with a high-tension coil, so that the interrupter or contact-breaker is "shunted" across the path from magneto to coil, instead of being in "series" with it (as in Fig. 38), the action would be slightly different as shown in Fig. 39.

PRIMARY WINDING ON IGNITION COIL

Fig. 39. Low-tension magneto connected with the primary winding of a high-tension coil, but the interrupter or contact-breaker is "shunted" across the circuit.

The primary current from the magneto would have two paths: one through the interrupter points (**P**), and the other through the primary winding (**PRY**) of the coil. The current takes the easiest path through the interrupter points, and consequently there is no current flow in the primary of the coil and its core is free from magnetism. Thus when points (**P**) are opened by the cam, this sudden break of the current flowing through the armature and interrupter points, or the shunt circuit, causes, with the assistance of the condenser, an induced current to be set up in the armature winding, as explained in connection with Figs. 35 and 36. This rush of self-induced current, having no other outlet, rushes through the coil primary winding (**PRY**). As the coil core is demagnetized, because of the fact that no current was flowing through it previously, the magnetic lines-of-force build up rapidly around the turns of wires, causing a momentary high voltage in the secondary winding, and thus causing a spark to jump the gap at the spark plug which is in the cylinder.

---

[1] Even though the circuit is open at the interrupter, we term it a circuit if there is sufficient self-induced voltage in the wires to cause the electric current to jump the gap.

[2] It would appear that the "make-and-break" system would be the simplest, which it is, but the movable contact points in cylinders exposed to intensity of the heat soon get out of adjustment.

Note in Fig. 38 that **the lines-of-force in the coil core were made to collapse,** to produce the high-tension spark, whereas in Fig. 39, **the lines-of-force are built up in the coil core** to produce the high-tension spark. This was possible in this instance, because there was no current flowing in the primary winding of the coil, and its core was completely demagnetized. Thus the lines built up rapidly, generating a high induced voltage in the secondary. This system is the one in general use where a low-tension magneto is used with a high-tension coil.

It is well for the reader to grasp the difference between **generated e.m.f.** and **self-induced e.m.f.,** in order that he may clearly understand the foregoing explanations.

Generated e.m.f. refers to the e.m.f. generated in a wire when a wire is made to cut the lines-of-force, as when the armature is revolved between the pole pieces. In such a case the wires cut the main magnetic lines-of-force, and lines-of-force are built up around the turns of the wires.

Self-induced e.m.f. is where the lines-of-force have been built up around the wires, as described above, and then the circuit is suddenly opened, or the direction of the lines-of-force is changed. This causes a collapse of the lines-of-force, which cut the wires as it collapses into the core, thus causing what is termed a self-induced e.m.f. which causes current to flow.

Two Sparks or Impulses[1] per Revolution of Armature

With the shuttle type of magneto armature there are two positions of the armature during one revolution, called **"maximum position."** These are the points at which the e.m.f. is the highest and are the position in which the armature is when the contact points should open, or slightly later, owing to "armature reaction," as already explained.

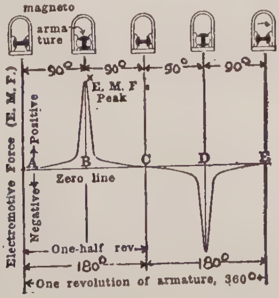

Fig. 40. Voltage wave.

In explanation of this, let us refer to Fig. 40, which shows the open-circuit voltage wave. Start with the position of the armature at (**A**) on the left. Note that the armature is in a horizontal position and the e.m.f. (electromotive force[1]) is at zero, because the lines-of-force are passing freely through the iron armature core, as is also shown in Fig. 34. Thus, at this point the wires on the armature are not cutting any lines-of-force.

When the armature travels 90°, or a quarter-revolution in the direction of rotation (clockwise, in this instance), it is in a vertical position (**B**). Technically this is the position where the highest break of e.m.f. or voltage is reached, because the wires are cutting the greatest number of lines-of-force. Practically, however, the maximum position is just a few degrees farther in the rotation, as shown in Fig. 37, for reasons already explained.

When the armature travels 90° more, or half of a revolution, it has again reached the horizontal position (**C**). The voltage is again at zero value.

When the armature travels 90° more, or three-quarters of a revolution, it has again reached another maximum voltage position (**D**).

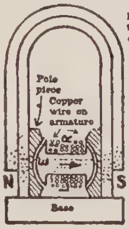

Fig. 41

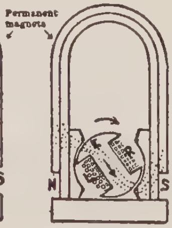

Fig. 42

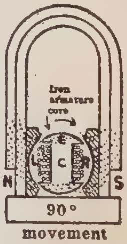

Fig. 43

Fig. 41. **Voltage is at zero.**

Fig. 42. The left (L) side of the coil is starting to cut the lines-of-force **up,** and the right side of the coil (**R**) is cutting **down. The e.m.f. is gradually increasing.**

Fig. 43. The e.m.f. is now at the highest peak because the greatest number of lines are cut in this position. The (**L**) side of the coil is still cutting lines up, and the (**R**) side down, therefore the voltage polarity is still the same.

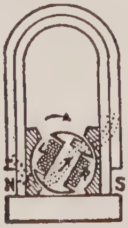

Fig. 44

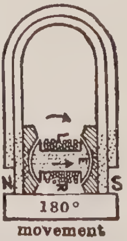

Fig. 45

Fig. 44. **The e.m.f. begins to weaken** because less lines are being cut. The voltage polarity is still in the same direction, because the (L) and (R) sides of the coil are still cutting the lines-of-force in the same direction.

Fig. 45. The armature has now turned one half-revolution. No lines are now being cut; the voltage (**e.m.f.**) strength is **at zero.** Thus we have had the positions as represented in Fig.40; (**A**) to (**C**), where the e.m.f. was in one direction. During the next half-revolution, the same action of the wires cutting the lines-of-force is repeated, except that the (**R**) side of the coil will now cut up and the (**L**) side will cut down. In this case, therefore, the e.m.f. will be in the opposite direction during the next half-revolution, as shown in Fig. 40, (**C**) to (**E**).

---

[1] The word "impulse" is also used in connection with the ignition of gas in the cylinder; for instance, when the explosion takes place in the cylinder, the piston receives an "impulse."

[1] Refers to voltage.

When the armature travels 90° more, or a full revolution of 360°, it has again reached zero voltage position (E).

Thus we have during one revolution[1] of the armature two positions (B and C) when the voltage is at its highest voltage peak, and two positions (C and E) when it is at zero voltage.

The voltage wave is in one direction (A) to (C), which we will call positive, and in another direction (C) to (E), which we will call negative, or two directions during one revolution, termed "alternating" current. Thus the voltage wave changes polarity at (A) and (C), as will become clear by the following sequence:

The Current Wave

The voltage wave (Fig. 40) differs slightly from the current wave (Fig. 46). The e.m.f. or voltage generated is necessary to force the current to flow.

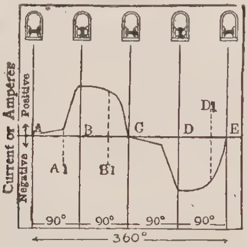

Fig. 46. Current wave diagram

The e.m.f. starts to build up at about 60° from (A) or at (A1), (Fig. 46), and consequently the current in the closed-circuit winding also starts to flow in a positive direction from (A) to (C) and reaches maximum when the contact points are opened at (B), or slightly afterwards.

Position (B) would correspond to the extreme **advance** position of the contact-breaker, and position (B1) to the extreme **retard**, or about a 35° or 40° movement.

Therefore if the contact-breaker housing was advanced so that a spark would occur before (B), or retarded after (B1), the spark would be weak.

There are two points in a revolution from (A) to (E), where a strong spark can be obtained, namely: between (B) and (B1), which represents half a revolution of the armature with the current flowing in a positive direction; and between (D) and (D1), which represents another half-revolution of the armature with the current flowing in a negative direction.

It is clear that **the contact-breaker must be opened at a certain position of the armature** and the armature and cam must be driven at a fixed speed, which is termed "setting" or "timing the ignition."

The cam: As the change takes place twice during one revolution of the armature, it is necessary that a two-point cam be used on the contact-breaker in order to break contact twice during one revolution.

To set the magneto: As stated, the point at which the armature cheek is just breaking from the pole (Fig. 37) is the correct position in which to set the magneto armature, and at the same time the interrupter points should just separate. Both operations should occur at the same instant.

Advancing and retarding: The cams are made of steel and are in a casing, and by having this casing made so that it can be moved through, say, the one-tenth part of a circle, the time of the interruption of current can be advanced or retarded with relation to the movement of the armature. This means the spark will occur early or late, relative to the movement of the pistons.

The low-tension magneto described is one which uses a shuttle-type armature, called the "armature" type of magneto. The wires revolve with the armature.

The inductor-type magneto is a magneto where the coils or wires are stationary.

Splitdorf Model "D" Low-Tension Magneto and Coil System: a "Dual Ignition System"

The illustration (Fig. 47) shows a Splitdorf dual system, using a low-tension "armature-type" magneto and high-tension coil with battery to start on and magneto to run on. The contact breaker on the magneto is utilized for either the battery or magneto system. The primary circuit through the armature, however, must be opened to prevent the battery from demagnetizing the magnets when the battery is used.

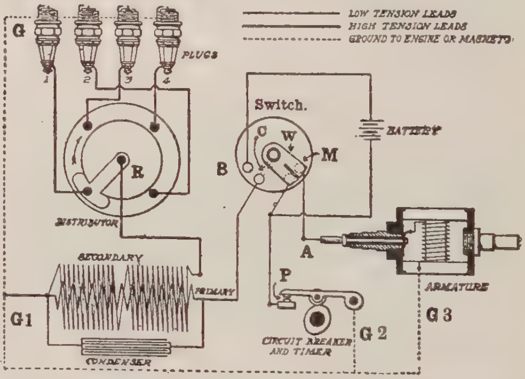

Fig. 47. Splitdorf model "D" low-tension magneto and high-tension coil—a "dual" ignition system.

Magneto circuit: from (A) to switch blade (W), through connection (C) to primary wire of coil, through ground (G1) and (G3) to armature. The breaker points (P), it will be noted, are connected or shunted across the magneto primary circuit, similar to what is shown in Fig. 39, page 252. The circuit proper is through the armature and circuit breaker, and the coil primary winding receives only the kick of the armature (extra current) when the contact points open, as explained on page 252. It will be noted that the battery circuit is open at the switch.

Battery circuit: the switch blade (W) should now be on (B) side, connecting the two terminals, and the magneto terminals on the (M) side are open. Current travels from top of battery (+) to switch point, to primary winding of coil, to ground (G1) to (G2), thence through interrupter points (P) to a lower connection of battery. Note that the armature is cut out entirely, but not the interrupter.

High-tension current is distributed from the secondary winding on the coil to brush (R) on the distributor (the distributor is on the low-tension magneto and is driven from the armature shaft), thence to the spark-plug center electrode, thence through the spark gap to plug-shell ground (G) of the engine and frame, back to the coil where the primary and secondary connect.

---

[1] On some magnetos for eight and twelve-cylinder aero engines the pole pieces are arranged so that four maximum positions are reached per revolution. The K.W. magneto, page 246 produces 4 maximum positions or sparks per revolution.

Condenser: Although this is located in the coil, if the circuit is traced it will be observed that it "bridges" the points of the contact-breaker.

Splitdorf Model "T" Low-Tension Magneto and Coil System; "Dual Ignition Systems" Using a Dash Coil and a Tube Coil

The diagrams below show the Splitdorf low-tension model "T" magneto used in connection with a dash type of high-tension coil (Fig. 47A) and with a tube type of coil (Fig. 47B). The coils are also termed "transformers." Both systems are typical "dual" ignition systems of the interrupted shunt-current type.

Note that the distributor for distributing the high-tension current to the spark plugs from the coil is mounted on the low-tension magneto.

Also note the connections on the coil for the battery. By switching to one side, the magneto supplies current to the coil, and by switching to the other side, the battery supplies current to the coil.

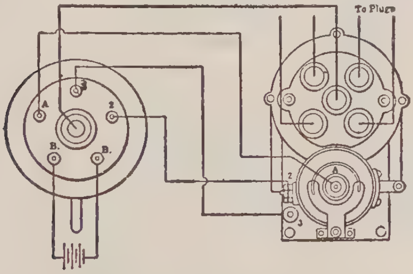

Fig. 47A. Splitdorf model "T" low-tension magneto used in connection with a "dash" or "box type" of high-tension coil.

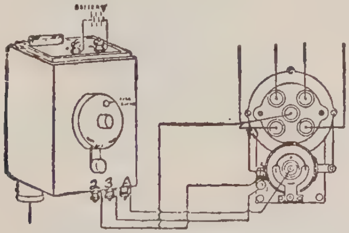

Fig. 47B. Splitdorf model "T" low-tension magneto used in connection with a "tube type" high-tension coil.

The Oscillating Low-Tension Type Magneto

This type is a regular shuttle or armature type magneto (Figs. 48 and 49), and is the original magneto principle, designed for slow-speed engines. The armature does not revolve, but oscillates back-and-forth from position Fig. 48 to Fig. 49 (30°).

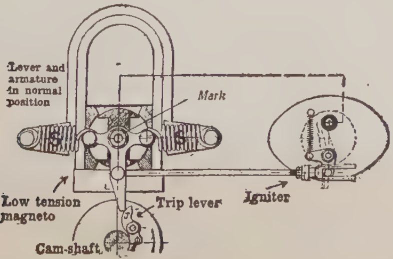

Fig. 48

Magnetic spark plug

Magnetic plug used with low-tension oscillating type magneto.

Fig. 49

It can be used with an igniter arrangement (Fig. 48), which is similar to that shown in Fig. 13, page 185, except that the igniter rod is actuated by lever (L) on the magneto, which is tripped by trip (J). It can also be used with a magnetic plug, as shown in Fig. 49, which is screwed into the cylinder.

The Magnetic Plug

The principal parts of the magnetic plug (Fig. 50) are: magnetic coil (5), pole-piece (2), interrupter (20), and contact-piece on plug shell (21). The plug is screwed into the cylinder.

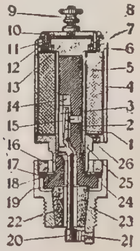

Fig. 50

Principle: owing to the sudden flow of current through coil (5), the upper portion of hammer bar (1), called the armature, is attracted to pole-pieces (2), which effects a quick separation of contacts (20) and (21), producing a spark at these points.

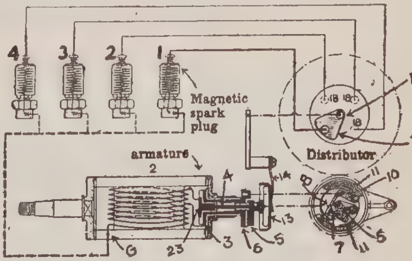

Fig. 51

The use of the magnetic plug is shown in Fig. 51, in connection with a low-tension magneto (type "K4" Bosch) with a revolving armature, with a main and auxiliary winding, one being a continuation of the other, and with a distributor for connections to the magneto plugs. This system is termed the Honold system, and is for 2, 3, 4, 6 and 8-cylinder engines.

The systems just described are not used for automobile ignition, but are designed for slow-speed heavy-duty stationary and marine engines.

INSTRUCTION No. 26

THE HIGH-TENSION MAGNETO: Principle; Construction; Types

Preliminary Explanation

The high-tension magneto is not only a mechanical generator, or a substitute for the battery, but combines all the elements of a complete ignition system, except the plugs and switch.

It performs three separate essential functions as follows: generating current; transforming the current to a high pressure; distributing the high-tension current to the individual cylinders. Besides these main functions, a number of minor functions have to be performed. The high-tension magneto differs from the low-tension magneto in only a few particulars.

The high-tension magneto can be of the "inductor" type or of the "compound-armature" type.

We shall deal here with the armature type and explain the inductor type farther on.

Armature winding: The armature (armature type) on the high-tension magneto is wound with an additional winding, called the "secondary winding," whereas the low-tension magneto has but one winding, called the primary winding.

Instead of using a "separate" high-tension coil, as with the low-tension magneto, explained in the preceding instruction, this second winding on the armature of the high-tension magneto takes its place. This secondary winding is carefully insulated from the primary winding, except at one end, where it connects at (N), (Fig. 1), with the primary winding. As the primary winding is grounded at (GP), the secondary winding is thus grounded through the primary winding. (PW) is the primary winding, and (SW) is the secondary winding.

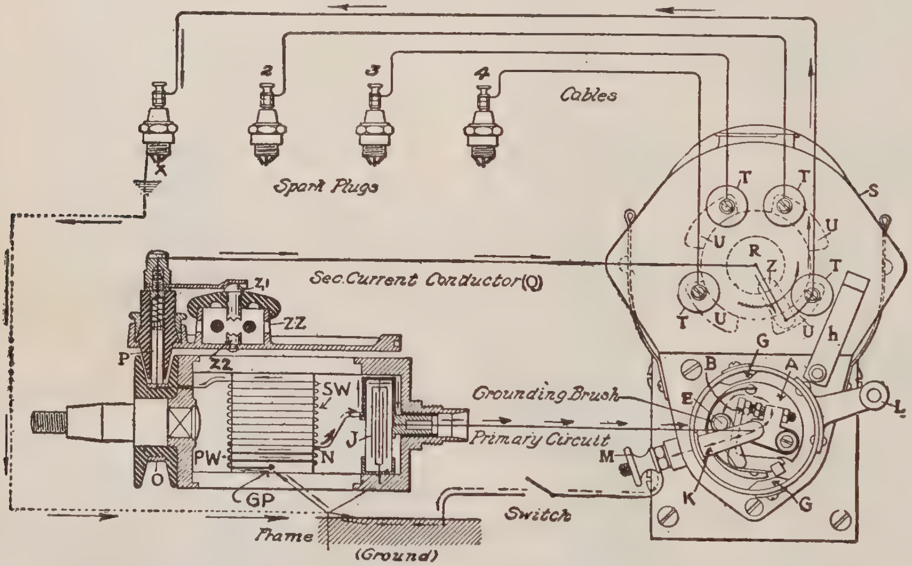

Fig. 1. Diagram of a high-tension "compound-armature-type" magneto, showing internal connections of armature The armature is double wound. It revolves between permanent magnet pole pieces with its wire winding.

One end of (SW) is led, carefully insulated, to a collector ring (O) mounted on the armature shaft, and a carbon pencil or brush (P) rubbing on this collector ring takes off the secondary current and leads it to the distributor brush (Z). The primary winding circuit is explained farther on.

The other respect in which this type differs from the low-tension magneto is that **the condenser** which is employed in connection with the interrupter is usually built into the high-tension magneto (J, Fig. 2), whereas with the low-tension magneto, the condenser is in the separate high-tension coil.

The condenser is usually, though not necessarily, located on the armature shaft in order to get it as close to the interrupter as possible, and it is there shown in Fig. 1 (J). In some magnetos, for the sake of greater accessibility and other reasons, the condenser is located outside the armature in a stationary sealed box.

Owing to the fact that the secondary coil of the high-tension magneto is located on the armature itself, it follows that it not only receives an induced current, due to the breakage of the primary current, but itself induces a current like that of the primary coil, but smaller in volume.

It has the same form of armature, field magnets, and principle of interrupter as the low-tension magneto, but of varied construction. The armature coil, however, is different, having a primary winding with a secondary winding over it, as previously explained.

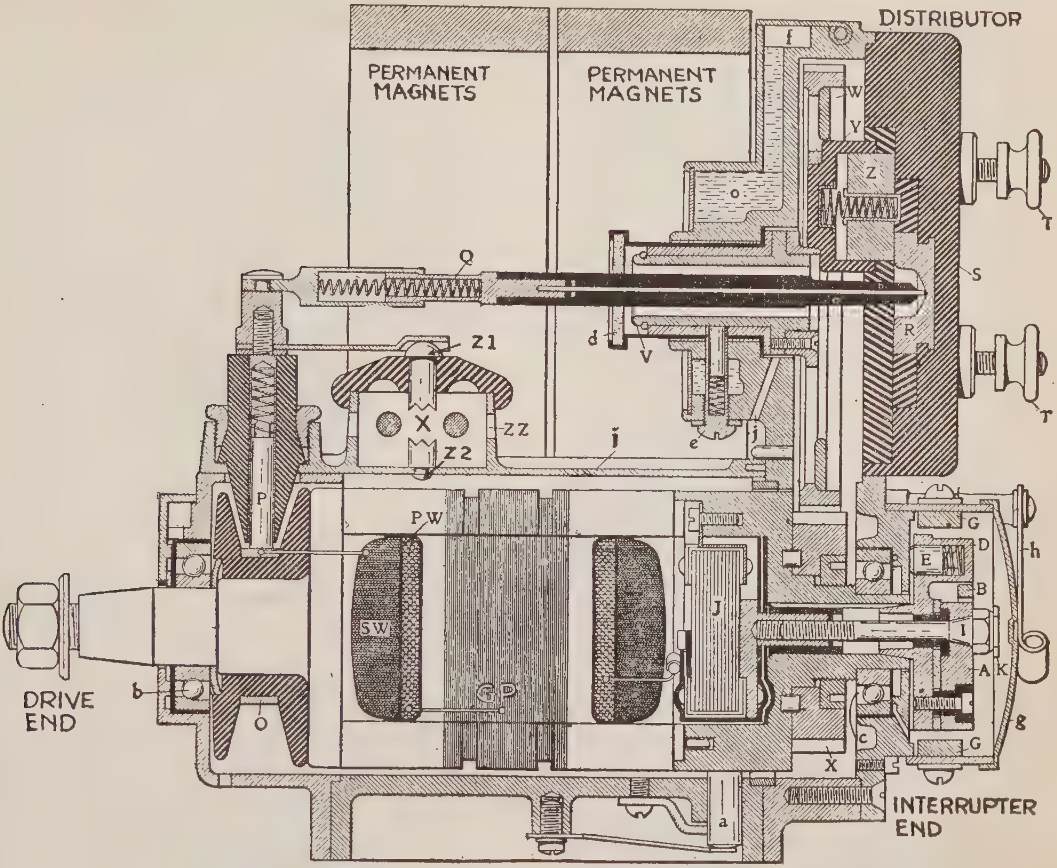

Fig. 2. Longitudinal section of Bosch type DU4 high-tension magneto. Note that distributor brush (Z) is revolved by a large gear (W) which is driven by a smaller gear (X) on the armature shaft. The armature is driven by the engine.

Principle of Operation

The primary winding usually consists of about 200 turns of No. 19 to 24 B. & S. gauge insulated copper wire.

The secondary winding usually consists of about 12,000 turns of very fine wire, No. 34 to 38 B. & S. gauge, and is of enameled silk-covered copper wire. The ratio is about 60 to 1.

We have already learned that the electromotive force induced in a winding depends upon the rate of change in the number of lines-of-force and the number of turns of wires the lines-of-force cut. Therefore with this great additional number of turns of secondary wires on the armature, the e.m.f. will be greatly increased.

The principle is very much the same as that explained on pages 251, 253. The interrupter breaks the primary circuit when the armature is in maximum position, or just when the armature cheek is leaving the pole tip. Thus the armature core is demagnetized, and the lines-of-force collapse and cut the secondary and primary wires at a very rapid rate. And, since there is such a large number of turns of wires in the secondary winding, the result is, that a very high voltage is induced in the secondary winding, which at normal speeds will cause a spark to jump across a gap of the spark plug. This spark is maintained to some extent by the voltage induced in the secondary by reason of the constant change of magnetic lines-of-force or flux in the iron core produced by the rotation of the armature during the period in which the contact points remain open. The cam then permits the contacts to close again, and the operation is repeated.

Importance of Condenser and of Quick Opening of Contact Points

The condenser is provided in order to absorb the spark at the interrupter points when the primary circuit is interrupted or separated. In other words, if the condenser were not across the points, the lines-of-force collapsing so rapidly would produce a very high voltage in the primary winding and thus cause a heavy spark at the breaker points, before they had time to separate properly, just as it does when used with a low-tension magneto and make-and-break igniter. As explained before, this results in burning the platinum points.

If the contact points could be opened quickly enough, the condenser could be dispensed with. In fact, if this were possible, the magneto would be better without it, because the condenser absorbs the initial current rush from the primary, produced by the collapsing lines-of-force, until the points are fully opened, thus preventing sparking at the points. But this is accompanied by the disadvantage of preventing the voltage from building up to a high value before the contact points have had time to separate properly. At the same time that it retards the development of the primary voltage, it retards the secondary voltage in building up also. Therefore the condenser capacity should not be greater than just enough to suppress the spark at the points. Of greater importance is the **quick opening of the contact points,** and proper adjustment.

An advertisement of a magneto manufacturer reads as follows: "The most perfect interrupter that has ever been placed on a magneto. Its quick opening is largely responsible for the efficiency of the magneto." This is mentioned so that the reader will appreciate the importance of the quick opening and the proper adjustment of the interrupter points.

In the instruction book of the K. W. Ignition Co., the following wording appears relative to the interrupter points:

> "A word of warning at this time, as to the proper distance to set the contact points to open, might be of value.
>
> "The volume of spark produced depends to a large extent on the proper break of the points. If they are opened quickly and make a clean break, the maximum spark is produced. When the points are too close, they do not break clean, as the arcing at the point causes the current to linger in the primary. When the points are too far apart, they may not close tight enough to allow current to flow, and in addition the opening of the points occurs too early and causes an unnecessary pounding on the roller. You will, therefore, note that the proper adjustment of the points will safeguard both electrical and mechanical difficulties.
>
> The points should be set to open 1/64" in order to get the best results. (This is on the K.W. high-tension magneto.) As a rule magneto manufacturers supply a gauge to which these points should be accurately set."

There are many different constructions of interrupters, some of which are shown farther on.

CONSTRUCTION OF A HIGH-TENSION MAGNETO

The following description refers to the **"compound-armature type" magneto.** As an example, the Bosch type "DU4" will be used. See Figs. 1, 2, 3, 4, and 5, and also other exaggerated illustrations in order that the purpose of the parts may be clearly understood.

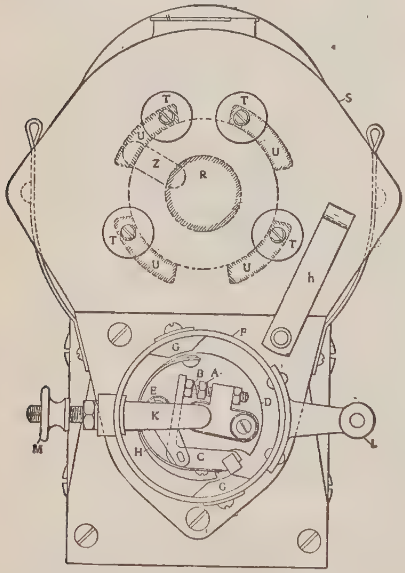

Fig. 3. Front view of Bosch 'DU4" magneto.

Interrupter Parts

A—Platinum point on insulated contact-breaker block which connects with one end of primary winding.

B—Platinum point on grounded breaker arm (C).

C—Contact-breaker arm; platinum point at one end and lug at other end, which comes in contact with cam (G) as (C) revolves.

D—Brass disk, fastened to armature shaft and rotating with it. (A), (B), and (C) are fastened to this disk and revolve with it, but (A) is insulated from (D) while (B) and (C) are grounded to it.

E—Carbon brush grounds (D) to magneto frame (see Fig. 2, page 257).

F—Cylindrical breaker-box housing which can be shifted by (L), to advance or retard.

G—Cam blocks which cause arm (C) to separate points at (A) and (B).

H—Spring keeps points (A) and (B) closed until separated by (G)

K—Connects with (A) or one end of primary, and connects with terminal (M) (insulated).

M—Connects with switch as shown in Fig. 1. Other side of switch is grounded. When switch is closed magneto is 'off".

h—Spring for holding cover in place.

Distributor Parts

T—Terminal to spark plugs.

Z—Distributor brush connecting with (R).

R—Connects with pencil brush (P) on collector ring (O), through contact conductor (Q), as in Fig. 2.

U—Segments or contact pieces connected with terminals (T) on which brush (Z) slides.

Magnets and Pole Pieces

Magnets and pole pieces: In any standard magneto made on this principle the general construction would be as follows: The permanent field magnets consist of two—or three—pairs. One magnet of each pair is superimposed above the others, as in Fig. 6; or 2 magnets are sometimes placed side by side.

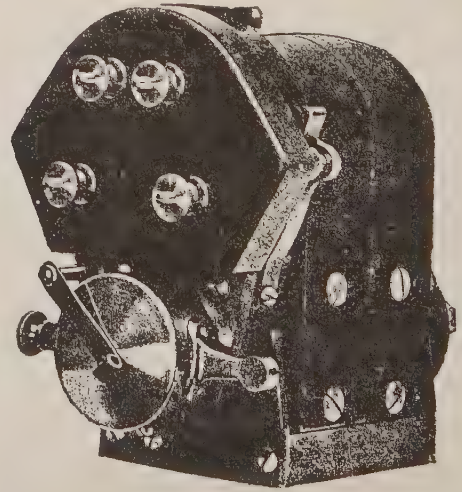

Fig. 4. Bosch "DU4" high-tension magneto for a four-cylinder engine. Note single magnets. Type "DU6" is the same, except that it is for a six-cylinder engine. Type "D4" has three-bar magnets; type "DR4," two-bar magnets.

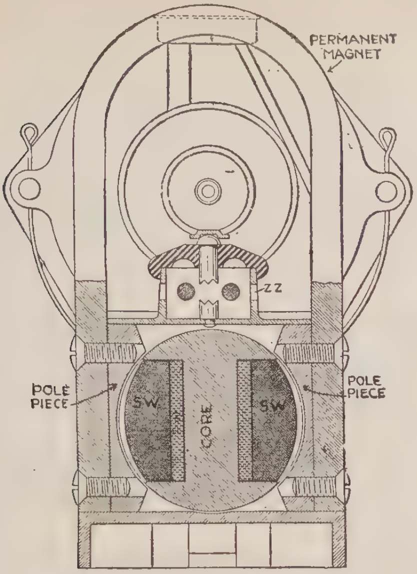

Fig. 5. Rear sectional end view. Note safety spark gap (ZZ); see also, Figs. 1 and 2. Note pole-pieces screwed to end of field magnets. The dark shaded part on the armature represents secondary winding; light shading, primary winding.

In some few cases three magnets are placed one over the other. For instance, on the Bosch "DU4," four-cylinder engine magneto, there are two magnets side by side. On the "D4" there are three magnets, and on "DR4," two magnets, as will be clear by examining Fig. 6. The magnets are set to give correct north and south polarity. All north poles on one side and all south poles on the other side.

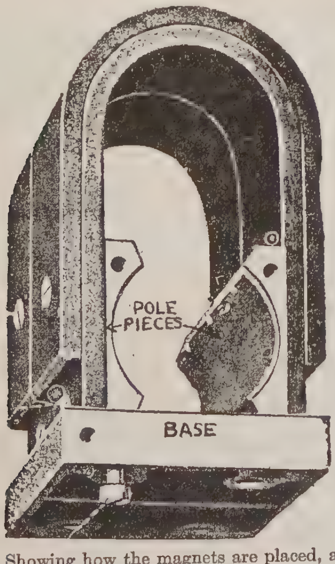

Fig. 6. Showing how the magnets are placed, and also the end pole pieces.

The ends or poles embrace "pole pieces" of soft iron bored out to allow the armature to rotate quite freely, but very closely to the pole faces; in some cases the clearance is only .002 inch. See also, Fig. 5.

Armature

The armature: This consists of a core of soft iron of H-shaped (Fig. 7) cross-section; it is also referred to as a "shuttle" armature. This core of soft iron serves to form a bridge for the magnetic flux between the pole shoes, and also to carry the winding in which the current is induced.

Fig. 7. Armature of the revolving compound type (double wound).

The armature is found in practically every standard type of the well-known "shuttle" type. The best class machines have the armature built up of thin stampings of soft iron, each insulated from the other by a thin film of varnish. This form of construction is known as a "laminated armature core." A laminated armature core is shown in Fig. 4, page 243, and a complete armature wound with double winding is shown in Fig. 7. Laminated cores have the advantage over a solid cast-iron core in that the electrical efficiency is higher through the absence of "eddy" currents in the iron core which represent considerable waste of energy and cause heating.

By laminating or breaking up the core into thin sections, the currents are prevented from circulating through the iron (spoken of as "eddy currents"). In the case of a solid core, the iron would be annealed to render it as "soft" as possible, to obtain the best magnetic effect.

Armature winding: The armature core is first insulated with mica or similar material. Then it has several layers of heavy insulated wire wound upon it. The Bosch DU-4 magneto has approximately three layers of No. 21 insulated primary wire and seventy to seventy-two layers of No. 36 silk-covered secondary wire.

To the end of this heavy primary wire is connected the beginning of a very fine secondary wire (see **N**, Fig. 1), insulated with silk, which is wound on the core until the slot is filled almost to the height of the cylindrical portion. After this a wrapping of insulating cloth is applied, and bands are put around the circumference of the armature to prevent the wire and insulating material from flying out and coming in contact with the pole shoes when the armature is rotated at high speed. To the ends of the armature the steel shaft or spindle is fixed by brass end plates (Fig. 7).

It will thus be noted that there are really two windings on the armature, whereas the low-tension magneto has but one winding—an inner winding of relatively few turns of heavy wire, and an outer winding of a large number of turns of fine wire.

The armature shaft is mounted in annular ball bearings (Fig. 2, **b** and **c**), which are provided with oil guards so that any lubricant supplied to them will not be easily lost or reach the insulating parts. The armature tunnel is closed on top by an aluminum cover **i**, (Fig. 2), and the front of the circuit-breaker housing is provided with a brass cover (**g**), which is held in place by means of a hinged flat spring (**h**), so that it can be removed and replaced.

Primary Winding and Circuit

The winding of heavy wire, or primary winding, serves primarily for generating the current, and in connection with the fine wire or secondary winding, it also serves for multiplying the pressure or voltage to such an extent that it will produce a spark at the gap of the spark plug in the cylinder.

The primary circuit (Fig. 1) begins with the primary winding (**PW**) on the armature. It flows through the contact-breaker screw (see I, Fig. 2), to the stationary contact (**A**), thence across to the movable contact (**B**), from which it is led through the contact brush (**E**), into the metallic framework of the magneto, whence it returns to the beginning of the primary winding, which is also connected or grounded to the frame (**GP**).

Interrupter or Contact-Breaker

The interrupter, also called a "contact-breaker." To accomplish this breaking of the primary circuit at the proper moment and then to close it again, a device known as a "circuit-breaker" or "interrupter" is used. This is carried on the armature shaft opposite the driving end.

In order clearly to explain the construction of an interrupter, exaggerated illustrations will be used as, for instance, in Figs. 8 and 8**A**.

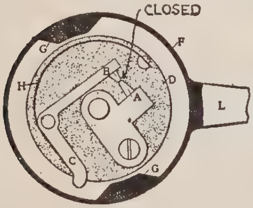

Fig. 8

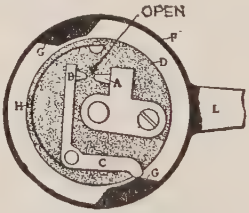

Fig. 8A

It consists essentially of a stationary insulated contact point (**A**), (Fig. 8), and a movable contact point (**B**) on one arm of the bell crank (**C**). Both of these parts are mounted on a brass disk (**D**), which is securely fastened to the armature shaft and rotates with it.

The stationary contact (**A**) is insulated from the supporting disk (**D**), while the movable contact (**B**) is in metallic connection with it, and the disk (**D**) is grounded to the frame of the magneto by a carbon brush (**E**). (See also Fig. 2.)

The circuit-breaker is surrounded by a cylindrical housing (**F**), to the interior surface of which, at diametrically opposite points, are secured steel cam blocks (**G** and **G1**).

Ordinarily the two contact-points (**A** and **B**) are kept in contact by a spring (**H**). As the disk (**D**) rotates, the outer arm of the bell crank (**C**) comes in contact with the cam blocks (**G**), whereby the contact-points (**A** and **B**) are separated momentarily, as in Fig. 8**A**.

As soon as the end of the bell crank (**C**) passes the cam block (**G**), the spring (**H**) brings the two contact-points (**A** and **B**) together again, as in Fig. 8.

The stationary contact-block (**A**) is connected with one end of the primary winding of the armature, through a screw (I, Fig. 2), which is screwed into the center of the armature shaft.

The other end of the primary winding has metallic connection with the armature core; in other words, it is grounded, as at (**GP**), (Figs. 1 and 2).

Secondary Winding and Circuit

The beginning of the secondary winding (**SW**, Figs. 1 and 2), is connected to the end of the primary winding at (**N**) (Fig. 1), and since one end of the primary winding is grounded at (**GP**), the secondary is also grounded through the primary. The end of the secondary winding leads to an insulated contact ring (**O**) (Fig. 2), at the driving end of the magneto.

From this ring the current is taken off by a carbon contact-brush (**P**). From the brush holder the current is carried through a spring contact-conductor (**Q**) to the central distributor contact (**R**).

The collector ring is made of hard rubber with a brass ferrule (**O**) surrounding it, against which ferrule a heavily insulated stationary carbon pencil (**P**) bears. The hard rubber spool has wide flanges for the purpose of preventing the high-tension current from escaping.

Secondary Distributor

The distributor consists of a disk of insulating material (**S**), in which are imbedded on the inner side one central cylindrical contact-piece (**R**) and four annular sector-shaped contact-pieces (**U**, **U**, **U**, **U**, Fig. 1).

The distributor also comprises a shaft (**V**, Fig. 2), which carries a gear wheel (**W**) meshing with a pinion (**X**) on the armature shaft. The gear wheel (**W**) has twice the number of teeth as the pinion, and the distributor shaft (**V**) therefore makes one turn while the armature makes two.

Distributor speed: The reason for driving the distributor at one-half the armature speed is as follows: The armature, as already stated, turns at the speed of the engine crank shaft. The magneto here described is for a four-cylinder, four-cycle engine. In such an engine, each cylinder requires a spark once in two revolutions of the crank shaft.

The distributor is therefore geared so that it makes one revolution to two revolutions of the crank shaft and establishes connection between the high-tension or secondary winding of the armature and the spark plug to each cylinder once in every two revolutions of the crank shaft.

Regardless of the number of cylinders an engine may have, the distributor rotor always turns at engine cam-shaft speed.

The gear wheel (**W**) carries a brush holder (**Y**) containing a carbon brush (**Z**), which is adapted to make contact simultaneously with the central distributor contact (**R**), and with one of the annular distributor contacts (**U**).

This type of distributor is the "brush" type, as it makes a wiping contact. The "gap type" is shown in the Berling, explained farther on.

The distributor sectors (**U**, Fig. 1), are surrounded at the inside and outside by annular rings of a highly insulated material, since they carry the high-tension current.

Each of the four annular contact segments (**U**) has secured to it a binding post (**T**) on the face of the distributor disk, and each of these binding posts is connected by a high-tension (highly insulated) cable to one of the spark plugs.

The connections from distributor terminals (T) to the spark plugs are connected according to the firing order of the engine.

If distributor rotor (Z, Fig. 1) revolved as shown by the arrow point and the firing order of the engine was, say, 1, 3, 4, 2, the terminals (T) would be connected with the spark plugs accordingly.

The secondary circuit to the spark plugs is from (P) (Figs. 1 and 2), to (R), to (Z), to (U), to (T), to spark-plug center electrode, through spark-plug gap (X), through engine to ground (GP) on the magnets to (N) (Fig. 1), where the secondary is connected with the primary winding.

There are numerous methods of **taking the current from the secondary winding on the armature,** but in the Bosch a carbon brush pressing on an insulated ring is adopted, thus allowing the armature to rotate freely, and also enabling the induced current to be drawn off.

The distributor is, in effect, a rotary switch, especially insulated and provided with a number of contacts equivalent to the number of cylinders on the engine.

The distributor shaft is mounted in a plain bronze bushed bearing (V, Fig. 2), which is lubricated by means of a wick oiler (e). A felt washer (d) encloses the inner end of the bearing, while at the distributor end is provided a channel (j) for the escape of any oil working out of the bearing so that it will not reach the distributor. A large-sized oil well (o) is provided for the wick oiler and is closed by a hinged cover (f) on top.

Ground Brush

Some of the mechanical details of the magneto may be seen in Figs. 1 and 2, which are views of the Bosch model "DU4." It will be observed that a spring-pressed contact brush (a, Fig. 2) is placed in the base of the magneto bearing against the circumference of one armature end-plate. The object of this contact brush is to make absolutely sure that the revolving grounded metallic parts of the magneto are at all times in good metallic connection with the stationary part and the frame of the car; in this construction, therefore, the armature bearings carry no ground current.

Magneto Condenser

Condenser principle: When the two contact points (A) and (B) of the interrupter (Figs. 1, 2, and 3) are suddenly separated, there is a tendency for the current to continue to flow across the gap, since it possesses a property similar to the inertia of matter. This would result in a hot spark being formed between the contact points, which not only would burn the points away rapidly, but also would prevent a rapid cessation of the current, which, as already explained, is necessary in order to effect a rapid change in the lines of magnetic force through the armature and a high inductive effect in the secondary winding. To obviate this effect a condenser (J, Figs. 1 and 2) is employed, which, in the Bosch magneto, is placed in a hollow of the armature end-cover at the circuit-breaker end.

Condenser construction: This condenser consists of two sets of tinfoil sheets, sheets of opposite sets alternating with one another, and being separated by sheets of insulating material. All the sheets of each set are metallically connected, and one set is connected to the conductor leading from the primary winding to the stationary contact point (A), while the other set is grounded. In other words, the condenser is shunted across the interrupter.

Such a condenser is capable of absorbing an electrical charge, and its capacity is so proportioned that it will take up the entire charge of the extra, or self-induced current produced when the contact points (A) and (B) separate; that is, the extra current, instead of appearing in the form of a spark across the gap between (A) and (B) passes into the condenser (J). In this way the objectionable arcing or burning at the contact points is avoided, and the current flow in the primary circuit is more quickly stopped. See Index under "Condenser principle."

Magneto Safety Spark Gap

Purpose: This is practically a safety valve for the high-tension current. If, for example, a wire became detached from the sparking plug or from the distributor so that the ordinary path of high-tension current was barred, there would be considerable danger of the current forcing a circuit through the insulation of the armature, and thus doing very considerable damage, were it not given some easier escape.

In order to protect the insulation of the armature and all other parts from injury due to excessive voltage, a **safety-spark gap** (Z1, Z2, Fig. 2) is provided to permit the passage of the current to ground without injury. The current will pass across the safety-spark gap (X, Fig. 2) in case a high-tension cable is disconnected, if the spark-plug gap is too great, or if for any other reason the spark-plug or distributor circuit is open.

Discharge should not be permitted to pass through the safety spark gap for any great length of time, however. This should be particularly guarded against if the engine is operated on a second or auxiliary ignition system. When the engine is operated on such a system, the magneto should be grounded (by closing the primary circuit) in order to prevent the production of high-voltage current. See also Index under "Safety spark gap."

A magneto must be so designed that it will give a sufficiently hot spark at a comparatively low engine speed, and the ability to do this implies the ability of generating very large and hot sparks and enormously high tension at high engine speed.

The actual electromotive force or tension produced in the secondary winding is, however, limited by the size of the spark gap in the spark plug, for as soon as the tension reaches a point sufficient to jump this gap the discharge occurs, and there is no further increase in the electromotive force.

Suppose, however, that the terminals of the spark plug are by chance bent unduly far apart, or that one of the high-tension connections to the spark plug accidentally comes loose, then there would be no chance for the spark to pass in the ordinary way and the electromotive force in the secondary winding might build up to such an extent as to puncture the insulation of the winding, which would ruin the armature. To avoid this the safety spark gap is provided.

Safety spark gap construction: It consists of a little chamber (Fig. 2) formed on top of the armature cover plate with a top of insulating material (ZC). Into the top and bottom of this chamber, spark terminals (Z1, Z2) are set.

The spark terminal in the bottom is, of course, grounded, and that in the insulated top is connected with a high-tension contact brush (P) by a strip connector. Or, in other words, the safety gap is shunted across the secondary circuit.

The gap (**X**) between the two terminals (**Z1, Z2**) is longer than the gap between the spark plugs, and ordinarily no spark will pass between these terminals. But if, owing to the conditions already mentioned, no spark can pass at the regular spark plug and the electromotive force in the secondary winding attains an abnormal value, a discharge will occur at the safety spark gap, thereby preventing the secondary electromotive force from rising still higher.

The width of gap should be 5/16″ to ⅜″, and, of course, is always more than the width of the spark-plug gap, otherwise the spark would occur at the safety gap.

For high-compression engines it should be set at ⅜″. Under high compression, the sparks may fire across the safety gap instead of firing in the engine. Missing under such conditions can easily be remedied by opening the safety gap so that it will offer a greater resistance to the secondary current than the spark-plug gap, under compression.

A number of other illustrations are also shown of the Bosch DU4 magneto, in Figs. 3, 4, and 5, which may aid those not familiar with mechanical drawings to grasp the arrangement of the parts.

So far as the above description of the individual parts and their functions is concerned, it applies to any true high-tension magneto, that is, a magneto having both a low-tension and a high-tension winding on the armature. .

Each of the elements here described is always present, and serves the purpose indicated, though the relative location of the parts varies somewhat.

To Cut Off the Magneto Ignition; the Switch

It is necessary to be able to stop the magneto from producing sparks when it is desired to stop the engine. (See Fig. 2.) To this end a sheet-metal strip (**K**) is provided which makes contacts with the stationary contact point (**A**) of the circuit-breaker and leads to a binding post (**M**) on the circuit-breaker housing. From this binding post a wire is carried to a switch on the dashboard. One side of this switch is grounded.

When the switch is closed (Fig. 1), the current generated in the primary winding of the armature flows to contact-point (**A**), thence through strip (**K**), binding post (**M**), and connecting wire to the switch, whence it passes through a wire into the framework of the car and returns to the grounded primary (**GP**). The effect of this is that the primary winding is "short-circuited" all the time, and the opening and closing of the contact-points (**A**) and (**B**) has no effect. In other words, the circuit-breaker is "cut out."

When the switch is open, the circuit is then from primary circuit to (**A**), through points to (**B**), through ground (**GP**) to the other end of the primary. Thus when the circuit-breaker opens, it is in series with the primary circuit, and performs its regular duty.

The flow of the primary current can easily be followed in the diagram of connections (Fig. 1), where its direction when the magneto is working regularly is indicated by full arrows, and its return path when the magneto is running but not producing sparks, is indicated by dotted arrows.

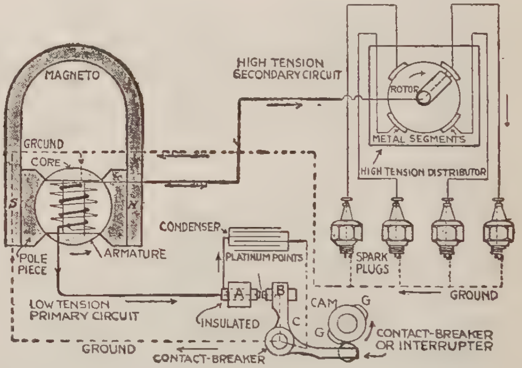

Fig. 9. Another simplified illustration of a high-tension magneto ignition system, showing circuit of primary wire winding on armature and its connection with interrupter. Note the condenser is "shunted" across the interrupter. Another view shows the distributor and spark plugs and connections. Dotted lines represent the earth or ground connection to frame.

HIGH-TENSION MAGNETO IGNITION SYSTEMS

High-Tension Magneto Alone

In Fig. 1, page 256, and in Fig. 1, below, note the high-tension magneto supplies current to the four spark splugs on a four-cylinder engine.

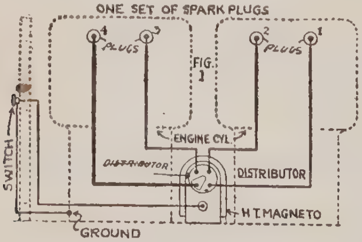

Fig. 1. A "single" high-tension magneto; engine is started direct from magneto current. Current is distributed to the one set of spark plugs. The switch connects to interrupter on magneto on one end, and to "ground" on the other. To stop magneto, the switch is closed, not opened.

The armature is double wound; therefore a separate coil is not necessary. The distributor on the magneto distributes the high-tension current to the spark plugs.

The advantage of using a high-tension magneto is that a well-designed magneto gives a very hot, fat spark and this spark exists for a definite period, thus firing all of the gas in each cylinder of the engine. The volume of the spark and the heat of the spark are important factors. Both are necessary to ignite the gas quickly, so that it will all be ignited before any part of the unburned gases can pass out of the exhaust. Thus it is clear that a heavy magneto spark has a very high degree of heat, whereas a lean spark takes longer to ignite the gas. Consequently, in the latter case, part of the gases have a chance to pass out the exhaust in an unburned state.

The disadvantage of this system is in starting. The armature on the magneto must be revolved fast enough to generate current before the spark will occur at the plugs. Therefore it is necessary to "spin" the crank. This is not very satisfactory unless an "impulse starter" or electric starter is provided to crank the engine. Hence this is one reason why "dual ignition systems" are adopted where a magneto is used. The starting of the engine is accomplished with a coil and battery system, and after the engine is started, the magneto is switched on.

The magneto, using an impulse starter (see Index) is used quite extensively on trucks and tractor engines, but is not used on passenger car automobile engines.

Dual Ignition

Dual system of ignition: Where a car has two ignition systems, for instance, a "coil and battery" and independent "magneto," but both systems using one set of spark plugs, this system is called a "dual" ignition system.

Dual ignition is quite common where magnetos are used, that is, before the advent of the "impulse starter"; the idea being to have an auxiliary battery and coil system to start on, and the magneto to run on.

There are two general principles of dual systems, which were formerly used to a great extent: the "low-tension magneto" and a separate "high-tension coil" and battery—as explained in pages 247, 254. The coil and battery were used for starting the engine; after starting, the magneto supplied the current to the coil.

The other method is the use of a "high-tension magneto" and a separate and distinct "high-tension coil" and battery ignition system. The engine is started on the battery and coil system, then switched over to the high-tension magneto which is independent of the coil and battery.

An example of a dual system using a high-tension magneto and separate high-tension coil and battery is shown in Fig. 2.

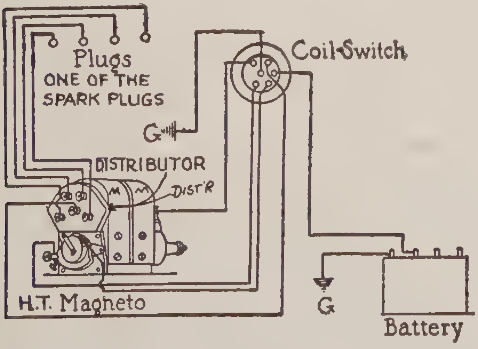

Fig. 2. A "dual" system of ignition; either the high-tension single coil with battery (using the distributor on the magneto) may be used or the high-tension magneto alone, may be used. Only one set of spark plugs.

Double Ignition

Double system of ignition: Where two sets of spark plugs are used with two independent ignition systems, this is called a "double" system. An example of a "double" ignition system using a battery, high-tension coil, timer, and distributor for one system, and a high-tension magneto for the other with two spark plugs in each cylinder, is shown in Fig. 3. Either of the two independent ignition systems can be used separately, or both can be made to operate at one time.

The positive (+) terminal of the battery is grounded and the negative (−) terminal led to terminal (5) of the stationary switch plate at the rear end of the coil. Switch terminal (1) is then connected with the binding post located on the under side of the timer-distributor. The second binding post on the timer-distributor, which is located on the under side of the timing control arm (7) is grounded. Switch terminal (2) is connected to the grounding terminal of the magneto.

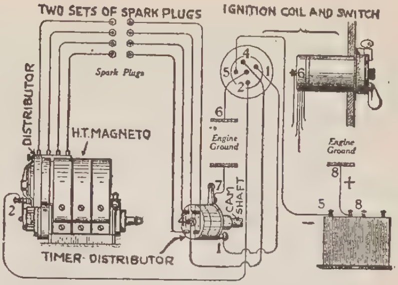

Fig. 3. Bosch "double" system of ignition—two sets of spark plugs and two independent ignition systems.

The distributor contacts on the magneto and timer-distributor are connected in accordance with the firing order of the engine.

When the switch lever is in the off position, the battery circuit is broken and the magneto is grounded, in consequence of which no sparks will be produced when the motor is cranked.

With the switch lever thrown to the battery side (B), the magneto will continue grounded, but the battery circuit will be completed, and, in consequence, the breaking of the circuit by the timer-distributor will result in the production of a spark that will be transmitted to the proper cylinder by its distributor.

The same condition will exist **with the switch lever thrown to position (MB)** (where both the magneto and the coil and battery are in operation), except that then the magneto ground circuit will be broken and magneto sparks will be produced in addition to the battery sparks.

With the switch lever thrown to position (M), or the magneto alone, the magneto will operate in the normal manner, and the battery circuit will be broken.

Two-Spark Ignition System[1]

Here we have two distributors on the one magneto, and two spark plugs are provided for each cylinder. The principle is similar to the "double" system, except that the one high-tension magneto has two distributors.

The purpose of the two-spark magneto (Figs. 4 and 5) is to produce ignition at two plug points in

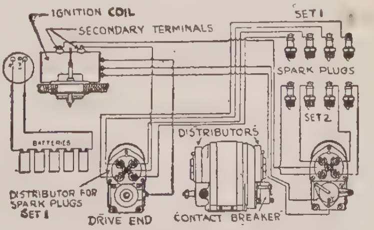

Fig. 4. Remy two-spark magneto ignition system; one magneto with two distributors connecting with two sets of spark plugs.

---

[1] The "two-spark" system was formerly used on the Stutz and Mercer. It has also been used on some Fiat, Locomobile, and Marmon cars. Some of these cars are now using a two-spark coil and battery ignition system.

each cylinder, in order to reduce the time interval between ignition and complete combustion; and, where it is possible, to locate two spark plugs in each cylinder (usually in T-head engines, one set of spark plugs being placed on the inlet side of the engine and one set on the exhaust side). The result is to reduce the ignition advance necessary, and thus to secure an increase in the efficiency and output of the engine.

The advantage of having two spark plugs fire at one time in each cylinder is the resulting increase of power and speed, explained as follows: By referring to the subject of "ignition timing," we learn that there is a difference between the time when the spark occurs and the actual time of combustion. Therefore with a weak spark, the time of the spark is made to occur earlier, that is, "advanced," before the piston reaches the top of the compression stroke, in order that it may have time to ignite the gas, combust, and expand before the piston gets too far down on the power stroke. With a "double" system or "two-spark" system, or a good hot spark, this advance of ignition is less, as the combustion is almost instantaneous. Consequently, with less advancement of spark, there is less liability of firing back on the piston before it reaches the top of the compression stroke. Furthermore there is a saving of gasoline, because with a good hot spark, all of the gasoline is ignited and used for power instead of part of it passing out of the exhaust, not fully ignited. In other words, a weak spark produces slow combustion, and a hot spark quick combustion.

The Remy two-spark magneto is shown in Fig. 4 and the Bosch two-spark magneto is shown in Fig. 5.

Bosch Two-Spark Magneto

The types "ZR4" and "ZR6" Bosch magnetos are produced with the two-spark, independent or dual form. The noticeable difference in the two-spark magneto from the single-spark magneto is in the double distributor (**DD**) (Fig. 5) and arrangement of the safety spark gap under the arch of the magnets.

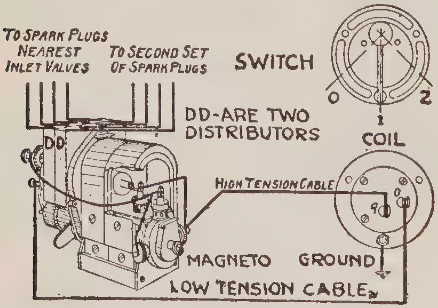

Fig. 5. Bosch two-spark magneto ignition system.

Fig. 5A (upper). Switch: 0, off; 1, one set of plugs operating; 2, both sets operating.

In the single-spark magneto, the beginning of the armature secondary circuit is grounded on the armature core through the armature primary circuit, whereas in the two-spark magneto, the two ends of the armature secondary circuit are connected to two sectional metal segments diametrically opposite on a single slipring.

Two slipring brushes are provided, which are horizontally mounted in brush holders on opposite sides of the shaft and plate. During the portions of the armature rotation when high-tension current is being delivered, each of the two slipring segments will be in contact with one of the brushes. One brush is connected to the inner distributor by means of a conducting bar similar to that used on single-spark magnetos. The second slipring brush is connected to the outer distributor by means of a short length of cable passing around the magnets. The rotating distributor piece is of double length and carries two brushes insulated from each other.

The four and six-cylinder types are fitted with eight and twelve distributor outlets respectively, each pair of outlets being connected to the spark plugs of the proper cylinder by the usual cables.

Advance and retard: The use of two-spark ignition permits the ignition lead to be cut down anywhere from 30 to 50 per cent. It will be understood that if the timing is correct for two-spark ignition, and one of the series of spark plugs is cut out of action, the remaining series will operate considerably in retard of what it would if the engine were timed for single-spark ignition. Therefore, if the two-spark ignition provides the full advance, the effect of retarding the spark is obtained by cutting out one series of plugs.

The switch (Fig. 5A) provided for the two-spark independent magnetos is so arranged that ignition may be secured, either with both sets of spark plugs, or with but one set. The purpose of this is to give the effect of retarding the spark, without altering the relation between the interrupter opening and the armature, as is done under normal conditions. The connections should be so made that the system of plugs that is operative when the switch is thrown to the single position is located near the inlet valve.

In starting, throw the switch lever to "single plug" position. This gives the effect of a retarded spark.

For ordinary running, operation should be on both series of plugs; **for slow work** through traffic, or when the engine is running idle, use the single plugs, or only one set.

Timing: "Time" in this connection refers to timing a single-spark magneto (interrupter retarded and piston on top of compression stroke). It will be found however that this timing will likely give two great a spark advance when the interrupter is fully advanced, as the two-spark magneto should have from one-third to one-half the advance of that of a single-spark magneto. Therefore retime, so that the interrupter points will open slightly later. A good method to follow is as given below.

To replace a single-spark magneto with a two-spark instrument, the maximum advance for the single-spark magneto is to be marked—preferably on the flywheel—and the two-spark magneto timed in the advanced position, so that the interrupter opens the circuit at a point midway between the mark on the flywheel indicating the single-spark advance, and that indicating top dead center retarded. A more exact timing may then be secured by experiment.

Berling Type "D" Two-Spark Magneto

This magneto is designed for four, six, and eight-cylinder engines where the charge in each cylinder is ignited simultaneously at two separate spark plugs.

The eight-cylinder type, shown in Figs. 6 and 6A, is designed to operate at twice the crank-shaft speed, and the six-cylinder magneto at one and one-half crank-shaft speed. The four-cylinder is designed to operate at crank-shaft speed. This type of magneto is designed for heavy duty, marine, and aeronautical engines.

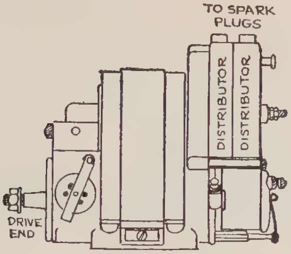

Fig. 6

In the type "D" two-spark Berling magneto, neither end of the secondary winding is grounded, but each is connected to one of the two separate segments on the collector ring.

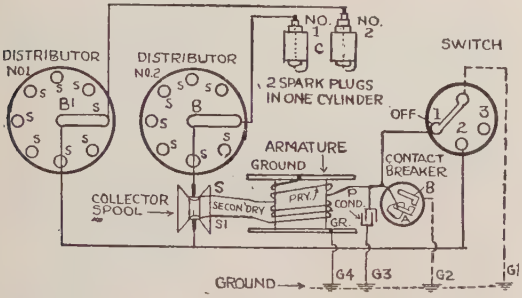

Fig. 6A

The distributing mechanism consists of two separate distributor blocks (Fig. 6) and one distributor finger carrying two separate distributor brushes (B), each brush connecting with the segments (S) of its respective distributor block. Thus, any two cable terminals directly opposite each other on the distributor blocks will practically possess an equal electrical potential relative to any part of the body of the engine.

When any two opposite cable terminals are connected each to one of two plugs in the same cylinder, the electrical circuit of the secondary or high-tension current will be closed the moment the spark gaps are bridged and that portion of the cylinder (C) between the two plugs forms part of the electrical circuit. The two sparks are the result of one break in the primary circuit by the interrupter, and are therefore absolutely simultaneous.

When the switch is in position 1 (Fig. 6A), the primary winding of the magneto is short-circuited and the magneto is "off." Note that the circuit is from (P) to (1), to ground (G1), to ground (G4), to the other end of the primary winding at "ground."

When the switch is on 2, note that the primary circuit is open at 1. Therefore the interrupter points on (A) and (B) perform their regular duty of opening the closed circuit at the proper time. The path is from (P) through (A) and (B) to (G2), to (G4), to "ground," or the other end of the primary.

The secondary circuit is then from (S) to (B), to No. 1 spark plug, through ground of engine, to ground (G1), to (2), to (S1), or to the other end of the secondary. Thus the magneto acts as a single-spark magneto and the entire voltage generated in the magneto is concentrated on the one spark plug for starting, instead of being divided in half.

When the switch is in position 3, the primary circuit is the same as when on 2 (in action), but the secondary is not grounded. Therefore, the secondary circuit would be from (S), to one of the two separate segments on the collector ring, to No. 1 spark plug, through cylinder (C) to the shell of the other spark plug (No. 2), across the spark-plug gap, to the distributor brush (B1), to the other segment on the collector ring, to (S1), thus completing the secondary circuit through both distributors with the result that the two spark plugs, which are thus in series with the secondary circuit, both fire at one time in the same cylinder.

Bosch Two-Spark Dual Ignition System

When the switch (Fig. 7A) **is thrown on the magneto side,** without the two-point switch (Fig. 7B) in the circuit, the path of the current is as follows: The low-tension current generated in the primary winding of the magneto passes through the breaker-points to ground. At the break of the points a high-tension current is set up in the secondary winding, this current leaving the magneto at 3 and passes to the point 3 on the coil, as indicated by the arrows. Then from point 3 to point 4 and thence to the distributor wire, along this wire to point 4 on the magneto. The distributor arm next receives the current which in turn is sent to the different plugs as indicated by the arrows. The current is sent to the ground after leaving the spark plugs, and the high-tension or secondary winding being grounded at one end, the secondary circuit is complete.

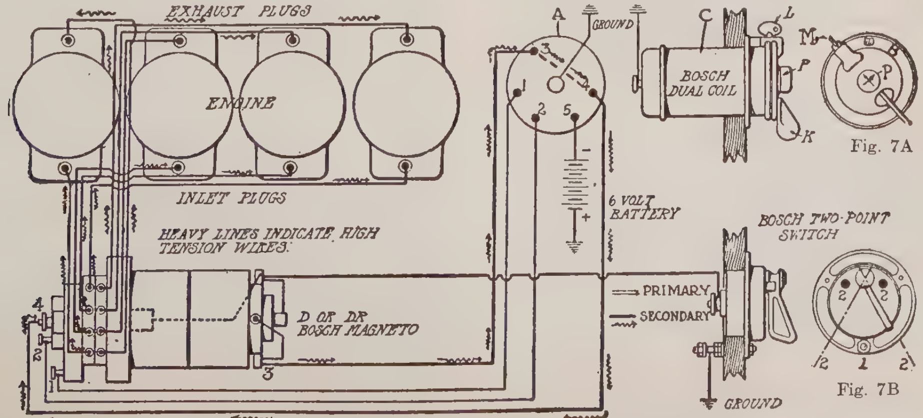

Fig. 7A

Fig. 7B

Fig. 7. Bosch two-spark dual ignition system. The coil parts (Fig. 7A) are: (L) key lock; (K) kick lever; (P) push button; (M) magneto operating both sets or one set according to position of two-point switch; (B) battery operating inlet plugs.

When the two-point switch (Fig. 7B) is thrown so that both sets of plugs are to come into play, both distributors of the magneto become operative. The path of the primary and secondary current to the magneto in this case is the same as before, but when delivered to the magneto, the current is passed to two distributors instead of one. In this way two distinct electrical currents are distributed to two different sets of spark plugs.

The coil and battery ignition is used independently of the magneto by switching to the (**B**) side of the switch (Fig. 7**A**) and one or both sets of plugs are connected with the two-point switch (Fig. 7**B**) (*Motor Age*).

Two-Point Ignition System

The "two-point" system is where two sparks occur at the same time but in different cylinders.

On a four-cylinder engine, the spark would occur at two spark plugs at once, but inasmuch as one of the pistons would be on exhaust stroke, this would make no difference.

The Bosch type "NU4" high-tension magneto is an example of a "two-point" system where two sparks occur at the same time, but in different cylinders.

Bosch Two-Point Magneto Ignition

The type "NU4" Bosch magneto differs from the usual type of magneto in that the distinct gear-driven distributor, common to other types, has been eliminated, and in its stead is a double slipring combining the functions of current collector and distributor. Otherwise it is about the same as any other form of magneto.

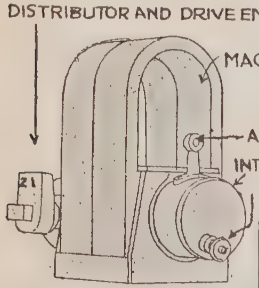

FIG 8 - INTERRUPTER END

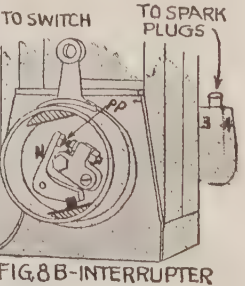

FIG 8 B - INTERRUPTER END

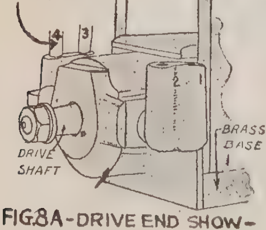

FIG 8A - DRIVE END SHOWING COLLECTOR RING ASSEMBLY

The spark occurs in two cylinders at one time with this system, but one of the cylinders in which the spark occurs has not completed its exhaust stroke; therefore the spark does no harm.

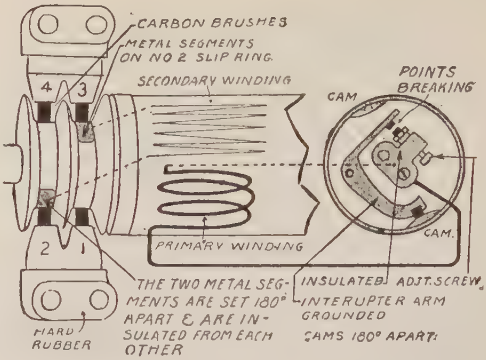

Fig. 8C

The interrupter contacts in the full retard position should open not later than top dead center of the compression stroke; therefore **the effective spark** is produced in the cylinder always toward the end of the compression stroke and **the surplus spark** will always occur near the end of the exhaust stroke and never during the inlet stroke. In any four-cylinder, four-cycle engine, regardless of firing order, when cylinder No. 1 is nearing the end of the compression stroke, cylinder No. 4 is nearing the end of the exhaust stroke, and vice versa; similar conditions apply also to cylinders Nos. 2 and 3.

ARMATURE AND SLIP RING HAS TURNED 180° A HALF REVOLUTION SAME AS ENGINE CRANK
NOTE FLOW OF CURRENT

Fig. 8E

The brushes, when making contact with the metal strip in the collector rings, collect the high-tension current and carry it to the spark plugs. Note the connections from ring to plugs. When brushes 2 and 3 are making contact, follow the circuit in Fig. 8D, and note the arrow points. Now if the piston makes another stroke, or 180° travel, the armature will turn 180° or half a revolution also, as it runs at engine speed in the four-cylinder, four-cycle engine. Therefore the contact on the ring will turn 180° or a half-revolution and cylinders 4 and 1 will fire as in Fig. 8E. This type of magneto was used on the model 80 Overland.

Timing the "NU4" magneto: With the average engine, this result is obtained by connecting the magneto so that its interrupter housing is in full retard position, and the platinum interrupter screws just about to separate, when the piston of No. 1 cylinder is on top dead center of the compression stroke.

At the same time the metal segments of the slipring should be in contact with the brush marked "1" in each brush holder, and this can be observed by removing one of the holders.

The installation is completed by connecting the brush marked "1" with cylinder No. 1, and the other with cylinder No. 4, and the two remaining brushes, marked "2" and "3," with cylinders Nos. 2 and 3.

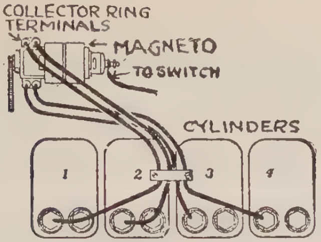

Fig. 8F. Note connections from collector ring terminals to spark plugs.

It is important to note that the type "NU4," driven, as it should be, at engine speed, produces a surplus spark in each cylinder exactly 360° behind the effective or power spark and, in coupling the magneto to the engine, it must be timed so that the surplus spark occurs during the exhaust stroke and not after the inlet valve has commenced to open.

Bosch Vibrating Duplex System

The Bosch vibrating duplex system is designed to permit easy starting on cars that are cranked by a starting motor at such a low speed that the ignition current from the ordinary magneto is insufficient to give certain ignition.

Do not confuse this system with an electric system of starting by movement of the crank shaft. The principle of this system is to supply a separate battery and vibrating coil to start the engine on, doing away with a dual system.

How it operates: The arrangement is such that, while the magneto circuit is absolutely independent and complete in itself, the battery circuit includes both the coil and the magneto.

Fig. 9. Bosch vibrating duplex ignition system.

With the switch in the battery position, the battery and coil are in series with the primary winding of the magneto armature, and the current from the battery supplements that generated by the magneto. Thus there is induced in the secondary winding of the magneto armature a very powerful sparking current, which, on account of the vibrator action of the coil, appears not as a single spark, but as a series of intense sparks that will act with certainty on any explosive mixture. The sparking current so produced is distributed in the usual way by the magneto distributor.

After the engine is started, the switch is turned to (**M**) side, and the coil and battery are disconnected.

THE BOSCH DUAL-IGNITION SYSTEM

The parts of this system are shown in Fig. 10. This system provides a coil and battery system and a high-tension magneto system, both independent. One set of spark plugs and one distributor on the magneto is used for both systems.

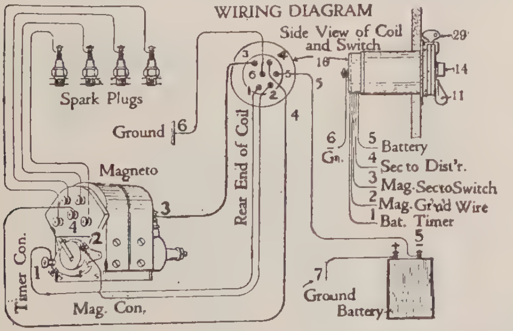

Fig. 10. Wiring diagram of the Bosch "DU4" dual-ignition system. The "DU4" type magneto is fitted with two interrupters as in Fig. 11, instead of one as generally used.[1]

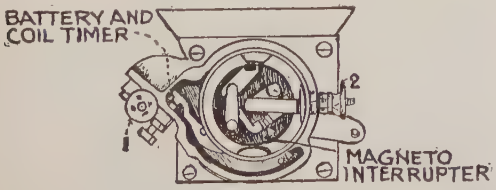

Fig. 11. The magneto is the regular "DU4" high-tension magneto fitted with an **independent timer** or interrupter for the coil and battery system. This contact-breaker has no electrical connection with the magneto. The second alteration from that of the regular single "DU4" high-tension magneto consists of the removal of the connection (see Fig. 2, page 257), which on the ordinary magneto connects the high-tension collector-ring to the distributor; when the distributor does duty for two ignition systems, the current must be carried to it through the switch, via wire 4 when the battery and coil system are switched on (see Fig. 10), or via wire 3 when the magneto is switched on.

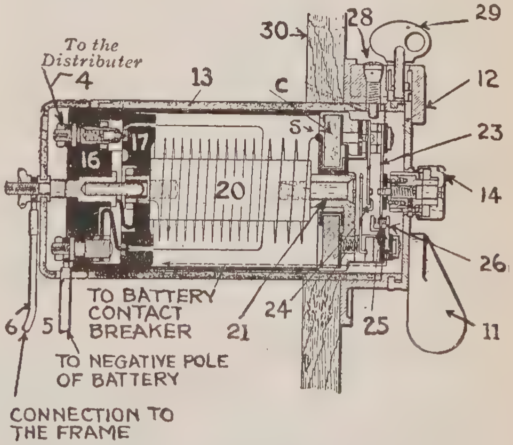

Fig. 12. The coil and switch (mounted on dash) are shown: The coil is a double-wound high-tension coil. The switch controls both ignition systems. Note that when switch (11) is turned, the coil with its core (20) and winding, and end of coil (17) turn also. Switch plate (16) is stationary.

Parts of the switch and coil are as follows: 11, switch handle (also called, kick-switch); 12, movable switch cover; 13, coil case; 14, starting press button; 16, fixed or stationary switch plate (see also, Figs. 17 and 18); 17, movable switch plate on rear end of coil (see Fig. 16); 20, iron core of coil over which primary and secondary are wound; 21, plate carrying starting arrangement and condenser; (C) condenser. Primary winding connects to it at (S); 23, contact spring; 24, trembler blade also called vibrator blade; 25, auxiliary contact-breaker; 28, screw holding switch plate to coil; 29, locking key; 30, dashboard or cowl.

---

[1] In practice, connections from distributor to spark plugs are not as shown; if so, it would fire 1, 2, 4, 3, or 1, 3, 4, 2. The main purpose of diagrams is to show the switch circuits.

Fig. 17. Inner side of stationary switch-plate (as shown at 16, Fig. 12) showing connections 1, 2, 3, 4, 5, and 6, which make contact with connections (**Z**, Fig. 16) when switch is turned to (**B**) or (**M**) side.

Fig. 18. Rear-end view of switch-plate (16, Fig. 12) showing terminals to which wires are connected as shown in Fig. 10.

Starting Engine

The engine is usually started by the switch being placed on the (**B**) or battery side; the interrupter (1) on magneto being used for the primary winding on coil and the distributor on magneto being used to distribute the high-tension current to the spark plugs. Otherwise the magneto has no connection with the battery and coil-ignition system when the switch is on the (**B**) side.

In order to start the engine with the starting handle (or electric starter, if one is provided), the press-button (14, Figs. 10 and 12) is pressed down and then turned at right angles, a process which locks it in position for the trembler spark.

The engine can also be started on the switch or "ignition," as it is often termed. The switch is turned to (**B**) side and then the brass press-button (14) is pressed down. Often this will start the engine, if the cylinder has a charge of gas in it. If not, then it will be necessary to crank the engine after locking the press-button as explained above.

To understand this ignition starting feature, see Fig. 19. The six-volt storage battery (or 10 dry cells) is supposed to be switched on (**B**) side.

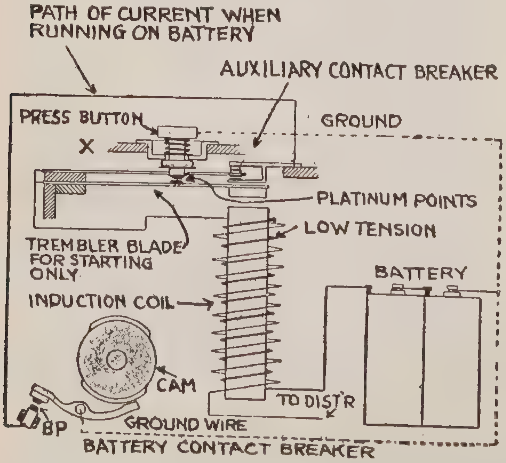

Fig. 19

Starting from the left-hand storage battery terminal (to make it easier to understand), the current passes through the primary winding and arrives at the end of the trembler blade and the blade above, called the auxiliary contact-breaker. The current cannot travel beyond the trembler blade because, as will be seen, the platinum points are separated. Neither can it complete the circuit along the auxiliary contact-breaker blade because the main contact-breaker (left-hand lower corner) also stands open, being the position in which the contact-breaker always comes to rest when the engine stops, save for the few occasions when the engine stops with the piston about dead center.

To start the engine, therefore, we have only to press the button so that the upper platinum point comes into contact with the lower one, and immediately the circuit will be completed, the trembler will start buzzing, and a shower of sparks will be sent through the plug of the cylinder which is next to fire. Now the work of the trembler blade is done, the engine has started, and the main contact-breaker is set in motion. The current troubles no longer about the trembler blade, but follows the upper path along the auxiliary contact-breaker and through the main contact-breaker, the making-and-breaking of which does the work of the trembler and creates the high-tension current. The engine may be kept running in this manner at the pleasure of the driver.

The auxiliary contact-breaker (Fig. 19): Now let us take the exceptional case of the engine stopping with the pistons about dead center and the main contact-breaker points (**BP**) closed. The current this time finds an easy circuit through the closed points, the iron core becomes magnetized, the trembler blade is held down on the core, and pressing the button as before has no effect. No spark is made because there is no break in the circuit. But if the reader will examine the diagram closely, he will observe that the act of pressing the button presses the auxiliary contact-breaker blade away from its upper platinum point and on to its lower one, the momentary break thus caused in the circuit being sufficient, under the circumstances we are supposing, to create the necessary high-tension current for the spark in the cylinder and so to start the engine.

When the engine stops in the more usual way with the storage battery contact-breaker open, the opening and closing again of the auxiliary contact blade has no effect. The diagram (Fig. 12) shows the coil as it actually exists.

Battery and Coil Position

The illustration (Fig. 20) is supposed to represent the rear of coil and switch. Points 3 and 4 are not connected, consequently the magneto secondary circuit is open. Note that the magneto primary wire is grounded at 2; therefore it is out of service.

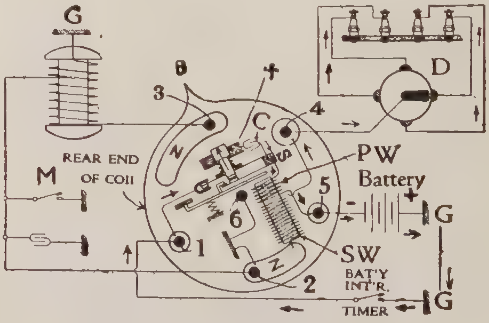

Fig. 20. Battery position.

Coil primary circuit: When the switch is on (**B**) side the current in the battery leaves it at the positive (+) side and travels through ground wire (G) to battery and coil timer or interrupter, which is operated by a cam on the magneto. The course is then to post (1) through mechanism in direction of arrows, to point (S).

It flows then through the primary winding (PW) of the coil, and as the arrows show, through point (5) back to the battery, thus completing the primary circuit.

Coil secondary circuit: In passing through the primary winding, a high-tension current is set up in the secondary winding (SW), when breaker-points separate.

This high-tension current flows to the distributor wire at (4), thence to magneto distributor (D). Here it is passed to the different spark plugs in order. It goes through the spark-plug center terminal across gap to shell of plug to cylinder, thence to ground back to other end of secondary winding (note lower end of secondary is grounded to bus-bar (Z) which is grounded with 6). The coil condenser is shown at (C).

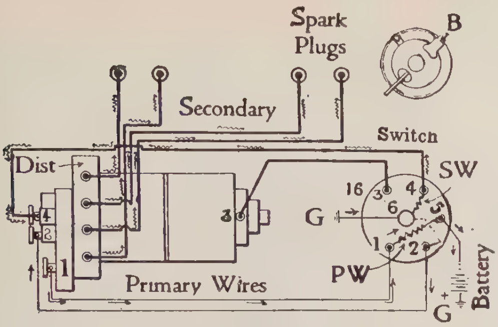

Fig. 21. Battery position.

The outside wiring of the battery and coil system is shown in Fig. 21, when the switch is on (B) side. (Note that points 3 and 4 are not connected, thus opening the magneto circuit.) The primary current leaves the battery and travels to ground (G). As (6) is grounded, current goes to (6), thence to (2) and along (2) to the magneto; then to (1) on magneto along wire as indicated by arrows to the point (1) on switch plate (16). Here it travels through primary winding (PW) of coil then to (5) and back to battery, thus completing the primary circuit. The secondary circuit is from (4) to distributor, thence to spark plugs.

Note: When the switch is turned, the rear end of coil (Fig. 16), with the bus-bars (Z) moves and connects with the inner side of switch plate (17). Therefore, when the switch is thrown on (B) side the point (1) on switch-plate (17) lines up with point (1) (one of the bus-bars Z) on rear end of coil (Fig. 16); likewise (2) and (5) line up with bus-bars on the end of coil. A study of Fig. 20 will help make this explanation clear.

Magneto Position

Note in Fig. 22 that the switch is now on (M) magneto side and there is but one closed circuit; it was made by connecting (3) and (4) on switch plate (16) with bus-bar (Z) on rear of coil. Note all other points of contact are open, including the magneto short-circuiting or grounding wire connected with (2).

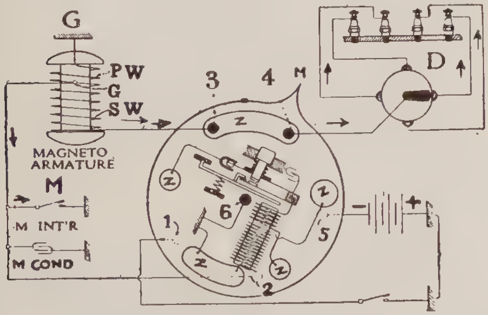

Fig. 22. Magneto position.

The magneto primary circuit is then from primary winding (PW) of magneto armature, to magneto interrupter (M), thence to ground. The other end of the primary winding (PW) is grounded, thus completing the primary circuit.

The magneto secondary circuit: One end of the secondary winding (SW) goes to (3) and (4) which are now connected with bus-bar (Z). From (4) it flows to distributor (D), thence to and through spark plugs. Here the current is grounded. The other end of the secondary winding (SW) is grounded, also by connection with primary wire, thus completing the high-tension circuit. Note the magneto condenser below the magneto interrupter.

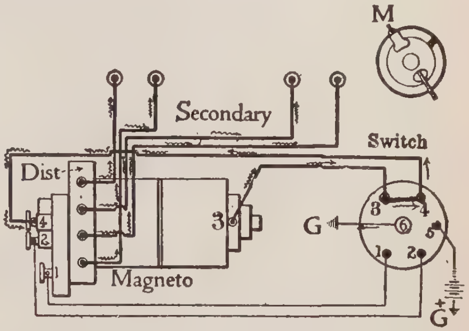

Fig. 23. Magneto position.

The outside wiring of the magneto position is shown in Fig. 23. Note points 1, 2, and 5 are not connected.

The high-tension (secondary) current generated in the magneto armature leaves the magneto at (3), travels to (3) on switch-plate (16), thence to distributor wire (4), then to the distributor, where it is then distributed to spark plugs.

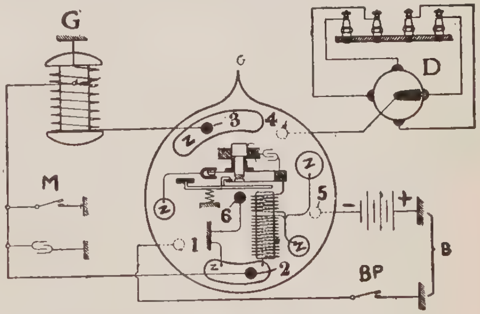

Fig. 24. Off position.

The off-position of the switch is shown in Fig. 24. Note in this position there is no complete circuit, as points 1, 5, and 4 of switch-plate do not coincide with points 1, 5, and 4 of coil switch-plate. Note, too, that the primary circuit of the magneto is short-circuited, or grounded at (2) on switch-plate; thus it is out of service. The magneto secondary circuit is open from 3 to 4.

Fig. 5. Winding of armature and connections. **The primary winding** leads from the upper part of the primary winding to (J), to points (**P**), to (17**M**), to (**CB**), to ground, to the lower end of the grounded primary winding.

The secondary winding leads from the upper part of the secondary winding, to the distributor brush, to the spark plug, to ground, through the grounded primary winding, to the lower part of the secondary winding, where it is connected with the primary winding.

The Eisemann "G4" type of high-tension armature-type magneto differs from other Eisemann types in that the make-and-break or interrupter mechanism is constructed on different lines. The platinum contact springs (17**M**) (Fig. 5) connect with a carbon brush (**CB**), which revolves in a brass ring (**A**). Ring (**A**) is stationary, whereas the spring (17**M**) revolves with the other contact plate (**J**). Contact plate (**J**) is insulated from (17**M**). One end connects with primary winding on armature, and when contact is interrupted by (17**M**) and the point on the screw in plate (**J**), the spark is given as usual. Rings (**A**) and (17**M**) are grounded.

The points of (17**M**) and the screw on plate (**J**) are separated by the timing device (Fig. 4) which goes over the ring (**A**). The contact spring rides over the fiber cams.

The novel features of this system, besides the breaker, are: its accessible and efficient grouping of the working elements all at one end, and its waterproof qualities.

To set the time of spark: Place piston of No. 1 cylinder on top of compression stroke. Set interrupter points to break in full retarded position.

With these systems it is merely necessary to bring No. 1 piston to top dead center, rotate the magneto until the setting mark on the distributor is opposite the pointed screw at the top and couple up the drive. Use marks (**R**) or (**L**) (Fig. 2) for right or left-hand rotation, respectively, as needed—rotation being judged from the driving end.

Adjustments: The breaker gaps should be set .012″ and spark-plug gaps 1/64″ to 1/32″.

To stop or cut off ignition: On all magnetos the magneto is stopped generating by closing or short-circuiting the primary circuit—not by opening the circuit, as in a coil system.

EISEMANN AUTOMATIC SPARK-CONTROL MAGNETO

Construction of the Eisemann high-tension armature-type automatic spark-control magneto is the same as that of the standard high-tension magneto with the addition of the automatic mechanism.

As for the details of the method by which the **automatic timing is obtained,** a cage is mounted on an extension of the armature shaft, and a rectangular block slides in this cage. This block is drilled and threaded for the reception of a helically-cut shaft (**T**). This shaft is the driving shaft which is attached to the gearing. It has a thick, double thread which is square cut and the block slides back and forth on this threaded shaft.

Centrifugal governor weights are attached to the blocks by means of links. The weights fly outward when the shaft is revolved, and the action of the links causes the block to slide in the cage. In so sliding it travels along the threaded shaft, and as a result the block is slightly rotated.

The drive of the magneto is applied through the shaft which therefore is unyielding, and as the block rotates it carries with it the cage in which it works and the armature shaft to which the cage is fixed. The armature is thus advanced, and the contact-breaker, attached to the other end of the armature shaft.

When the speed drops, the reverse motion takes place, assisted by action of a spring against which the governor works at all times. With this device automatic advance may be obtained from 18° to 57°.

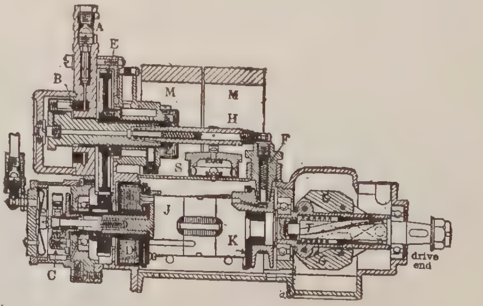

Fig. 6. Sectional view of Eisemann automatic spark-control magneto.

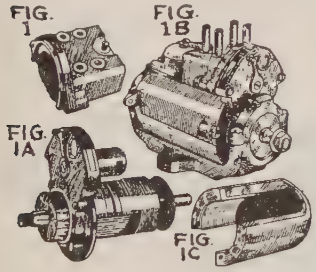
MEA MAGNETO

In the "Mea" high-tension armature-type magneto the design is such that the **magneto field can be moved round simultaneously with the contact-breaker,** so that the armature is always in the same position relative to the field when the break occurs. This is effected by having a bell-shaped magnet mounted horizontally, the axis of the armature and the magnet coinciding. As the contact-breaker is moved, so also is the magnet to a similar distance, and the result is that the spark is of ample strength at the retarded position, even allowing for the slow speed of rotation. This bell-shaped magnet (Fig. 1C), it is claimed, has some other advantages over the ordinary U-shaped magnet, inasmuch as it can hold a greater amount of magnetism and retain it at full strength for a longer period. The range of advance and retardation on this magneto is 40°. The armature and distributor are made practically on the lines of the standard magneto with fixed magnets.



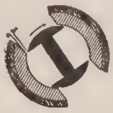


Fig. 1D. Advanced.

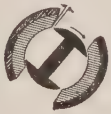

Fig. 1E. Retarded.

Fig. 1. Parts of Mea magneto: Cover: **1A**, armature and distributor units; **1B**, complete machine; **1C**, movable bell-shaped field magnets. The relative positions of the pole pieces and armature are shown in Figs. 1D and 1E. Note that 1D shows the armature advanced, and 1E in retarded position, showing that the "maximum position" where the armature breaks from the pole piece is not altered.

Timing the "Mea" magneto: Unless the timing of the magneto can easily be changed by advancing or retarding the gear driving the magneto, the coupling should not be keyed to the tapered shaft before the magneto is first placed on the engine, but it should be clamped on so that the timing may still be somewhat modified if found desirable.

Place the magneto in the position of its maximum retard (Fig. **1E**), by turning the magneto housing or timing lever in the direction of the armature rotation. Remove the cover from the breaker box and turn the armature shaft in direction of rotation until No. 1 appears on the indicator (Fig. **1B**) in the front plate of the magneto, and until the contact-breaker begins to open.

With the dual-type magneto, remove the cover over the battery breaker (driven end of magneto), and the number of the cylinder firing can be seen opposite the red line on the magneto housing. Turn the armature of the magneto until No. 1 on the distributor gear is opposite the red line on the housing and until the magneto-breaker (not battery-breaker) just begins to open. Then turn the engine to dead center of cylinder No. 1, and if of the four-cylinder type, about 1½" beyond, measuring on the circumference of the fly wheel, or from 1/16" to 3/32" downward on the explosion stroke. With six-cylinder engines, it is preferable to time full retard only slightly beyond dead center.

After the magneto and engine have thus been set, effect a positive connection between the two. Of course contact hole No. 1 of the distributor is connected with cylinder No. 1 by means of cables, and so on until all the cylinders are properly connected.

With the "Mea," the engine should be started with the spark fully retarded, and by increasing the speed gradually it can readily be determined if the engine will stand all the advance which the magneto can furnish with the original setting, or whether the whole timing can be further advanced. After it has become assured that the best timing is obtained, the coupling should be keyed to the magneto shaft.

DIXIE MAGNETO[1]

The large number of magnetos commercially in use prior to the advent of the "Dixie" were of the "armature type." It is therefore necessary to make a comparison in order thoroughly to explain the "Dixie."

Armature-Type Magneto

An "armature"-type magneto is shown in Figs. 1, 2, and 3. Referring to Fig. 1, note that the magnetic lines-of-force, hereinafter referred to as "flux lines," flow from the N to the S pole of the U-shaped magnet through the revolving armature in the direction indicated by the arrow. The shaded end (E) of the armature is shown in the figure as being under the influence of the N pole of the magnet.

In Fig. 2, the armature has revolved to the right sufficiently for the end (E) to come under the influence of the S pole of the magnet. Immediately the direction of the flux lines is reversed through the armature as shown by the arrow, and at the instant that current is generated in the winding about the armature, the spark occurs. In practice, more than one winding is employed, also an interrupter and a condenser are used. But the function of these parts need not be referred to here, it being the purpose now to show only the differences in the operation of the **magnetic circuit** of the two types.

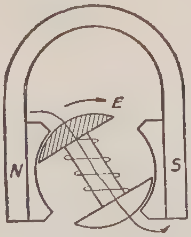

Fig. 1

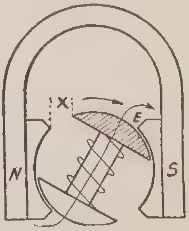

Fig. 2

Now it is obvious that the mass of iron in the armature must reverse its magnetic polarity. In Fig. 1, it is saturated with magnetism flowing in one direction. In Fig. 2, the direction is reversed. This reversal must take place in each rotation, so at high speeds the quicker the iron reverses the better the spark. As a laminated armature, or one built up of a number of pieces of iron, reverses quicker than a solid one, all good armatures are laminated. But it is also evident that to secure the desired amount of current the armature must be of a certain size to contain the necessary wire, and therefore contains a certain amount of iron in some form. Now, the more iron beyond a certain limit, the slower the reversal; also the reversal is not as abrupt.

---

[1] Most of the text has been taken from the printed circular of the Dixie magneto.

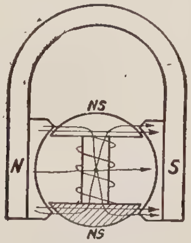

Fig. 3

Fig. 3 shows the "neutral" position of the armature wherein it is subject to flux-flowing across through its ends as shown. This position does not permit of an abrupt change of flux-flow as hereafter described, and such as occurs in the Dixie. The armature is never completely out of the flux, but simply turns around in the flux-stream, twisting the lines about, but not actually abruptly breaking them.

Dixie Principle

The "Mason" principle, on which the Dixie operates is shown in Fig. 4. The magnet has two rotating polar extremities (N) (S), which are always of the same polarity, never reversing. These poles are in practical contact with the inner cheeks of the permanent magnet (**M**), all air gaps being eliminated. Together with the U-shaped magnet, they form a magnet with rotating ends.

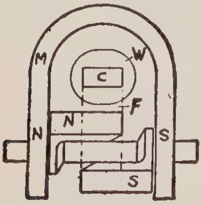

Fig. 4

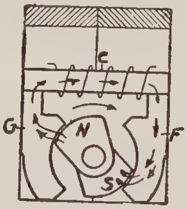

Fig. 5

The magnet is positioned at right angles to the rotating poles or ends of a field structure consisting of laminated pole-pieces (**F**) and (**G**) (Fig. 5), carrying across their top the laminated core (**C**) carrying the windings (**W**). When (N) is opposite (G) the flux flows from one pole (N) of the magnet to (G) and through the core (C) to (F), this action corresponding to what happens in the armature type with the armature in the position shown in Fig. 1.

In Fig. 6, the pole (N) has moved over to (**F**) and the direction of the flow of flux is reversed, it now flowing from (F) through (C) to (G).

Fig. 7 represents the rotating poles occupying a position midway between that shown in Figs. 5 and 6. Here the field pieces (F) and (G) are magnetically short-circuited, as it were, thereby completely scavenging stray lines of flux out of the core (C). Compare this with the uncertain corresponding action that takes place in the armature type, when the armature is in the same position (Fig. 3).

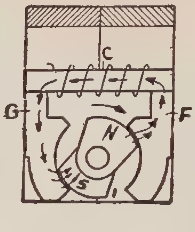

Fig. 6

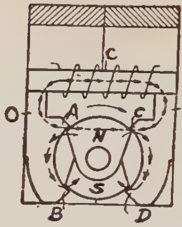

Fig. 7

Now the first great difference between the Dixie and the "armature" type is in the fact that the rotating poles in the Dixie do not reverse their polarity at any time, consequently the lag due to the magnetic reluctance in this part is eliminated. This partly accounts for the high efficiency of the Dixie at low speeds, for motorcycles and for high-speed engines. In the Dixie, the windings are never actually in the field. The flux is shot through them, as described, producing a hot, "snappy" spark of peculiar and highly efficient igniting power, owing to the quick break and absolute reversal of the flux at each revolution.

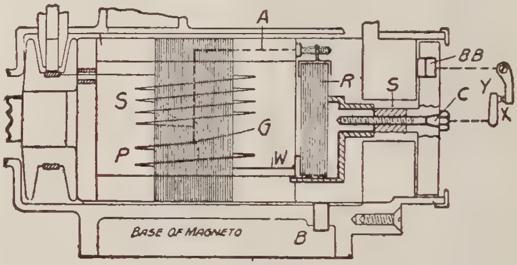

Fig. 8. Armature-type magneto armature.

With the armature-type machine, it is the central core or part actually enclosed by the winding that is laminated, as the ends adjacent the windings must be solid. In the Dixie type, not only the core (C), around which the wire is wound, is laminated, but also the pole shoes (G) and (F), consequently all parts of the magneto subject to reversal of flux are "laminated."

The armature-type magneto (Fig. 8) has a rotating element carrying windings, a laminated core, a condenser, a collector ring, etc.

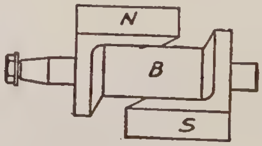

Fig. 9. Rotating element in Dixie.

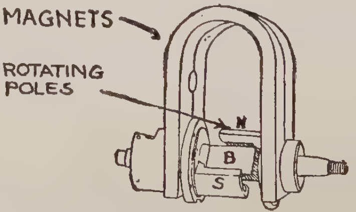

Fig. 10. Showing how the rotating poles (Fig. 9) are placed between magnets of Dixie magneto.

The Dixie rotating element, or armature construction, consists of two pieces of cast iron (N and S) (Fig. 9), and a brass block (B) placed between them. There are no rotating wires. Figs. 10 and 4 show more clearly how they are positioned between the poles of the magnets. On the four and six-cylinder magneto, there are two N and S poles and on the eight and twelve-cylinder magneto there are four.

The generating winding (W) (Fig. 4) in the Dixie is carried on a small coil placed across the upwardly projecting ends of the two pole-pieces (C) (Fig. 4).

Comparison of Primary Circuits

Fig. 8 shows **the usual primary circuit** in the armature-type machine, and Fig. 11 the same circuit in the Dixie. (A) (Fig. 8) denotes the revolving armature on which is wound the primary winding (P) and the secondary (S). Grounding brushes (B) and (BB) are necessary to insure a good contact between the grounded end (G) of the primary and the breaker point (X), the latter being positioned in the breaker mechanism which is movable for timing purposes. It will be seen that the free end (W) of the primary connects to the condenser (R), and attention is called to the fact that this condenser is built into the armature and revolves with it, and the armature must be disassembled to get it out. The shaft (S) is made hollow, and a bolt (C) is carefully insulated where it passes through. This bolt connects the free end of the primary and the condenser to the insulated point (Y) of the breaker which revolves as a unit with the armature.

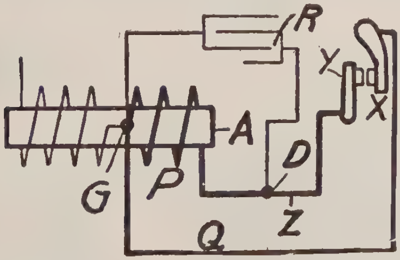

Fig. 11. Simple primary circuit of Dixie. No brushes or contacts except breaker points.

In the Dixie, the core of the coil (A) (Fig. 11) is stationary, and the inner end (G) of the primary winding (P) is grounded on the core. (Q) indicates the metal frame of the machine, which is put together with screws, so that there are no brushes or sliding contacts. Therefore brushes (B) (BB) (Fig. 8) are eliminated.

The brush (B) is necessary in the armature type to insure a good circuit from the revolving armature to the frame of the magneto and thence to the engine.

The condenser (R) in the Dixie is positioned immediately above the coil and is readily removable, it being only necessary to take out two screws. This condenser does not revolve as in the armature type. The terminal (D) is a screw on the head of the coil, and the wire (Z) connects to the contact (Y) of the breaker.

High-Tension Circuit

Fig. 12 shows **the high-tension circuit in the armature-type machine.** In the metal armature head (A) is the insulating bushing (B), through which the free end (C) of the high-tension winding passes. This connects to a metal ring (D) carried on the rubber spool (E). A brush (F) engages the ring and carries current to the terminal (G), which in turn supports one end of connector (H), which has a sliding portion (I), so that it can be removed. The outer end of (H) connects at (J) to the traveling contact of the distributor, which in turn contacts on the segment (L), to which is connected the spark-plug cable. It will be understood that the high-tension circuit is completed from the frame of the armature (N) through brush (B) to the frame of the magneto and to the engine and spark plug.

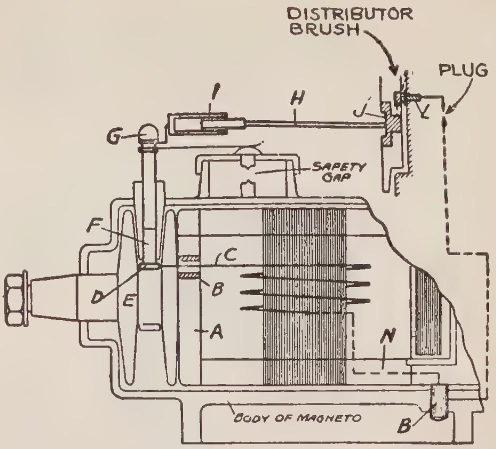

Fig. 12. High-tension circuit in an "armature-type" magneto.

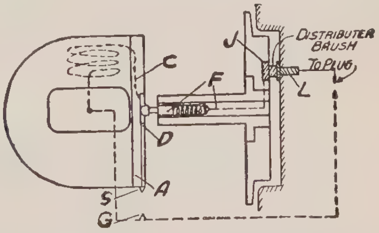

Fig. 13. High-tension circuit of Dixie magneto. Note direct path from spool to distributor; no revolving contacts except at distributor.

Fig. 13 shows the **Dixie high-tension circuit.** Here the end (C) of the high-tension winding goes to a metal plate (D) carried on the rubber side (A) of the coil. Against (D) bears a connection (F), which is practically one piece with the traveling contact (J), which connects to the spark-plug segment (L), the circuit being completed through the spark plug, engine frame, and frame of magneto in the usual manner without brush (G). The first difference to be noted in the Dixie construction is that the secondary winding being stationary, the spool (E), the revolving ring (D) and the brush (F) bearing thereon are entirely eliminated, as are also all their troubles, such as punctured insulation in the spool (E), wear of the brush (F), collection of oil on (D), etc. And the sliding connection (I) and member (H) are eliminated, their equivalent being a steel point (F) turning in contact with the plate (D).

Safety Gap

An efficient safety-gap arrangement is provided by the point (S) arranged in proximity to the framework indicated at (G), (Fig. 13). The width of gap should be 5/16″ to ⅜″. **For high-compression engines** set ⅜″. Under high compression, the sparks may fire across the safety gap instead of firing in the engine. Missing under such conditions can easily be remedied by opening the safety gap so that it will offer a greater resistance to the secondary current than the spark-plug gap, under compression. Sparks should not be permitted to discharge across the safety gap for any length of time.

Dixie Contact-Breaker or Interrupter

Contacts are stationary and do not revolve as in the "armature" type. See Fig. 14 and compare it with the armature type (Figs. 1 and 2, pages 256, 257).

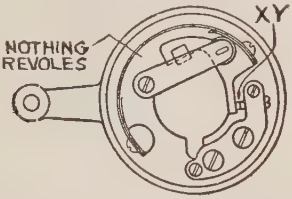

Fig. 14. Breaker (or interrupter) of Dixie magneto. A cam (Fig. 15) opens the points by raising the end of the arm. The cam is the only part of the breaker mechanism which revolves. Cam is not shown.

To adjust Dixie interrupter points (XY): This can be done while the magneto is running and the intensity of the spark can be seen while adjusting.

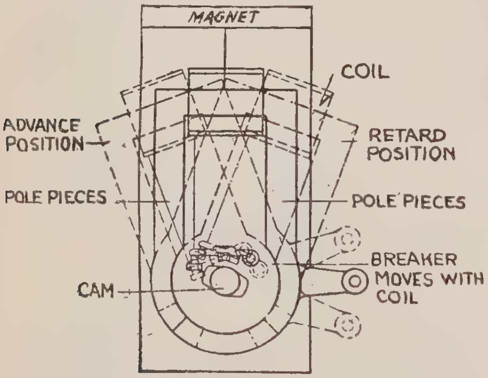

Fig. 15. Shows breaker and housing of the Dixie which, when retarded or advanced, moves the coil structure with which it is attached, giving the same intensity of spark at full advance or retard.

"Armature"-Type of Magneto Timing

The advance and retard of a magneto is necessary to make up for the "lag" in engine operation as well as variation of speed, fuel, etc.

Setting an "armature"-type magneto armature to the time of break of interrupter points is usually accomplished by measuring the distance (X) (Fig. 2, page 271) between one of the pole pieces and the adjacent edge of the armature. The breaker is then adjusted so that the points are just separating. This is taken as the advanced position of the magneto, and with this setting the maximum spark is obtained.

Timing an "armature"-type armature with engine: The usual practice is to place the piston on top dead center of compression stroke with the breaker box fully retarded and with points just opening. This of course increases the width of opening of (X) (Fig. 2) with a corresponding weakening of the spark. To advance the spark, the breaker box is moved so that the points open sooner in relation to the piston, thereby obtaining the best spark when running.

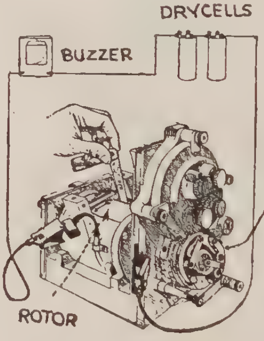
It is clear that the spark will be weak at retard position, because gap (X) is wide. Consequently the sudden surge of the flux line through the armature has already passed its maximum.

It has therefore been customary with some armature-type magneto manufacturers to use a compromise setting for the breaker in which the maximum efficiency of the machine is not utilized at full advance setting on the engine. This compromise setting permits a mechanical advance in such magnetos of approximately 30°, but it is doubtful if in many of these machines the effective range exceeds 12° or 15°, as the maximum spark of the magneto is never utilized.

Dixie Timing

The advance and retard of the Dixie magneto is obtained by shifting the breaker box. But note in Fig. 15 that it is attached to the "coil structure" (C-F-G, Figs. 4 to 7). Therefore the breaker housing and coil structure are all advanced or retarded at the same time. An absolute advance of 30° or more is obtained by simply rotating the coil-carrying structure to which the breaker box is attached, around the axis of the rotating poles N, S (Figs. 4 to 7 and 15).

Setting Dixie armature or "rotor" to breaker points: The distance (X) (Fig. 2, page 271) (armature-type illustration used to explain Dixie) is usually .020", just as points are breaking. The maximum rate of change of flux occurs in this position of rotor (X, Fig. 2), where the rotor wings have just reversed the direction of the flux through the core.



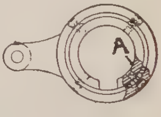


Fig. 17

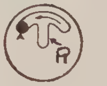

Fig. 18

Fig. 16

Fig. 16. A simple method of synchronizing the position of the rotor with the time of opening of breaker points, is explained below, and as shown in Fig. 16. Contact points should separate .020" when opened by cam.

If a buzzer is connected as shown, it will be in circuit with the contact-breaker points. While the contact points are closed, the buzzer will operate. Turn the armature slowly (direction of rotation) until the instant when the buzzer ceases. Just at this time the distance between the "rotor" and the "pole piece" should be .020". The spark-plug gap is set at .025".

Fig. 17. The breaker housing is adjustable. Being screwed to coil-carrying structure, it can be moved in the same direction as the cam operates—if rotor gap is too small. If too large, rotate in the opposite direction (to adjust for wear of fiber bumper also).

Fig. 18. Correct position of distributor brush in contact with segment (A) when breaker is fully advanced. Correct position prevents back-firing and tail-burning of distributor segment.

To facilitate this setting of the relation between the rotor and separation of contact points, a buzzer can be used, as shown in Fig. 16. The most effective distance for (X) is never varied on the Dixie.

To position breaker or interrupter box so that points open at desired point: Note that the breaker housing (Fig. 17) can be moved by means of set screws around the cam, so that the break can be made to occur without interfering with the adjustment of the points.

To time the Dixie magneto to the engine: (1) place piston on top of compression stroke; (2) uncouple magneto; (3) place breaker in retarded position; (4) rotate driving shaft of magneto in direction it is driven until platinum points are about to separate; (5) couple magneto; (6) connect distributor terminals as explained on page 294.

This timing is for the four and eight-cylinder magnetos, and also one and two twin-cylinder motorcycle type (M1 and M2); also Dixie models 11 and 21.

On the eight-cylinder, the distributor brush (A2, Fig. 20) should be in contact with No. 1 terminal of distributor block (see Figs. 22 and 23).

To time six-cylinder, model "60" magneto, place piston 1/16″ ahead of the end of the compression stroke with timing lever in full retarded position and breaker points just separating. The distributor terminal is connected with No. 1 plug terminal.

To time twelve-cylinder, model "120" magneto, place the piston 3/16″ ahead of the end of the compression stroke. With the breaker or timing lever retarded, turn the magneto drive shaft in the direction of rotation until carbon brush is in contact with the segment connected with terminal No. 1 of distributor block (Figs. 21, 24, and 25). When the points are about to separate, couple the magneto. See under Figs. 24 and 25 for distributor connections.

Cams on four and six-cylinder interrupters have 2 lobes; on eight and twelve-cylinder interrupters, 4 lobes.

Dixie Eight-Cylinder Distributor

Four sparks are produced during each revolution of the drive shaft, at the instant of the "break" from the edge of the field structure. There are four rotating poles to the eight and twelve-cylinder magneto. On the four and six-cylinder magneto there are two.

The magneto is driven at crank-shaft speed, because an eight-cylinder magneto four-cycle engine fires four cylinders per revolution. This eight-cylinder magneto generates four sparks per revolution. As the firing of the cylinders takes place at cam-shaft speed, the distributor is geared down two to one of the armature shaft.

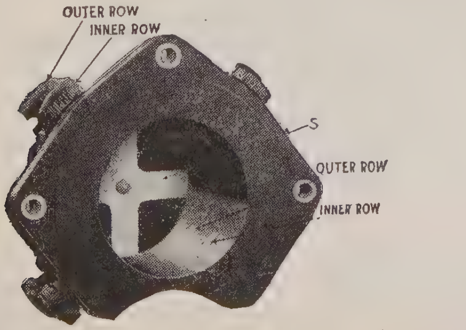

Fig. 19. 8-cylinder distributor. Note there are two rows of segments.

Distributor: On the four and six-cylinder magneto the segments are placed in one row, the proper distance apart. On the eight-cylinder magneto there are two four-cylinder distributors (Fig. 19), placed side by side, but moulded together, and having a double "finger" or rotor (Fig. 20). Contacts are so arranged that one segment in each row is alternately in contact. The rotor is hard rubber.

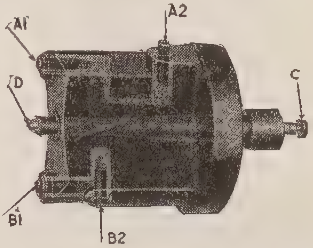

Fig. 20. The "rotor" of the 8-cylinder distributor (also for the 12-cylinder).

The high-tension current is collected by brush (**C**) (Fig. 20), which is in contact with the high-tension winding (see Fig. 13, page 273), and conducted through the center of the "finger" or rotor, to brush (**D**), thence by means of a metal sector (**S**) (Fig. 19), moulded in the hard rubber block. The current is conducted to either of two sets of brushes (**A1**, **A2**, **B1**, **B2**, Fig. 20) in the wings of the distributor rotor.

These brushes, arranged in sets, become alive alternately at the moment when they are actually in contact with a segment in either of the two rows of four segments in the block, making it impossible for the spark to jump to the wrong segment, as in this manner a spark received at any post in the inner row of the block will be followed by a spark from a post in the outer row, but 180° away.

Dixie Twelve-Cylinder Distributor

Four sparks are produced with each revolution of the drive shaft of the magneto. There are four rotating poles, the same as on the eight-cylinder.

Six cylinders must be fired with each revolution of the crank shaft. Therefore the magneto will turn 1½ revolutions to 1 of the crank shaft. The distributor is geared 3 to 1 of the armature shaft.

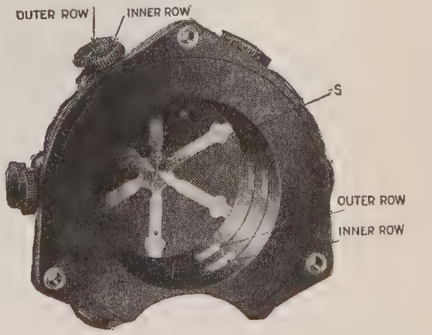

Fig. 21. 12-cylinder distributor. See also Figs. 32, 33, 34, page 278.

The distributor consists of two six-cylinder distributors moulded together as in Fig. 21. Note sector (**S**) in Fig. 21, how it differs from the eight-cylinder sector (**S**), (Fig. 19).

The "rotor" of the twelve is similar in construction, as in Fig. 20.

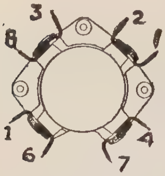

Fig. 22. Right-hand rotation.

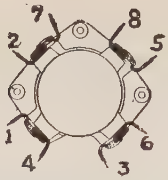

Fig. 23. Left-hand rotation.

Figs. 22 and 23 show order of sparks delivered by eight-cylinder distributor.

Figs. 24 and 25 show order of sparks of twelve-cylinder distributor.

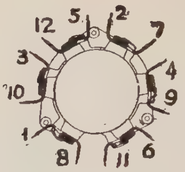

Fig. 24. Right-hand rotation.

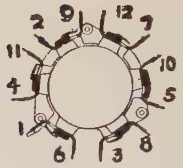

Fig. 25. Left-hand rotation.

Terminals on 24 and 25 are marked 1R–12R for right-hand rotation and 1L–12L for magnetos left-hand rotation.

Therefore, the right-hand rotation connects the cable from terminal 1R to spark plug No. 1 cylinder; cable from 2R to spark plug next in sequence of firing, and so on.

Parts of the Dixie Magneto

To replace parts on the Dixie: First remove the distributor plate carrying contacts. Then pull out the travelling contact and all its insulation. This leaves the coil and metal plate—and, if the spark does not jump the safety gap, a new coil may be put in in a few minutes.

For timing the Dixie magneto, see page 274.

Fig. 32. Rotating poles on the Dixie model "120" for 8 and 12-cylinder engines. Note that there are four rotating poles. On the 4 and 6-cylinder there are two.

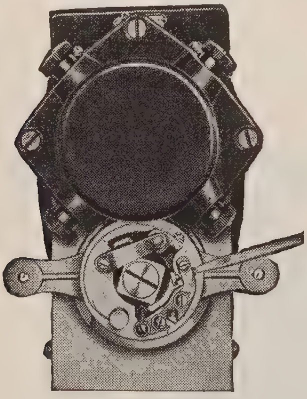

Fig. 33

Fig. 33. Showing method of raising or lowering the platinum point screw in (7) Fig. 31. The usual distance to set these points is .020″ or 1/50″. This adjustment can be made with a screwdriver. The spark-plug gap is set .025″.

Note. The contact breaker box is permanently attached to the pole structure or part (Fig. 30), which carries the coil and condenser. When moving the breaker to retard or advance, all the parts (Fig. 26) 1, 3, 24, 22, 21, 16, 15, 14, 13, 12 move with it (also shown in Fig. 15, page 274).

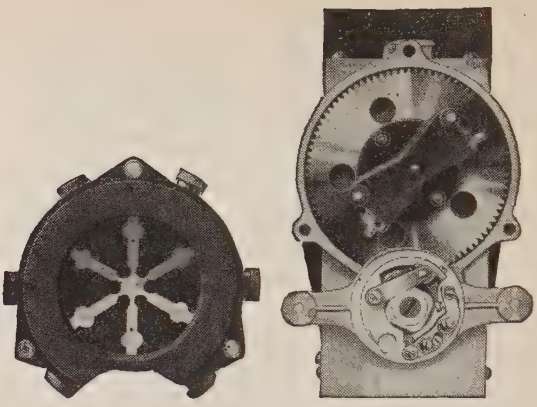

Fig. 34. Front view of Dixie model "120" 12-cylinder magneto. Note the distributor to the left and the distributor rotor and gear which is placed behind it and which drives the distributor rotor and which is driven from a gear on a rotating pole shaft. Note that the distributor rotor is arranged differently from (2) in Fig. 31, a 4-cylinder rotor.

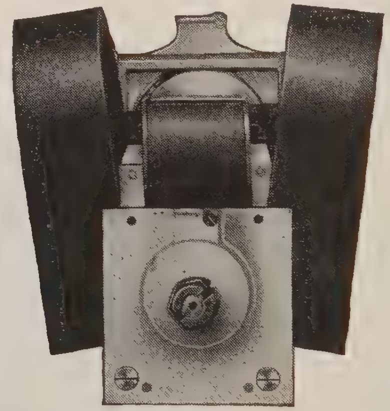

Fig. 35. Rear view of magneto. Note that by taking out four screws, the winding coil (23) and condenser (1) (Fig. 26) can be removed. The magnets (2) (Fig. 26) are exposed and removed when taking off the cover.

REMY HIGH-TENSION MAGNETO "SERIES 1500"

This magneto is a double-wound high-tension "armature-type" of magneto. The design of this magneto has been towards accessibility.

The circuit breaker, cam, and distributor rotor are mounted on a vertical shaft driven by hardened spiral gears which run in grease.

The circuit breaker and distributor parts form a complete and independent assembly which may be removed from the magneto by simply loosening one screw.

The circuit diagram(Fig. 2)shows clearly how short and direct both primary and secondary circuits are, and how accessible are all parts of these circuits.

The inner end of the primary winding is grounded to the core (**G2**) and from this point the current flows through the primary wire to a collector ring which is of copper and insulated from the armature head. Here it is picked up by a brush (**B**) carried by means of a copper pig-tail to the primary brush-holder

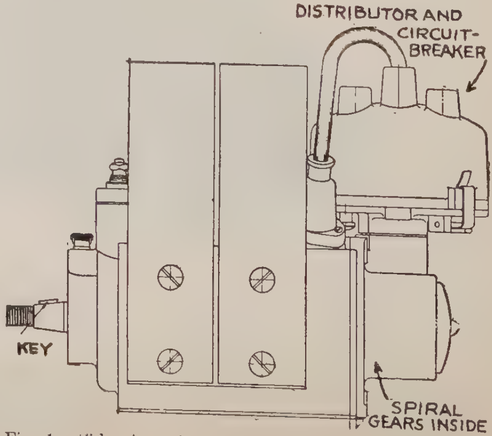

Fig. 1. Side view of the Remy "Series 1500" high-tension magneto.

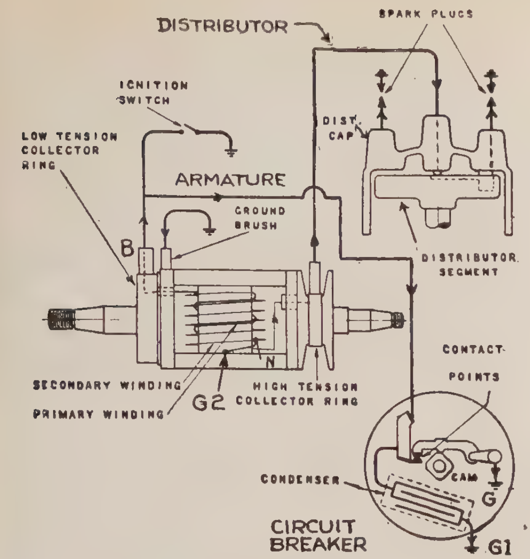

Fig. 2. Wiring diagram of the Remy "series 1500" high-tension magneto.

terminal, from which it passes through an insulated cable to the circuit breaker, condenser, and ground (G) and (G1) to ground (G2) on the magneto armature core.

Ground brush: Immediately under the primary brush holder is a brass plate grounded to the magneto frame, to which is connected a collector or "ground brush" which makes contact with the bronze head of the armature and by means of which the ground circuit is more fully completed, as, for instance, oily or gummed bearings would prevent good contact, hence the reason for using a ground brush.

The secondary or high-tension circuit is from grounded end (N), through the secondary winding, which consists of a great many turns of very fine copper wire, to the high-tension collector ring. This collector ring is bronze moulded between two flanges of hard rubber and the current is picked up from this ring by a carbon brush in the high-tension brush holder.

From the brush holder the current goes direct through a heavily insulated cable to the center terminal on the distributor cap. From here it is distributed by the rotor under the cap by means of a wipe contact to the segments. The distributor cap is of molded material with a hard-rubber track over which the distributor brush travels. From the distributor, the secondary current goes to the spark plug, to ground, to ground (G2) on the armature, to (N) where the secondary connects with the primary, thus completing the circuit.

The drive gear is fitted to a taper on the armature shaft.

Interrupter-gap clearance: Contact points on the interrupter should have a maximum opening of .020″ to .025″.

Spark-plug gap: The spark-plug gap clearance should be .030″.

Safety gap: The safety-gap clearance should be slightly more than the spark-plug gap clearance.

The safety gap on this magneto is formed between the end of the pointed screw which projects from the magneto housing and the high-tension collector ring. When this screw is in place and properly tightened, the safety gap will automatically be adjusted to the proper distance which is 7 m.m. or .275.″

THE K-W MAGNETOS

The K. W. magneto is of an "inductor" type, the principle of which is explained on page 246, and below. Unlike other magnetos, it generates four impulses per revolution instead of two, as explained on page 246. The K. W. magneto is used extensively on truck, tractor, marine, and stationary engines. The K. W. magnetos are made with two windings for high-tension work (**A**), and with a single winding for low-tension work (**J**). They both generate and deliver alternating current.

K.W. High-Tension Magneto

The K. W. magneto differs from other magnetos in many ways, and possibly the clearest information that can be given, is to assist in a careful study of the diagrams and accompanying explanation.

Diagram "A" shows a longitudinal sectional elevation of the model "HK" high-tension magneto. By referring to the numbers in the following description, a clear idea may be obtained of the function of the various parts.

Diagram "B" shows the rotor (which is the only revolving part in the K. W. magneto) and the complete assembled winding. The rotor is made up of soft Norway sheet-iron stampings, which are riveted together and very accurately machined, as these rotor blocks, which run on high-grade annular ball bearings, have only .003″ space between their face and the face of the pole-pieces. The rotor blocks are made in two halves and are held on the shaft by a taper pin, and are mounted at right angles to each other.

In mounting the winding between these rotor blocks, the pin is taken out of one half, and the rotor block is withdrawn from the shaft to allow the winding to be placed in the center.

Diagram B, showing the stationary secondary and primary winding (113 and 114) (as in Diagram A) mounted between the rotors (180) which revolve.

The winding: Complete assembled winding (diagram C) consists of a primary winding of heavy copper wire and a secondary winding (see also diagram A) ,which is made up of a great number of turns of very fine wire, these coils being wound circular in shape, assuring the largest number of turns with the least length of wire, which makes the most efficient type of coil.

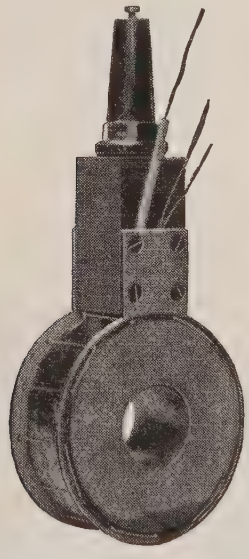

Diagram C, showing the windings (113 and 114) (as in Diagram A) and also shown in (B).

These windings are given an impregnation of high-grade insulating compound by the vacuum process, and the secondary winding is given 27 separate coats of varnish, each one being baked twenty-four hours, which thoroughly insulates it from the primary winding and also assures it being as near water and oil proof as it is possible to make any high-tension coil. These windings are assembled with the secondary outside of the primary, and then enclosed in a brass housing with a hard rubber plug, through which the high-voltage secondary is carried through parts 186 and 100 to the distributor brush of the magneto.

The condenser, No. 126, in diagram **A**, is made up of a number of alternating sheets of tinfoil and mica, every other sheet of tinfoil being connected together, which makes two series of tinfoil layers separated from each other by sheet mica. Each sheet of mica is tested separately, before being used, with 5,000 volts for breakdown and after it is assembled, it is given a test of five to six times the normal working voltage to which it is subjected, assuring reliability under adverse conditions.

The safety gap, No. 118, diagram **A**, is a necessary part of any high-tension magneto, its object being to form a path for the high-tension current to jump across in case a secondary cable, that leads to the spark plugs, should be off when the engine is running. This safety gap, as its name implies, prevents the winding from burning out, for as long as there is a path for the high-tension current to pass through, it will never puncture the insulation of the secondary winding.

The magnetic field of the magneto is composed of four horseshoe magnets, No. 73, shown in diagram **A**, which are mounted on two cast-iron pole-pieces, spaced 90° apart. The rotor, No. 180, revolves within this magnetic field, and as the rotor blocks are spaced 90° apart, they create four current waves for each revolution of the magneto shaft.

When the rotor is revolved within this magnetic field, the magnetic lines-of-force are caused to alternate through the center of the rotor, producing an electric current in the primary winding, which is carried up through part No. 14 to bridge No. 1, then through spring No. 29 to the circuit-breaker cap, and through the contact points in the circuit breaker back to the other side of the winding, completing the circuit.

When the current has reached its highest point, the circuit-breaker points are open, and the change of the magnetic flux causes a high voltage to be set up in the fine wire secondary winding. This induction is assisted by the condenser, which is connected across the circuit-breaker points, absorbing the spark which would occur if the condenser were not in circuit, and also assisting by the discharge which takes place immediately after it is loaded.

The high-tension current is carried up through the hard rubber plug to the bus bar, No. 186, then through lead No. 100 to the distributing brush, which distributes it to the different segments on the distributor block, these segments being connected by high-tension cables to the different spark plugs on the engine.

The distributor block is made of hard rubber into which are molded brass segments, one for each cylinder. The distributor brush holder which turns with the gear of the magneto is also molded of hard rubber and carries a carbon brush, which bears lightly on these segments as it passes, and the magneto is timed so that the circuit-breaker points open and the high-tension current is generated just at the instant this brush goes to the segment.

The K.W. Circuit Breaker

The entire circuit breaker is removable. Release spring No. 29 by pushing it aside. Pull out complete breaker box and remove cover nut No. 79. This allows removal of the circuit-breaker cap and gives access to the breaker parts. The same type of circuit breaker is used on all K. W. high-tension magnetos, and is shown by diagram **D**. It is arranged to have 30° of advance or retard for regular work.

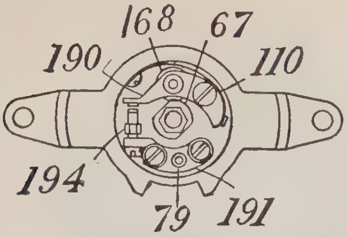

Diagram D, showing the circuit-breaker (also termed contact-breaker).

When the points fail to separate, or when the distance is too far apart, adjust part 194 with a small screwdriver inserted through the hole for that purpose in the housing. The proper distance apart is 1/64″. A gauge is sent with every magneto. Spark plug 1/64″.

The firing point of the magneto is just when the points are beginning to open or break the circuit, not when they touch.

To Open Distributor

Remove the high-tension lead No. 100, by turning it to the right, which releases it at the bottom. Unscrew nut at top of spider, and remove the bridge or spider No. 1, thus releasing the cap on the distributor block and giving a view of the distributor and brush No. 119.

Impulse Starter

Diagram **E** shows the impulse starter as applied to the model "HK" magneto, and diagram **F** shows a sectional view of the impulse starter only.

The impulse starter consists of two separate members, one of which is called the ratchet, and one the starter case. The ratchet is fastened directly to the rotor shaft of the magneto, and the case connects to the coupling, which is fastened to the shaft that drives the magneto. Interposed between these two members is a clock spring which performs the function of driving the rotor when the starting mechanism is used.

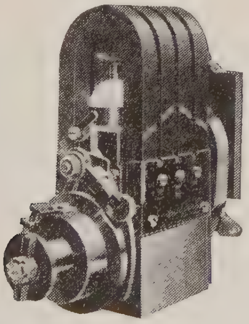

Diagram E, showing impulse starter mounted on the K. W. high-tension magneto.

When the engine is to be started, the ratchet catch lock (ST–14) is pressed down, which allows the ratchet catch (ST–13) to engage with a notch on ratchet (ST–6). Thus while the starter case (ST–2) is turned by the drive shaft, the ratchet (ST–6) remains stationary and the spring inside of the case is wound up. After the case (ST–2) has turned 80°, trip cam (ST–11) comes up into such a position as to disengage ratchet catch (ST–13).

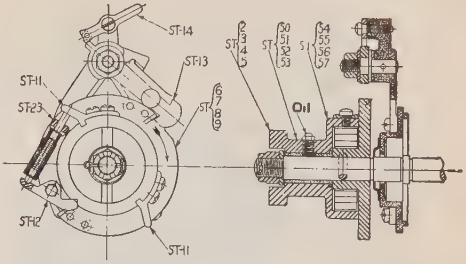

Diagram F, showing parts of the impulse starter.

As soon as the ratchet is released, it is thrown forward to its original position relative to the starter case (ST–2). In doing this, it carries the rotor of the magneto with it, and as the circuit-breaker points open during this period, an intensely hot spark is produced at the proper moment, regardless of how slowly the engine is turned over.

The starter continues to operate until a predetermined speed has been reached, when the ratchet catch is thrown up and latched, and the magneto is driven direct. The speed at which the starter throws out of engagement is determined by the tension of the cushion spring on the hook dog.

To Time Magneto to the Engine

First, Turn over crank shaft of engine, placing No. 1 cylinder from 3° to 5° past top dead center on firing stroke.

Second, Mount the magneto and turn the impulse starter case until it is just ready to disengage the ratchet catch. In this position couple it securely to the drive shaft of the engine.

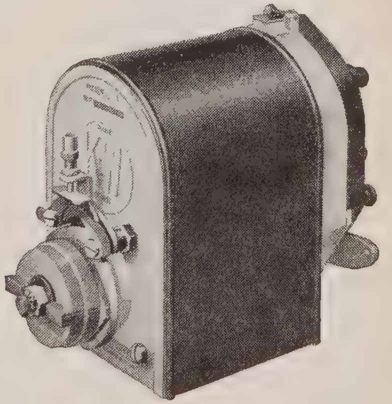

Diagram G, showing K. W. high-tension magneto, model "TK."

Diagram **G** shows K. W. high-tension magneto, known as model "TK," while diagram **H** shows a cross-sectional view of this magneto. It will be noted that the principle of the model "HK" and "TK" magnetos is exactly the same, the only difference being in the size of the magnetos and their appearance. The same principles of design and construction, are employed in both. Model "TK," however, has flat magnets.

Both magnetos are of the inductor-type construction, having a stationary winding and revolving rotor. This does away with all moving wires, collector rings, special contacts, etc., and is considered by the manufacturers the simplest form of construction.

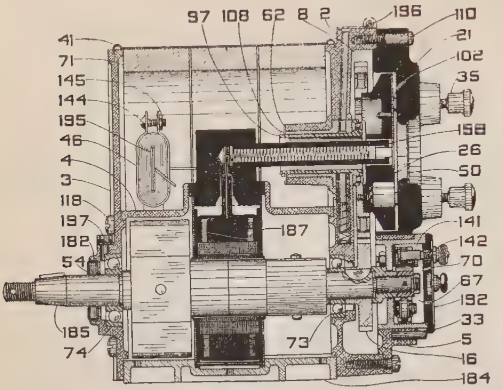

Diagram H, showing sectional view of model "TK" high-tension magneto.

K.W. Low-Tension Magneto

These generators are made for ignition, using a vibrating spark coil and low-tension timer, and are made in several models, for either friction or belt drive.

They are also made for tractor and motor-boat electric-lighting systems, feeding the current direct to the lamps. These generators will not charge a storage battery, as they produce alternating current.

Internal Construction

Diagram **I** shows the internal construction and extreme simplicity of the K.W. low-tension magneto, designed somewhat similar to the K. W. high-tension magneto, except that there is but one winding: the primary. This magneto is also termed an inductor type, designed on entirely different principles from other makes of magnetos, and patented by the makers. Instead of having wires wound longitudinally around a revolving armature, it has a stationary spiral winding of copper ribbon, as is shown in the center of diagram **J** and also in diagram **I,** which is a view of the inside of a low-tension magneto. The rotor changes the direction of magnetic flux through the winding, four times per revolution, and thus produces the electric current. This rotor revolves in two sets of high-grade ball bearings, and does not rub against or touch any other part on the entire magneto, as all other parts stand still.

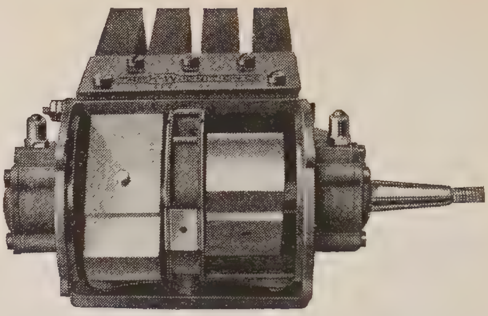

Diagram I, showing bottom view of the K. W. low-tension magneto and also showing rotor and primary winding.

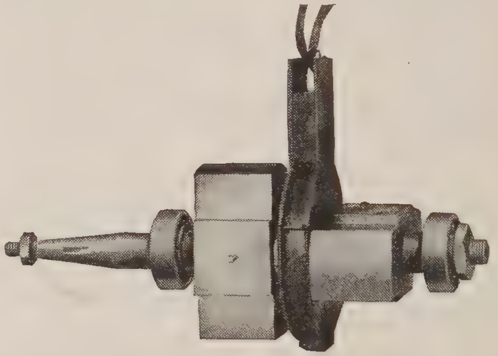

Diagram J, showing rotor and stationary winding with a single primary winding of the K. W. low-tension magneto.

The terminals of the winding extend through the top of the pole pieces in which the rotor revolves, and are securely connected to the winding posts, which are located at the end of the magneto.

The electrical part is housed in a case, making the magneto practically waterproof. It will stand any amount of spray or rain.

All models of K. W. lighting magnetos or generators, in addition to having a special winding suitable for lights, are so constructed and designed that the voltage can never exceed that actually required, regardless of speed. This takes care of various engine speeds, and entirely eliminates the use of automatic cutouts or other regulating devices.

The manufacturers of K.W. magnetos are the K. W. Ignition Co., Cleveland, Ohio.

REMARKS RELATIVE TO THE DIFFERENT MAGNETOS

If the reader will master **the purpose and principle of the following,** it will then be easy to analyze any system of ignition he may come across. For instance, learn the difference between: low-tension coils; high-tension coils; low-tension magnetos; high-tension magnetos.

Other details to classify would be: the difference between the ignition commutator, timer and interrupter, and sources of electric supply, as direct-current chemical generators (dry cells and storage batteries); direct-current, mechanical generators (dynamos); alternating-current, mechanical generators (magnetos); methods for distributing the secondary current to the spark plugs, by a distributor as used on a magneto, or by an ignition commutator in connection with a vibrator coil.

In other words, very nearly all of the systems comprise one or more of the parts of the four principles of ignition.

Difference in Makes of Magnetos

An inspection of the illustrations of **the different leading makes of magnetos** will give the reader an idea of the variance in construction. In these pages we illustrate magnetos of low-tension type and magnetos of high-tension type.

As previously explained, the low-tension type of magneto employs an armature wound with only one winding of wire, which is called the primary winding. We learned in a previous instruction that when a magneto employs a single primary wound armature, then a transformer (high-tension coil), separate and distinct from the magneto, is necessary in order to step up or transform the low-tension voltage (pressure) up to a high pressure.

By referring to pages 247,254, we find that the Remy and Splitdorf (in the models shown) have primary wound armatures and need separate coils or transformers. But going a little further into detail, we find that the Splitdorf, Eisemann, Bosch, Mea, and the pivoting magnetos all have armatures which **revolve with the winding wound on the revolving part.**

In the Remy model "RL," page 247, and K.W., as well as the Dixie and Ford inductor-type magnetos, we find that **the winding does not revolve,** but is stationary.

"Armature" and "Inductor" Type; "Primary" and "Compound" Wound Magnetos

The revolving type of armature, with the wire wound thereon, is called the "armature" type, and the type where the wire is stationary is called the "inductor" type.

If there is only one winding it is called a "primary" wound armature. **If there are two windings,** then it is called the "compound" type.

The primary wound armatures are low-tension, and require separate coils.

The compound wound armatures are high-tension, and do not require separate coils—except as a matter of convenience for easy starting or dual systems of ignition.

By referring to the K. W. magneto, in Fig. 6, page 284, we find that the winding on this type is also stationary, but instead of being a single primary winding, as on the Remy, it is a double or compound wound armature like the Bosch, Eisemann, and Mea—but differs from the last-mentioned in that the winding does not revolve.

In the Bosch, Mea, and Eisemann the armature is compound wound, and of the "armature" or revolving type. The principles of the magnetos are about the same, with some few minor differences in construction.

"Pivoting" or "Rocking" Type of Magneto

The Mea magneto (Fig. 2, this page) differs in that the magnets can be turned from side to side (called pivoting type); they are bell-shaped, and placed horizontally; therefore, unlike the customary horseshoe type, are mounted vertically. In this construction the magnets and breaker are moved simultaneously instead of the advance and retard of the contact-breaker alone.

This style of magneto, owing to the fact that it is rocked from side to side, gives an unlimited range of advance, and thus adds wonderfully to the flexibility of the car on which it is mounted. This great range of advance makes this instrument especially suitable for two-cycle engines, which require a much greater degree of advance and retard than the four-cycle type.

Magneto; Automatic Advance

The Eisemann automatic advance of spark (page 270): With all magnetos treated up to the present time, the advance and retarding of the time of spark is accomplished by hand, called "manual" advance by means of a spark lever on the steering wheel. With the Eisemann automatic advance, the same thing is accomplished by a governor arrangement automatically. This type of magneto is extensively used on commercial cars.

Illustrations of Some of the Different High and Low-Tension Magnetos

Note that while the magnetos may vary in construction, the principle is very much the same.

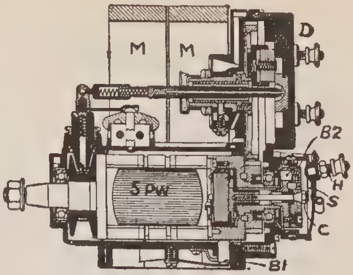

Fig. 1. The Bosch high-tension magneto. Armature revolves. The Simms, Eisemann, and other types are similar. (M), magnets; (D), distributor; (PW), primary winding; over this winding is (S) the secondary winding; (H), is the terminal which connects with the switch.

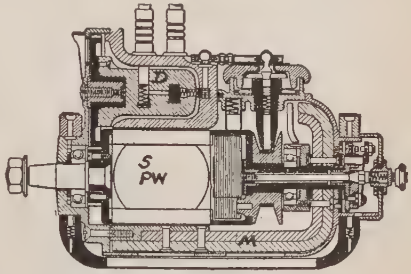

Fig. 2. The Mea high-tension magneto. Pivoting type. Revolving armature. Note that the armature is of the double-wound, shuttle-revolving type. Instead of shifting the interrupter housing, in order to advance or retard, the field magnets with the interrupter are shifted.

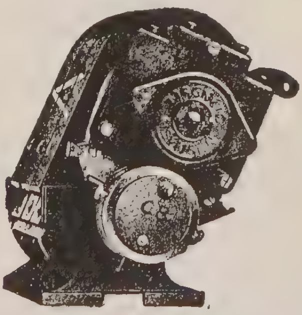

Fig. 3. The Eisemann high-tension magneto, pivoting or rocking advance magneto. The advance and retard are obtained by rocking the magneto bodily on its cradle. Otherwise the magneto is the same as other magnetos. The armature revolves.

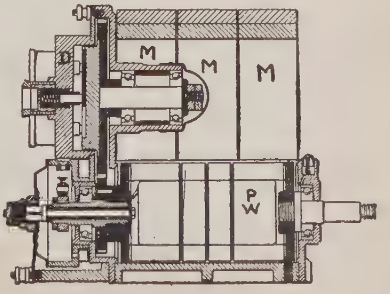

Fig. 4. The Splitdorf low-tension magneto. Armature is primary wound. Armature revolves and is of the "armature" type. A separate high-tension coil, called a transformer, must be used with this magneto. The Splitdorf Co. also manufactures a high-tension type magneto.

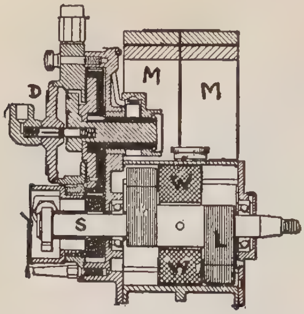

Fig. 5. The Remy low-tension magneto armature is primary wound—only one winding. The magneto is of the "inductor" type. Armature does not revolve. The winding (W) is stationary, and rotating magnets (L) revolve. Separate high-tension coil (called a transformer) must be used with this magneto. The breaker gaps are set .025″ apart.

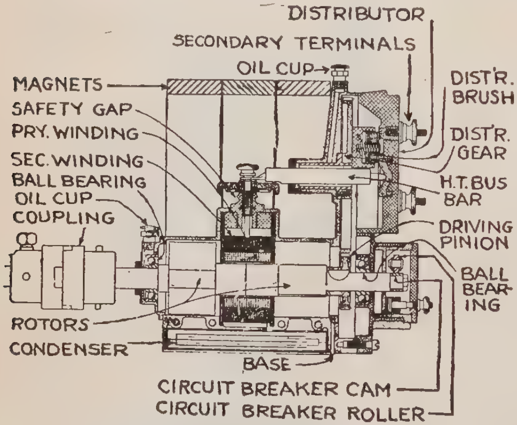

Fig. 6. The K.W. high-tension magneto with an inductor-type rotor. There are two windings on this type: a primary and a secondary. The windings are stationary, however, and the inductor rotors revolve. The principle of inductor-type magnetos was explained on page 246. The same principle applies here, with the exception that the two windings obviate the necessity of a separate high-tension coil, as it is here provided for in the secondary winding of the stationary coil winding. By referring to the Index under "Impulse and waves of current," and also on page 246, you will note that the K.W. gives four waves or impulses per revolution. However, either one, two, or four sparks per revolution can be obtained by using a single or a double cam.

On the K.W. there are four sparks per revolution, with a two-point cam, therefore the magneto would be driven at crankshaft speed for an eight-cylinder engine, and at 1½ times crankshaft speed for a twelve-cylinder.

The setting of the inductor-type armature is similar to the setting of any other type. The fact of its having two inductors, placed crosswise, is a bit confusing, but in the setting, only one is taken into consideration, and is therefore as simple to set as the ordinary type. The breaker and plug gap are set to 1/64″.

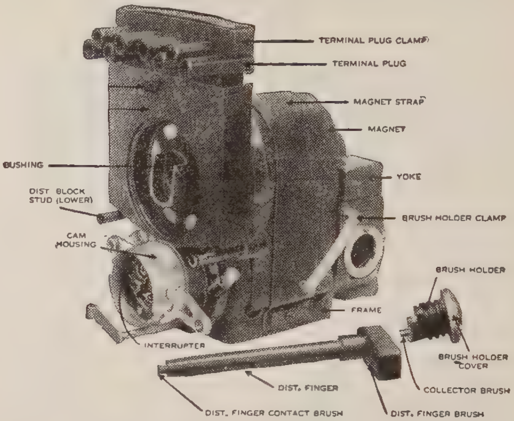

Fig. 7. Berling type D-81x-2, high-tension 8-cylinder single-spark, high-tension, revolving type of armature magneto, as used on the Curtiss training planes.

Fig. 7A. Interrupter or contact-breaker as used on the Berling magneto shown above.

Adjusting interrupter: With the fiber lever in the center of one of the embossed cams, the opening between the platinum contacts should be not less than .016″ and not more than .020″. The gauge riveted to the adjusting wrench should barely be able to pass between the contacts when fully open. The platinum contacts must be smooth, and if pitting of the contacts is in evidence, they should be smoothed off with a very fine file. When in closed position, the platinum contacts should make contact with each other over their entire surfaces.

"COMBINING" THE HIGH-TENSION MAGNETO AND COIL AND BATTERY SYSTEM INTO "DUAL" AND "DOUBLE" SYSTEMS

We have now explained the different leading low and high-tension ignition systems for firing the charge of gas in the gasoline engine. In order to explain more clearly the four systems of high-tension ignition, we will now place the four ignition systems (high-tension) on one four-cylinder engine.

Some of these systems (see Fig. 8) are out of date, but are shown in order that the reader will understand the different principles. The modern battery and coil-ignition system, using a closed-circuit interrupter, as explained on page 197, is not shown.

The system of using four ignition systems on one four-cylinder engine is not in actual use, but is intended to make the combination of "dual" and "double" systems clear to the reader, by showing how they can be combined.

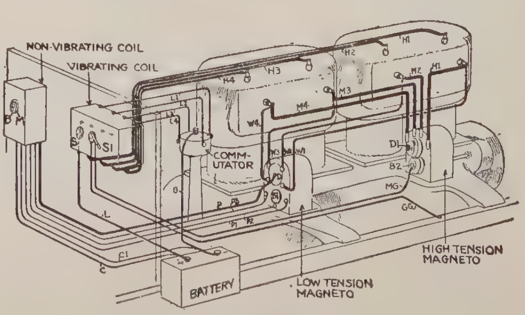

Fig. 8. Four high-tension ignition systems connected to one four-cylinder engine. Only two systems are usually placed on an engine. The idea is merely to show how the various systems can be combined into "dual" or "double" ignition systems.

The vibrating coil is seldom used. The low-tension magneto is seldom used. A modern "dual" and "double" system is shown on page 263. A modern "battery and coil" system is shown on pages 197, 211.

We shall first explain each system separately, showing how each would be connected.

First, **The "single" high-tension magneto system:** By referring to Fig. 8, we will put our pencil on the switch on the dash coil box (S1). If this lever is thrown to the left with all other switches "off," this high-tension magneto system will supply current for sparking the lower set of spark plugs (**M**1, **M**2, **M**3, **M**4). Note that these wires run from the distributor on the magneto.

Second, **The high-tension coil, battery and commutator system:** If switch (S) is thrown to the left, the four high-tension vibrating coils will spark the plugs (**H**1 to **H**4). The battery of either storage or dry cells (usually storage) will supply the electric current in this instance. The commutator, operated from one of the cam shafts through a system of bevel gears, will control the time of spark in each cylinder.

Third, **A non-vibrating single high-tension coil with battery,** using the circuit-breaker on the low-tension magneto as the timer, and the distributor on the magneto to distribute the current to the spark plugs: If the switch on the non-vibrating coil is on (**B**), the battery will supply the electric current, passing through the primary winding of the non-vibrating coil. The circuit-breaker (**B**1) on the low-tension magneto will take the place of the timer and vibrator. The secondary current from the coil will be distributed to the spark plugs (**W**1 to **W**4), through the distributor (**D**) on the low-tension magneto.

Fourth, **Low-tension magneto and separate high-tension coil:** If the switch is on (**M**) on the non-vibrating coil, the low-tension magneto will pass its current through this non-vibrating coil, increase it to high pressure, and then distribute the high-tension current through the distributor (**D**) to the spark plugs (**W**1 to **W**4), the circuit-breaker opening and closing the primary circuit of the magneto.

Combining into Dual Systems

If we were to combine the two last-mentioned systems, we should have **two systems of ignition using one set of spark plugs**—but only one system sparking the plugs at the time.

The single non-vibrating coil and battery would be used to start on, by throwing the switch to (**B**), and after the engine was started; then, by throwing the switch to (**M**), the low-tension magneto would take the place of the battery.

Another dual system: A vibrating coil with switch (S1), storage battery and commutator (timer), with secondary wires (**H**1 to **H**4), connected to the spark plugs (**M**1 to **M**4), in connection with high-tension magneto, connected to same spark plugs, would give another form of dual system.

Combining into Double Systems

The vibrating coil, timer, and battery with spark plugs (**H**1 to **H**4) would constitute one independent system. The high-tension magneto with its spark plugs (**M**1 to **M**4) would constitute the other. This would be called a double system.

Another double system could be formed by using the low-tension magneto and separate non-vibrating coil and spark plugs (**M**1 to **M**4). The vibrating coil, timer, and battery with spark plugs (**H**1 to **H**4) would constitute the other system.

There are many methods employed to combine the different ignition systems into "dual" and "double" systems.

A BRIEF REVIEW OF THE VARIOUS IGNITION SYSTEMS: ADVANTAGES AND DISADVANTAGES

We have now mastered the various methods of producing an electric spark for igniting the gas; with a "primary" or low-tension coil, and a "secondary" or high-tension coil, and a low-tension magneto; a low-tension magneto and a high-tension coil, and a high-tension magneto alone, or a high-tension magneto and a coil-and-battery ignition, as a "dual" system, also the "double" ignition system.

We shall now review the different systems as to their relative advantages and disadvantages.

Low-tension coil systems: The disadvantage of the "make-and-break" is its lack of "flexibility" and slow spark. It would be considered fairly good for a slow-running constant-speed stationary or marine engine.

Coil with vibrator: The disadvantage of a vibrator coil is its tendency to miss; if the battery is weak, the vibrator will not operate. If too strong, the points on the vibrator will weld together and stick, causing missing. The spark is not fast enough. The consumption of current is rather heavy.

Master vibrator coil: Where a system is already equipped with a multiple of vibrator coils, this would be an excellent method to improve it. Its disadvantage is a sticking vibrator, with all work on one vibrator and a succession of sparks.

Dry battery as a source of electric supply: Its disadvantage is unreliability. A battery of 5 or 6 dry cells will do fairly good work when fresh for short periods of time—provided two sets are used and the use alternates from one to the other. It gets weaker as used, however, and is unreliable. Intended for "intermittent" work—as ringing door bells, etc., where used only for a few seconds at a time.

Storage batteries are better, as they maintain their pressure until exhausted. They contain a greater quantity of current and are far more satisfactory. Their disadvantage lies in the fact that they must be recharged when exhausted, and the operator must watch it for fear of running down.

Battery, coil, and magneto: The battery and coil ignition, using dry cells or a storage battery, could be used for starting the engine and the magneto can be used for ignition after starting. The disadvantage would be that dry cells would soon get weak and the storage battery would require charging in time. If a generator or dynamo (direct current) was connected to the engine to charge the battery, this would be an improvement, but would add another piece of machinery. The magneto generates "alternating" current; therefore it is not suitable for charging a battery and can be used only independently for ignition.

High-tension magneto alone: The magneto generates a very hot and voluminous spark which is desirable as the time between ignition and actual combustion is less, with the result that more power is obtained (for the same reason that "double" and 'two-spark" ignition is an advantage). The disadvantage is that the magneto must be turned fast enough to generate current when starting, and this cannot always be relied upon when cranking by hand. Therefore some form of starter must be employed. The popular type of magneto starter is the "impulse starter," as explained on page 281. It is used extensively on truck and tractor engines. This overcomes the starting disadvantage, but is not altogether desirable for pleasure cars.

The low-tension magneto and separate high-tension coil are now seldom used, because the high-tension magneto is simpler, and thus the separate coil and wiring are dispensed with.

The high-tension magneto is a very desirable system of ignition. The spark is hotter, fatter, and exists across the spark-plug gap for a longer period of time than in other systems. Thus it fires all of the gas in each cylinder. The high-tension magneto is several times hotter than any other spark, and thus the gas is ignited more quickly. For reasons stated below, however, the magneto is not used on pleasure cars to as great an extent as formerly, and now that great improvements have been made with coil-and-battery ignition, this latter system is in general use.

The double system of ignition is an advantage. See pages 263, 264, explaining why.

The Electric System in General Use

Battery, coil, generator and electric starting motor: A very satisfactory system and one which is now generally used for pleasure cars is an ignition system using a high-tension coil without a vibrator, and a "closed circuit," "single spark" interrupter. The source of the electric supply for ignition and starting the motor is taken from the storage battery when starting the engine, and after the engine is up, speeding the "direct current" generator charges the battery and supplies current for ignition and lights. The advantages of this system would be a constant source of electric supply, a hot spark regardless of the speed of the engine, ease of starting the engine, and a constant source of electric current for lights when the car was idle or running.

The question then arises, Why use only a magneto on a truck, and this system on a pleasure car? The answer is, to avoid complication. The driver of a truck seldom runs the truck after dark, and seldom at a high rate of speed. A truck must be operated on an efficient basis, and for this reason the added complication of battery and starter is eliminated.

On the other hand, the pleasure car is driven considerably at night, and quite often at a high rate of speed. Therefore strong lights are essential. The pleasure-car driver also demands an easy method of starting. Inasmuch as a starting motor and strong lights consume a great deal of current, it is necessary that a generator be supplied that will continually charge the battery while running. Therefore, if a battery is required, and a generator to charge the battery, then by adding a timer, distributor, and non-vibrating high-tension coil, we have added an ideal ignition system, combining all the desirable features and eliminating entirely the magneto.

The disadvantage of the battery, coil, generator, and electric starting motor system would appear to be: (1) the probabilities of the dynamo at high speed burning out the ignition coil, as the voltage increases with the speed of the dynamo, or, (2) when running slow, the connection being between the storage battery and field coils, the current would flow from the battery into the generator. This, however, is all taken care of: (1) by "regulation" of the dynamo field windings, so that the output remains constant at low or high speeds; (2) by a "cut out" arrangement, which is explained farther on.

The greatest source of trouble with this system is the storage battery, as it requires careful watching. But by having the battery tested about every two weeks and seeing that the generator is charging the battery while running, which is a simple operation, battery troubles can be eliminated.

The Modern Battery and Coil Ignition System

The ignition system in general use today is the closed-circuit coil and battery system, illustrated on page 197.

The current is taken from a storage battery or the generator, then passed through the primary winding of a high-tension non-vibrating coil, using an interrupter and a distributor to make and break the primary current and distribute the secondary current to the spark plugs.

INSTRUCTION No. 27

MAGNETO INSTALLATION: Driving the Magneto; Magneto Speeds

Fitting the Magneto

One method of **fitting a magneto to the engine frame** is by means of pins, and is held down on its base by a strap of metal passing over the magneto, as in Fig. 1. The band is usually in two sections, as illustrated in Fig. 1, thus bringing the nut (A), which tightens or loosens the band at a point which is easily gotten at. In other instances, however, the magneto is bolted direct to its base, and since the nuts are below, it is almost impossible to remove the magneto after the engine has been placed in the chassis. It might also be worth mentioning, at this point, that some magnetos are strapped down on iron or steel brackets and no precaution taken to see that brass or non-magnetic fittings are used at the point where the tightening bolts join the straps. A little thought will show that, as illustrated, a portion of the lines-of-force will return by way of the bolts and base instead of through the armature. Although the effect of this may not be noticed at ordinary speeds, it will have much to do with determining the lowest speed at which a good spark is produced. Magnetos therefore must have a brass or aluminum base.

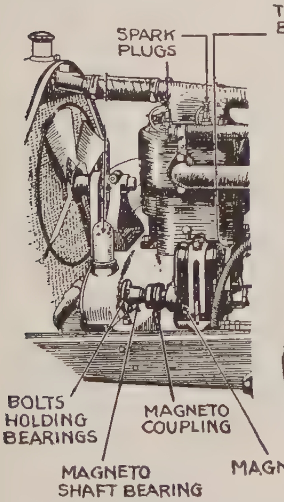

Fig. 2

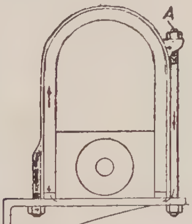

Fig. 1 (upper)
Fig. 3 (lower)

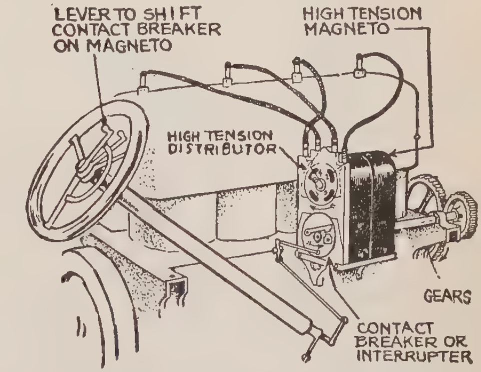
Figs. 1 to 3 apply to the types of high-tension magnetos with double-wound armatures.

Magneto Location

The magneto is usually placed alongside of the engine (see Fig. 2), mounted on a separate base provided for it. The base of the magneto is usually made of brass, as brass will not become magnetized; therefore the magnetism is confined to the magnets, otherwise they would soon lose their magnetism.

Magneto Drive

The magneto armature shaft can be driven by gears (Fig. 4), or a silent chain (Fig. 5). The usual practice is to drive with gears (see Figs. 5A and 5B).



LEVER TO SHIFT CONTACT BREAKER ON MAGNETO
HIGH TENSION MAGNETO

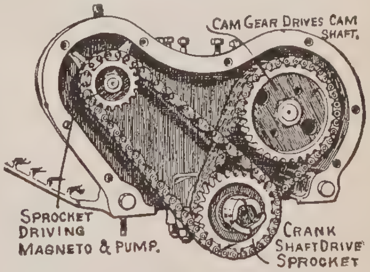
GEARS
CONTACT BREAKER OR INTERRUPTER

Fig. 4. Simplified illustration showing how the magneto is usually driven and how the interrupter, or contact-breaker, is connected with the spark lever.

The magneto which is timed to give a spark at a fixed time cannot be driven by a belt or friction, because the armature must be in a certain position in relation to the time of spark. A belt would slip.



CAM GEAR DRIVES CAM SHAFT.
SPROCKET DRIVING MAGNETO & PUMP.
CRANK SHAFT DRIVE SPROCKET

Fig. 5. The silent-chain drive method on a six-cylinder engine. Note that the sprocket driving the magneto gear is slightly smaller; therefore the magneto gear will turn 1½ revolutions to the crank shaft gear's 1 revolution. (The magneto is usually driven by gears.)

A coupling is usually provided between the drive shaft and armature shaft, as shown in Fig. 2. One type of coupling is the Oldham, shown in Fig. 3; another type is a flexible leather or fiber disk bolted between two flanges. By the use of a coupling, the magneto can be uncoupled from its drive member and properly timed without removing the gear-case cover.

The coupling and shaft are usually driven by a gear. This permits undue strain on the armature, if it is not exactly in line, and also reduces vibration to the armature shaft. The chain drive is the least desirable for magneto drive, but is a popular drive method for the interrupter of a coil and battery system of ignition.

If a gear is used to drive the magneto direct to a gear on the armature shaft, sufficient clearance must be allowed between the gear on the magneto and the driving gear, in order to reduce strain on the armature shaft.

The magneto must be driven at a fixed speed, because the armature must be in approximately a vertical position and with the interrupter point just breaking when the piston is in the correct position to receive the spark. The correct position for the piston to receive the spark is just an instant before it is at the end of its compression stroke.

FIG 5A

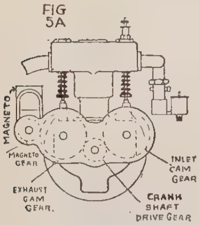


FIG. 5B

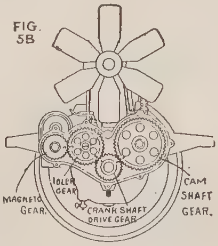

Fig. 5A. Magneto driven by gears on a "T"-head engine.

Fig. 5B. Magneto driven by gears on an "L"-head engine.

The armature is therefore set by meshing its drive gear in relation to the gear on the crank shaft, so that it will be in this position at this time.

The magneto drive shaft is usually tapered, therefore the coupling should be tapered to correspond. If driven by a gear, and teeth are meshed too tight, undue strain will result on the bearings.

Magneto Connection with Spark Lever

The method for advancing and retarding the time of spark is usually by means of a rod connected at one end with the spark lever on the steering wheel; the other end connects with the bell crank, thence by a rod to the interrupter or breaker-box housing (Fig. 4).

By shifting this housing in the opposite direction of the rotation of the cam, the cam would raise the interrupter arm and interrupt the flow of current earlier, or in "advance."

By shifting this housing with the direction of rotation of the cam, the interruption would occur later, or "retarded."

On some types of magnetos, such as the Mea, page 271, the field magnets are "advanced" and "retarded" by rocking the magnets bodily around the armature (called "pivoting advance").

The advance which can be obtained on a magneto is usually 22° to 35°.

Clockwise and Counter-Clockwise Drive

The drive-end of a magneto is the end where the drive gear or coupling connects with it. The direction of rotation of armature is always considered from the drive-end.

Clockwise rotation of the armature would therefore be as in Figs. 6A and 7A. Note that the direction of rotation of the armature is right hand, or as the hands of a clock move.

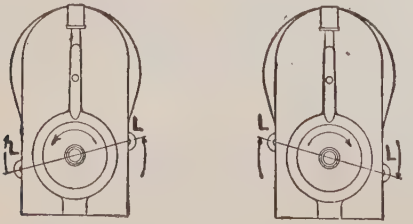

Fig. 6

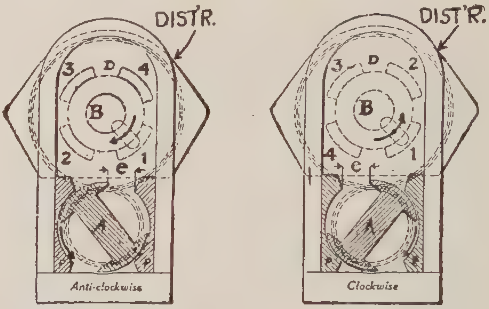
Fig. 6A

Fig. 6. Positions of full retard of the cam plate when looking at the driving end of the Simplex magneto. Fig. 6 is a view of the counter-clockwise setting and Fig. 6A, the clockwise setting.

Counter-clockwise rotation would be as in Figs. 6 and 7. Note that the direction is a left-hand direction, or opposite to that of the movement of clock hands.



Figs. 7 and 7A. Drive end of magneto which is opposite to the interrupter and distributor end.

Note in Figs. 7 and 7A that the distributor would revolve in the opposite direction to the armature.

Note also in Figs. 7 and 7A the position where armature (A) should be placed when the contact-points should open, with the contact-breaker fully retarded. The illustration on the right shows a clockwise rotation, and the left-hand illustration shows it as counter-clockwise, both armature positions being retarded. By this is meant that the contact-breaker points are retarded from separating until the armature has reached a position as shown at (e).

Figs. 6 and 6A show the drive-end of a magneto with the contact-breaker lever (L) retarded when running clockwise and counter-clockwise, as in Figs. 7 and 7A.

Meaning of "Advance" and "Retard" of Spark

Since in regular operation of the engine the charge is ignited just an instant before the top of the compression stroke, the magneto armature is so set, relative to the engine crank shaft, that the maximum induction effect occurs at this moment.

It is, however, necessary to be able to vary the point in the cycle at which the ignition occurs, since, **when the engine is cranked by hand,** the spark must occur after the end of the compression stroke, or else the engine may kick back.

If started by some form of self-starter, it is then possible to start with slightly more advance than when starting by hand, because the self-starter turns the engine crank somewhat faster; however, even with a starter, if advanced too far it will cause a back-kick and may result in damage to the starter.

The meaning of "advance" of spark is to cause the spark to occur earlier, before the piston is on top of compression stroke.

The meaning of "retard" of spark is to cause the spark to occur later. On engines that are cranked by hand, the spark is usually set "retarded" after top, so that there will be no danger of a kick back.

The exact position to "advance" or "retard" is determined by running as far "advanced" as possible at all times until a knock is detected, and then "retard" until the knock disappears. The driver will then soon learn the exact position where the engine gives the greatest power. Remember also, that a retarded spark heats up the engine.

Control of Spark

Principle: As the spark occurs only when the primary circuit is broken by the opening of the platinum contacts, the timing of the spark can be controlled by having these platinum contacts open sooner or later. This latter is accomplished by the angular movement of the timing lever (**L**) (Figs. 8 and 8**A**). This movement gives a timing range of about 34°. The spark is fully retarded when the timing lever is pushed as far as possible in the direction of rotation of the armature, and is advanced when pushed in the opposite direction.

Magneto spark control: In order to make it possible to vary the time of the spark on a magneto, the circuit-breaker housing is so arranged that it can be rocked around its axis, being provided with a lever arm (**L**) (Fig. 8) for the purpose, from which connection can be made to a spark lever on the steering post, as in Fig. 4.

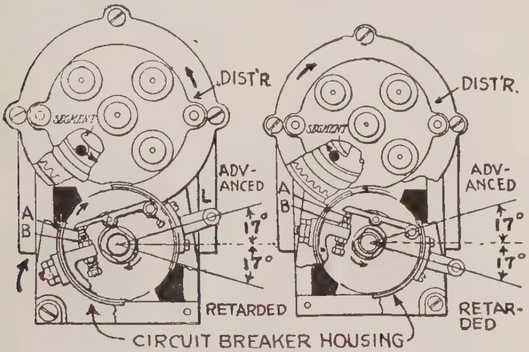


Fig. 8 Fig. 8**A**

Fig. 8. Illustration showing circuit-breaker in "advanced" position when magneto armature is running "counter-clockwise" (view from front of magneto).

Fig. 8**A**. Illustration showing circuit-breaker in "advanced position" when magneto armature is running "clockwise" (view from front of magneto).

It will readily be understood that if the armature shaft turns right-handedly (Fig. 8**A**) (view is from the distributor end, not the drive end), and if then the circuit-breaker housing is moved through a certain angle in a right-hand direction, the contact points (**A**) and (**B**) will separate later, or "retarded," with relation to the position of the engine crank shaft; while, on the other hand, if the housing is moved in a left-hand direction, the circuit-breaker point will open earlier, or "advanced," the position in which it is now in Fig. 8**A**. In this way the point at which the spark occurs can be shifted through an angle of about 34°.

Coil and battery system control: On the Delco and Atwater-Kent or similar systems, the advance and retard is obtained by shifting the housing surrounding the timer and distributor and also by governor action (see pages 202, 214).

Spark-Control Methods

There are three general principles used for control of spark: (1) by hand, to vary the spark position, which would be termed "variable spark"; (2) by a governor, which would also vary the spark according to speed; (3) by a fixed spark.

(1) **By hand** means that the spark lever on the steering post shifts the commutator or interrupter (see Fig. 4, page 287).

Where magneto ignition is used, the housing on which the interrupter arm is placed is shifted in the opposite direction of rotation to the armature to "advance," or cause the spark to occur earlier, or, in the direction of rotation to cause the spark to occur later.

When the spark is advanced or retarded by hand, it is left to the good judgment of the driver to manipulate the spark lever, except where the system is equipped with an "automatic" advance. The automatic advance is seldom used with magneto ignition.

(2) **The automatic advance** is probably the most satisfactory with a battery and coil system of ignition, because the spark occurs just at the right time automatically, and there is no guessing as to just how far to advance or retard at various speeds. See Index.

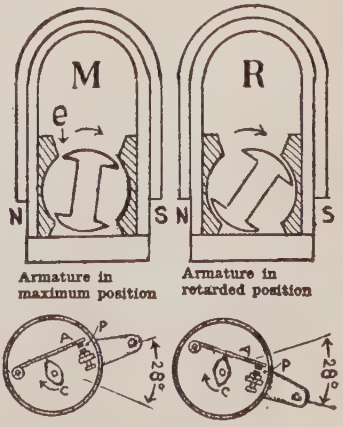
(3) **The fixed spark** is sometimes used with a high-tension magneto, which means that the time of spark is fixed at one position, usually advanced, and the contact-breaker breaks at one position, regardless of speed. This system has not proved very satisfactory on engines where speed varies, but would be satisfactory if the speed of the engine was constant and did not vary. The objection, however, would be in starting—liability of a kick—for the spark would necessarily be placed advanced for proper running.

The disadvantage in one instance: Suppose the car was running up hill, the charge of gas would be heavy and the throttle would be open, consequently there would be a high compression. If the spark was advanced, which it usually is with a fixed spark, the spark would occur at such a time that the combustion would take place before the piston reached the top, because the piston would be moving slow at, say, ten miles an hour; the result would be that the force would be exerted on the head of the piston causing the momentum of the piston to buck against the force of the combustion, which would invariably cause a knock and loss of power.

The fixed spark, however, is not at all advisable on variable speed engines.

Relation between Position of Armature to Contact-Breaker when Advanced or Retarded

Advanced position: Referring to (**M**), the armature cheek is just breaking from the pole tip (**e**), in the direction of rotation. This is the maximum position, or when current strength is strongest. At this time the contact-points (**P**) (Fig. 9) should separate.



Armature in maximum position **Armature in retarded position**

Fig. 9 Fig. 10

Fig. 9. Contact-breaker advanced.
Fig. 10. Contact-breaker retarded.

The magneto is set at the factory with armature in maximum position (**M**), and the contact-breaker housing (Fig. 9) is placed in an advanced position. That is, it is moved opposite to the direction of rotation of cam (**c**). The cam (**c**) is set so that it causes points (**P**) to separate when the contact-breaker housing is in the advanced position.

Retarded position: Suppose the contact-breaker housing is retarded, or moved with the direction of the cam rotation as far as it will go (Fig. 10) (28° is average range),[1] then points (**P**) of the contact-breaker would not separate until the armature had traveled farther[2] in the direction of rotation, approximately the position shown in (**R**). At this point the armature has passed the maximum position and is where the current strength is weaker. By referring to pages 253, 254, we learn that the current strength begins to weaken the nearer the armature travels to zero position after maximum position.

From this we learn that the spark is strongest at maximum position of the armature (**M**), with the contact-breaker in advanced position (Fig. 9), and that the spark is weaker when the contact-breaker is in retarded position (Fig. 10), because the armature has passed the maximum position.

Let us see what happens when we follow out the magneto-setting given on page 297, which says: Place piston on top of compression stroke, place contact-breaker in retarded position, then turn armature in direction of rotation until contact-points just start to separate.

This would place the armature in position (**R**), and the contact-breaker in position shown in Fig. 10; both retarded. In this position the spark would occur when the piston was on top of the stroke—but we must remember that the combustion is not instantaneous; therefore allowing for this lag, the spark would occur when the piston had moved slightly down after top—which at slow speed is desirable, but which is a weaker position of the armature for starting the engine on.

This is why spark-plug points ought to set close together, and why magnetos do not permit the engine to throttle down as slow as a constant source of electric supply, such as a battery. The contact-breaker is usually retarded when the engine is running slow and the magneto armature is turning over slowly. Therefore both actions tend to weaken the spark. Always run as far advanced on magneto ignition as possible.

As the speed of the engine increases, if the contact-breaker was retarded and combustion was not instantaneous, as explained above, then the piston, traveling fast, would move farther down after top before the spark occurred. Therefore as we have a range of 28° in which we can move the contact-breaker housing so that the spark will occur earlier, we then advance the contact-breaker more and more as the speed of the engine increases, so that the spark will occur before top of compression, thereby giving the combustion time to take place, when the piston is on top, or just starting down. The more we advance the breaker, the nearer we reach maximum or the strongest position of the armature. Therefore the current strength is greatest at high speeds.

When setting a magneto, the only point to consider is whether the breaker housing is to be retarded or advanced when interruption takes place, and the position of the piston.

---

[1] The average advance range of the armature is 22° to 34°—many magnetos actually having but 22° or 28° in which the breaker moves from full advance to full retard. The Bosch Co. states that the Bosch four-cylinder standard average speed (less than 2,000 r.p.m.) has a timing range of 35° figured on the magneto axis. On a timer or commutator, it is possible to get as high as 48°; for instance on the Atwater-Kent timer, the timer shaft will advance automatically about 15° at high speed, and the housing itself can be advanced about 33°.

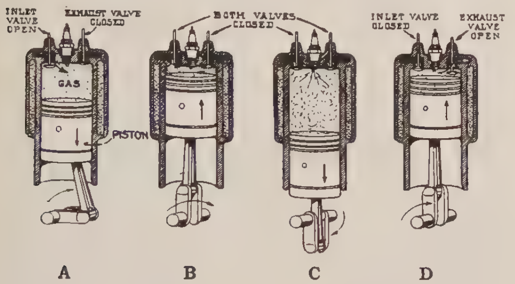
[2] About 1/16″ break from cheek of armature to pole-piece (e) when advanced, is the average break. The distance at full retard would be about 23/32″.

A four-cylinder engine, with a speed of 2,000 or less, is termed an average-speed engine, and the gap between pole-piece and armature cheek is 1/16″. An engine with speed of 2,000 to 3,500 r.p.m. would be termed a high-speed engine, and in this case the gap opening is increased to 5/32″ or 3/16″.

INSTRUCTION No. 28

IGNITION TIMING: Timing the Magneto; Timing Miscellaneous Ignition Systems

A study of Figs. **A** to **D** below will make clear the "four-cycle principle" which it is necessary to have in mind clearly in order to understand the explanations following. This explanation is also applicable to coil and battery ignition.



Suction or inlet stroke: In Fig. **A,** the piston moves downward, drawing a mixture of gas and air into the cylinder on top of the piston.

Compression stroke: In Fig. **B,** the inlet valve closes and the piston moves back in the cylinder, compressing the mixture of gas and air.

Power stroke: In Fig. **C,** the mixture of gas and air under compression is ignited by means of an electric spark; thus the expansion force of the heat pushes the piston downward. This is the power stroke. Note there is only one power stroke per cylinder for every two complete revolutions of the crank shaft.

Exhaust stroke: In Fig. **D,** the exhaust valve opens; the piston on the upward stroke forces out the burned gases, and the cylinder is again ready for a new charge, or the inlet stroke.

RELATION BETWEEN THE TIME OF SPARK AND TIME OF COMBUSTION

The combustion should take place as the piston is on top of the compression stroke, or slightly thereafter, as shown in Fig. 2 below, because at that point the gas drawn into the cylinder has been forced up into the head of the cylinder and is at the point of greatest compression. Hence more force is exerted on the head of the piston when the explosion occurs.

If it occurs after the piston has started down (as in Fig. 3 below), the compression is not as great. If it occurs before the piston reaches the top of the compression stroke (as in Fig. 1 below) it is not as great, because if the engine is running slow and the explosion occurs before the top of the stroke, the force will be exerted against the piston's upward travel, and will cause a knock and loss of power.

Fig. 2
Fig 2
Fig. 3
To get the most power, push down the moment pedal gets beyond center

An example: In Fig. 1, note that the piston is going up on compression stroke, pushing or compressing the gas (which was drawn in at the previous suction stroke) into the head of cylinder. At the point where piston is now, the gas is not very tightly compressed.

In Fig. 2, the piston has now reached the top of compression stroke and the gas is packed tight into the head of the cylinder. It is clear that if the combustion took place just as the piston started down, the expansion force against the piston would be greater than if the combustion did not take place until the piston had passed over the top and was on the way down, as in Fig. 3.

Also observe that if the combustion took place, before the piston reached the top of the compression stroke, as in Fig. 1, especially if running slow, the power would be exerted on the up-coming piston's momentum and would not only cause a falling off of power, but a knock would occur, caused by the sudden reversed force of the combustion on the piston.

Remember, the momentum of the fly wheel carries the piston up and down on the other three of the four strokes.

Note. The automatic spark control takes into account variations in speed only.

Time for the Spark to Occur

There is a difference in time, between the time the "spark" is made at the spark plug, and the time at which the "combustion" of the gas actually takes place. If combustion took place immediately when the contact was made or broken, then the proper time to set the spark to occur would be on top of the compression stroke.

But, as stated, there is a slight difference in time allowed for the gas to burst into full explosion after the spark occurs; but as we desire that full explosion occur at the highest point of compression, we will figure out just how we can make the combustion take place at the highest point of compression.

First: We must figure out how far in advance of the top of the compression stroke the spark must be set to occur, in order to have combustion take place on top of the compression stroke.

There are two main points to be considered; the system of ignition being one. If a coil and vibrator system is used, then it is natural to suppose that the time consumed in making contact on the commutator and the time of action of the vibrator will result in more time than a single contact, as in a magneto or single-spark system. Therefore if a vibrator coil system is used, we would have to set the spark to occur a longer time before the top of the compression stroke, than if a quicker single spark system of ignition was used.

The second consideration is speed. If the piston was traveling slow, the spark would be set (retarded) to occur later or nearer the top of compression stroke than if the engine was running fast.

Speed Relation to Time of Spark

Suppose the engine was running 500 revolutions per minute. Taking (X) (Fig. 6) as top of compression stroke, the distance to set the spark would be, say, at (Y), in order to give the combustion time to take place when the piston was on top of compression stroke.

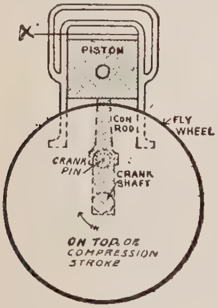

Fig. 4

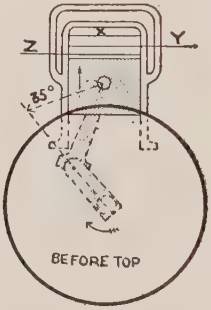

Fig. 5

Now if the spark was fixed to occur at (Y) (Fig. 6), and speed was increased to 1,000 revolutions per minute, then the piston would go to the top of compression stroke at (X), (Fig. 7), and pass over it and down to (Y), on the other side, or down in power stroke, before the process of combustion was completed. The result would be a loss of power during the piston's down travel between the points (X) and (Y) (Fig. 7), the full force of the explosion not being exerted on the piston until the latter point (Y) was reached.

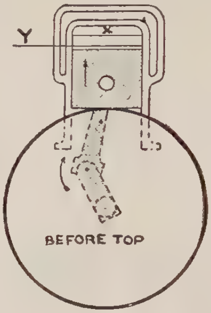

Fig. 6

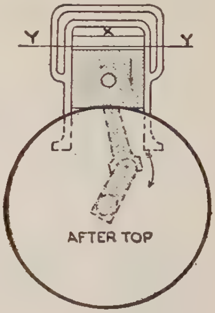

Fig. 7

To increase this, it will be necessary to recalculate the piston speed at 1,000 r.p.m. and set the spark at a point say, (Z), (Fig. 5), which will allow of complete combustion by the time the piston reaches the top of compression stroke (X).

Setting the time of spark to occur before the top of compression stroke is called advancing the spark.

In setting a magneto, the usual extreme range of advance is 22° to 35°; therefore if it was desirable to set the spark to occur at 35° at full advance position, so that the spark would occur 35° before top, when running at full speed, simply place the piston on top of compression stroke, and set the contact-breaker in "retard" position.

If only 30° advance was desired at full speed, place the piston 5° past the top of compression stroke and set the breaker-box housing at full retard.

RELATION OF MAGNETO DISTRIBUTOR AND ARMATURE SPEED AND OF THE CRANK SHAFT OF THE ENGINE AND THE CAM SHAFT

A high-tension magneto of standard construction produces a high-tension or jump-spark current, this current being generated in the windings of the magneto armature without the use of a separate induction coil.

Two ignition sparks are produced during each revolution of the armature in the "armature type" magneto, and these are transmitted to the proper cylinders by means of the high-tension distributor, which is integral with the magneto. Once during each half-revolution of the armature the primary circuit is broken, and the abrupt interruption of the primary current results in the production of the high-tension current in the secondary winding.

The variation in ignition timing is effected on the magneto itself, the arrangement permitting the interruption of the primary current to occur earlier or later in the revolution.

Armature and Distributor Speed

On a four-cylinder engine, four sparks are required during two revolutions of the crank shaft. The magneto gives two sparks or impulses to one revolution of its armature; therefore it would be geared to drive at the same speed as the crank shaft.

On a six-cylinder engine, six sparks are required during two revolutions of the crank shaft; therefore the armature would revolve one turn, and half of another turn, making three sparks, while the crank shaft made one turn. Therefore on two revolutions of the crank shaft, the armature would make three revolutions, or six sparks.

The distributor, however, on both the four and six-cylinder engine, would revolve at one-half the speed of the crank shaft, as the distributor brush would make one revolution, to two revolutions of the crank shaft.

The distributor rotor on all ignition systems revolves at one-half the speed of the engine crank shaft.

A two-lobe cam is generally used on the interrupter, with lobes or projections 180°, or one-half revolution apart. This causes an interruption of current every half-revolution of the armature.

Speed Relation between Crank Shaft of Engine and Cam Shaft

On a four-cylinder, four-cycle engine, the crank shaft turns two revolutions (or 720°) to complete its four-cycle operation. The cam shaft turns 1 revolution; the magneto armature turns 2 revolutions; the magneto distributor brush, 1 revolution.

Four sparks are necessary during the two revolutions of the crank shaft; therefore as the magneto armature turns two revolutions, the same as the crank shaft, it produces four sparks, or a spark at every one-half revolution.

The distributor brush is geared to turn one-half the speed of the magneto armature; therefore, it will turn one revolution (360°) to two revolutions of the crank shaft. As the four contact segments on the distributor are spaced 90° apart, then one revolution of the distributor brush will make four contacts, producing four sparks 90° apart during one revolution of the distributor brush, or 180° apart relative to the crank shaft, or four sparks to two revolutions of the crank shaft.

A two-point cam is used on the "armature type" magneto contact-breaker, which interrupts the primary circuit twice during each half-revolution of the armature.

Four-cylinder magneto speed: Refer to Fig. 8. Note that **when the piston makes a full stroke,** or when the crank shaft or fly wheel of the engine travels from (A) to (B), one-half revolution, or 180°, the armature also travels 180°. Both travel at the same speed.

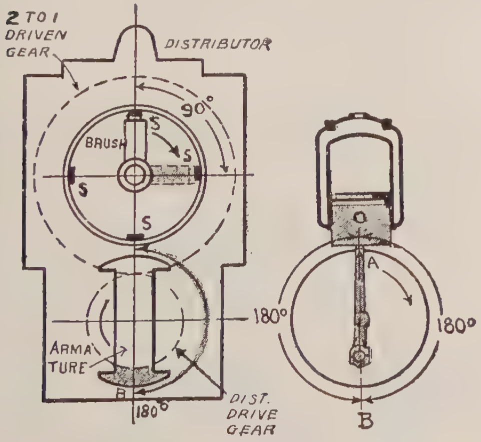

Fig. 8 Fig. 8A

Figs. 8 and 8A. A magneto for a four-cylinder engine.

The four-cylinder engine requires four sparks during two revolutions of the crank. **The armature** gives two sparks or impulses every revolution, therefore, traveling at the same speed as the engine crank, it will give four sparks during two revolutions.

The distributor would be geared for one-half the speed. Every time the crank shaft moved 180°, or one-half revolution, the distributor brush would move 90°, or one-quarter of a revolution.

The distributor always runs at one-half the speed of the crank shaft on all four-cycle engines.

On a six-cylinder, four-cycle engine, the crank shaft turns two revolutions to complete the four-cycle operation, just the same as the four-cylinder engine. The cam shaft also turns the same as the four-cylinder engine, that is, one revolution to two of the crank shaft.

But six sparks are necessary during the two revolutions of the crank shaft, because the crank shaft is divided into three pairs of throws (see page 45), each pair firing 120° apart, or one-third of a circle. It is then necessary to gear the magneto armature so that it will turn three times to the crank shaft's two, or one and one-half times to each revolution of the crank shaft. The armature produces three sparks during one and one-half revolution, or six sparks during three revolutions (see Fig. 9).

The distributor brush must turn one revolution to the crank shaft's two; therefore, if the armature turns three times when the crank shaft turns two times, the distributor is geared from the armature shaft to turn one revolution when the armature turns three revolutions, or one-half revolution when the armature turns one and one-half revolutions.

As the six contact segments on the distributor are set 60° apart, then one revolution of the distributor brush will make six contacts, producing six sparks 60° apart during one revolution of the distributor brush, or 120° apart relative to the crank shaft, or six sparks to two revolutions of the crank shaft.

Six-cylinder magneto speed: Refer to Fig. 9. Note that **when the piston makes a full stroke,** or when the crank shaft or fly wheel travels from (A) to (B), or 180° or one-half of a revolution, the armature would turn three-quarters of a revolution, or 270° (**A** to **B**).

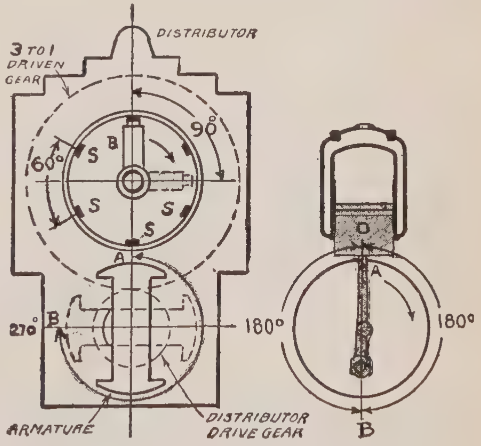

Fig. 9 Fig. 9A

Figs. 9 and 9A. A magneto for a six-cylinder engine.

Therefore if the crank pin made one complete revolution, the armature would make twice three-quarters or one and one-half revolutions. During this one and one-half revolutions it would have made three impulses.

When the engine crank makes another revolution, then the magneto armature would have made one and one-half revolutions more, or three revolutions to two of the crank; therefore, it would make six sparks during the three revolutions of the armature, or two revolutions of the crank shaft. Therefore the armature is geared to run one and one-half times as fast as the crank shaft.

The six-cylinder engine crank must make two revolutions to complete its four-cycle operation; therefore it would require six sparks during its two revolutions (720°).

The distributor, however, having the six plug connections to make during one revolution of its rotating brush (B), would have to be geared so it would make a connection every 60°, or 1/6th of a revolution. For instance: If the crank shaft traveled one-half of a revolution, or 180°, the distributor would travel 90°, or one-quarter revolution.

If the crank shaft traveled one revolution, or 360°, the distributor would travel 180°, or one-half revolution.

If the crank shaft traveled two revolutions, or 720°, the distributor would travel 360°, or one revolution.

If one of the cylinders fired every 120°, or one-third of a revolution (there being six cylinders to fire during two revolutions, or 720° travel of the crank) then we would need six sparks or impulses during 720° travel of the crank.

The distributor being geared one-half the speed of the crank shaft, the segments would be placed 60° apart; therefore, when the crank shaft traveled 120° and required a spark, distributor brush (B) would travel 60°. There being six segments 60° apart this would give six sparks or impulses during two revolutions, or 720° travel of the crank, or one revolution, or 360° travel of the distributor brush (B).

Magneto Distributor Speed

Fig. 10: Illustrates the ratio of gearing between the armature and distributor gear on the four and six-cylinder magneto (four-cycle).

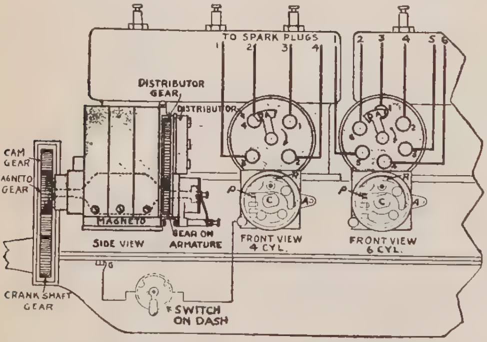

Fig. 10

On a four-cylinder engine, the armature and cam (C) turn at the same speed as the crank shaft, but the distributor rotor (DA) turns once to the crank shaft's twice.

On a six-cylinder engine, the armature and cam (C) turn one and one-half times to the crank shaft's once, or three revolutions to the crank shaft's two, but the distributor rotor (DA) turns once to the crank shaft's twice.

On the distributor of four-cylinder magneto (see illustration, Fig. 8), the contact segments (S) are 90° apart.

On the distributor of six-cylinder magneto (Fig. 9) the segments (S) are 60° apart.

Distributor Connections: Relation of Distributor Connections to Cylinders

The following discussion applies to distributors on coil and battery ignition as well as magneto ignition.

Before the magneto distributor can be connected with the spark plugs, the firing order of the engine should be determined, and in the case of four-cylinder four-cycle engines, the firing order must be either 1, 3, 4, 2, or 1, 2, 4, 3, or if a six-cylinder engine, it would probably be 1, 5, 3, 6, 2, 4, or 1, 4, 2, 6, 3, 5. The firing order may be determined by cranking the engine slowly and observing the order in which the inlet or exhaust valves operate, this order of operation being identical with the firing order.

The method of connecting the spark plugs with distributor on four-cylinder engines is shown below in Figs. 11 to 15, when the engine is firing 1, 3, 4, 2, or 1, 2, 4, 3. Note also the different method of connection when the magneto runs clockwise, and counter-clockwise. Clockwise means in the same direction as the hands of a clock move; counter-clockwise, in the reverse direction.

Note that when the armature revolves in one direction, the distributor revolves in the opposite direction. This is due to the motion of the gears. In the case of a magneto, the direction of rotation clockwise or counter-clockwise, is always stated by viewing the magneto from its shaft or driving end.

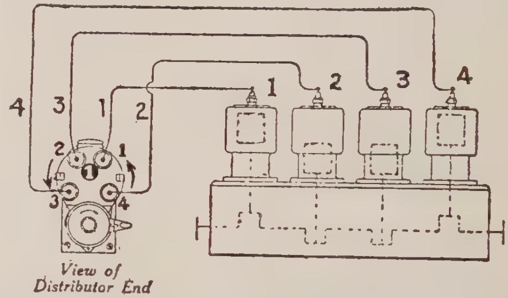

Fig. 11. Magneto armature is running counter-clockwise, if viewed from the drive end (opposite the distributor end). The distributor rotor is revolving as shown by the arrows, and is connected with the cylinders, so that the firing sequence of the cylinders is 1, 3, 4, 2.

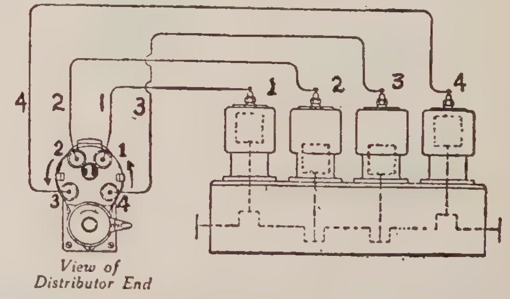

Fig. 12. Magneto armature is running counter-clockwise. The distributor rotor is revolving as shown by the arrows, and is connected with the cylinders, so that the firing sequence of the cylinders is 1, 2, 4, 3.

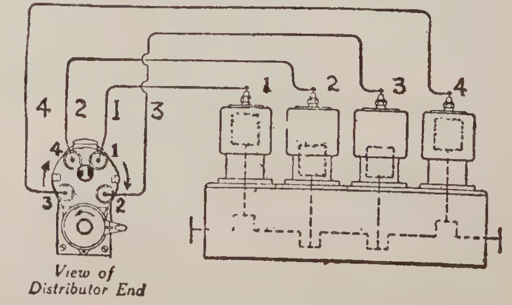

Fig. 13. Magneto armature is now running clockwise, if viewed from the drive end (opposite the distributor end). The distributor rotor is revolving as shown by the arrows, and is connected with cylinders, so that the firing sequence of the cylinders is 1, 3, 4, 2.

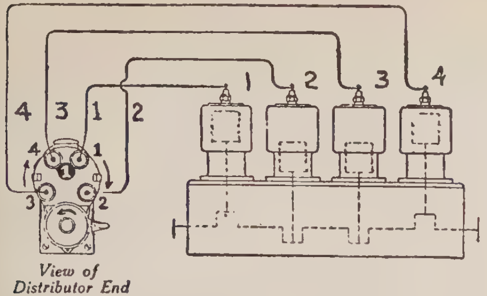

Fig. 14. Magneto armature is now running clockwise. The distributor rotor is revolving as shown by the arrows, and is connected with the cylinders, so that the firing sequence in the cylinders is 1, 2, 4, 3.

Never allow the ignition wires to lie on or near the exhaust pipe, as the insulation will burn off and lay the wire bare, causing a short circuit.

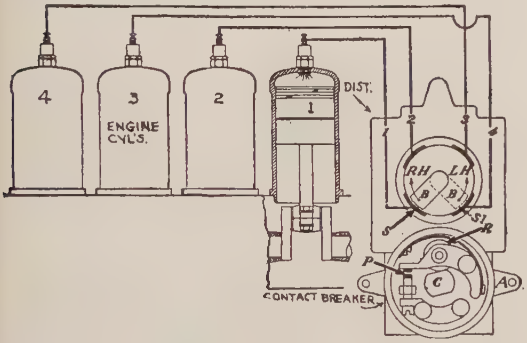

Fig. 15. K.W. high-tension magneto used as an example showing connections of spark plug wires to distributor on a four-cylinder engine, when firing 1, 2, 4, 3, or 1, 3, 4, 2, and when distributor brush rotates right-hand or left-hand. **RH** means arm **(B)** turns to the right hand, when cam (C) turns to the left; **LH** means arm **(B)** turns to the left hand, when cam (C) turns to the right; **P,** platinum contact points on interrupter; **R,** roller raised by cam (C) which causes separation of (P); **A,** interrupter or contact-breaker housing.

How to Connect Spark-Plug Cables with Distributor

It will first be necessary to determine the firing order of the cylinders of the engine.

If the firing order on a four-cylinder engine, for example, is 1, 2, 4, 3, then the direction of rotation of the rotor of the distributor is the next point to determine. See Fig. 15.

If cam (C) turns to the left when viewed from the front, set the distributor rotor (B) on segment (S) and connect cylinder No. 1 with (S). The next segment of the distributor in the direction of rotation (RH) would be connected with the second cylinder, the next with the fourth cylinder, and the next with the third cylinder.

If the cam turns to the right, when viewed from the front, place (B) on segment (S1) and connect cylinder No. 1 with (S1), then connect the segment or cable coming next in the direction of rotation with the second cylinder, the next with the fourth cylinder, the next with the third cylinder.

If the engine fires 1, 3, 4, 2, connect in the same manner so that the rotation of brush (B) will cause the engine to fire 1, 3, 4, 2, in order as they come.

If cam (C) is turned to the left, by shifting the interrupter housing down, by movement of lever (A), the spark would occur earlier, or "advanced." If (A) was shifted up, with cam (C) rotating to the left, the spark would occur later, or retarded.

Fig. 15 is that of the K. W. high-tension inductor-type magneto. It will be observed on page 246 that this magneto differs from the armature type and other magnetos, in that it gives four sparks or impulses per revolution of armature instead of two. By using a two-point lobe cam (C) and revolving armature and cam (C) at crank-shaft speed, there are but two interruptions of the primary circuit per revolution of armature and crank shaft, or four interruptions or sparks for two revolutions.

The distributor rotor, like all other ignition distributors, revolves one revolution to the crank shaft's two.

MAGNETO INTERRUPTERS[1]

The purpose of the interrupter, also termed a contact-breaker, and breaker-box, is to open the primary circuit when the magneto armature is at maximum position, as explained on pages 253, 289.

The interrupter housing can be shifted by movement of lever (L), so that the interruption will occur advanced or retarded; as shown in Fig. 1.

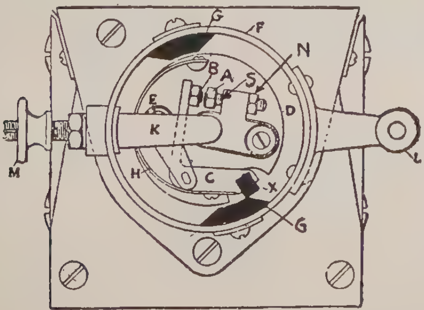

Fig. 1. Interrupter or contact-breaker as used on the Bosch "DU4" high-tension magneto.

On the "armature-type" magneto, the armature is in a maximum position twice during one revolution; therefore, if the interruption occurs twice during a revolution of the armature, two sparks will occur during one revolution. See page 253.

In order that the interrupter or contact-breaker points (A) and (B) (Fig. 1) may be separated twice during one revolution, two fiber cams (G), placed 180° apart, cause the points to separate twice during one revolution.

Note the arrangement in Fig. 1. Here we have two cam blocks (G) stationary to the inside of the interrupter housing (F) placed 180° apart. As the disk (D) revolves, the parts **C, H, E, B, A,** and **X** revolve with it.

At the extreme end of (C) is a projection (X). When this fiber projection (X) strikes cam-block (G), the platinum point contacts (B and A) are opened. (H) is a spring provided for holding the points together at other times. (K) is a flat metal spring which connects with terminal (M) and is used to carry current to grounding switch (see Fig. 1, page 256).

Interrupter Cams

The interrupter is constructed in various forms. The principle, however, is about the same.

---

[1] The S.A.E. designates the interrupter as "breaker box." The term "interrupter" is used in this book, owing to the fact that this term is the one more commonly adopted. In some instances the change will be made.

The interrupter on the four-cylinder, as well as on the six-cylinder engine magneto, must interrupt the current twice during one revolution. Therefore a cam with two projections placed 180° apart, as shown in Fig. 2, would serve the same purpose as the cam blocks (G) in Fig. 1.

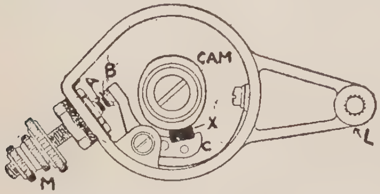

Fig. 2. Interrupter or contact-breaker used on the Remy "RL" magneto.

In Fig. 2, the cam revolves on the end of the armature shaft, thus at the same speed as the armature.

The production of the spark at a definite time is therefore controlled by the cam.

On a single-cylinder engine, requiring but one spark during two revolutions of the crank shaft, a single cam (Fig. 3) is used which is attached to the end of the armature, which revolves one-half the speed of the crank shaft.

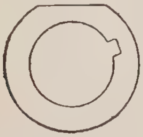

Fig. 3. Single-spark cam.

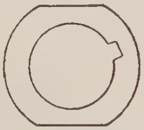

Fig. 3A. Two-spark cam.

The usual practice, therefore, is to pass over one of the two "maximum" positions of the armature, simply by omitting one of the two cams, thus leaving the primary winding short-circuited. Therefore as the magneto is driven at cam-shaft speed in this instance, a single spark is obtained.

On a four-cylinder engine, the cam would open the interrupter twice during one revolution. Therefore it would run at the same speed as the engine, causing four openings during two revolutions, and would have two high points or lobes, as in Fig. 3A.

Speed Relation of Interrupter Cam and Magneto Armature to Engine Crank-shaft Speed[1]

The following refers to a four-cycle engine where a two-lobe cam is used on an armature-type magneto.

Two and four-cylinder engines: half the speed of the crank shaft.

Three-cylinder engines: at three-quarter speed of the crank shaft.

Six-cylinder engines: at one and one-half speed of the crank shaft.

Eight-cylinder engines: twice the speed of the crank shaft.

The interrupter gap clearance mentioned above refers to the opening of the interrupter points when the cam is in such a position as to open the points to their fullest extent.

If the gap clearance of the interrupter points is not correct, the adjustment can be made by revolving the armature by hand until the arm (X) (Fig. 1, for example), is on the high point of cam (G), which causes the points (A and B) to separate fully. Then loosen lock nut (N) and adjust screw (S) until the proper clearance is obtained. Be sure and tighten the lock nut.

Widening the interrupter air-gap causes the interrupter points to open earlier, because, when lowering the screw (S, Fig. 1), the point (X) on arm (C) will begin to rise earlier, causing a spark to occur when the magneto armature is at a more favorable position—giving a more intense spark. Closing of the gap, by turning screw (S) up, is just the reverse of the foregoing. Usually, a small flat wrench is provided with the magneto for adjusting.

The proper opening as well as the quick opening of the interrupter points is a very important factor. See pages 257, 258, 252, 190, and read carefully.

If the engine misses with the spark retarded (and misses more at low than at high speed), the contact screw should be screwed out a notch at a time until the missing is overcome.

If the engine misses with the spark advanced (and more at high speed than at low), the contact screw should be screwed in a notch at a time until the missing is overcome.

As previously stated, there are many different methods adopted by the various manufacturers for opening the interrupter points.

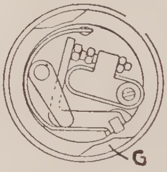

Fig. 4

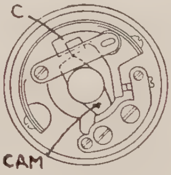

Fig. 4A

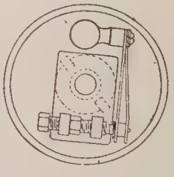

Fig. 4B

The Bosch is shown in Fig. 1 and in Fig. 4. In this the moving contact (X) is carried on a bell crank which rotates with the armature shaft, the cams (G) being inside the breaker box.

For **the Dixie**, see Fig. 4A and page 274. The cam revolves with the armature shaft operating a bell crank (C), which remains stationary so that adjustments can be made while running.

For **the Eisemann**, see Fig. 4B and page 269. This consists of two spring members separated by a fiber (S) piece; one of the springs carries the moving contact point. The cam is stationary.

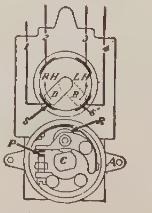

Fig. 4C

For **the K. W.**, see Fig. 4C. The cam (C) revolves against roller (R), thus opening contact points (P) when the highest point of the cam is against roller (R).

---

[1] Two-cycle engines: one and two-cylinder engines, same speed as crank shaft; three-cylinder engine, one and one-half the speed of crank shaft; four-cylinder engine, twice the speed of crank shaft; six-cylinder engine, three times the speed of crank shaft.

Interrupter Gap Clearance

There is one adjustment on the magneto which needs watching: that of the platinum point breaker contact screw. The interrupter air-gap clearance adjustment should be made so that the maximum break of the platinum points is about .015″ to .020″, which varies slightly on different magnetos as follows:

Bosch, approximately .016″[1]
Berling, approximately .015″
Dixie, approximately .020″
Eisemann as shown on page 270, .012″
Other Eisemann magnetos .016″
Remy low-tension .020″
Remy high-tension .020 to .025″.
K.W. high-tension 1/64″

The interrupter adjusting screw is very delicate and needs to be adjusted carefully. If the platinum points are "pitted," then they should be filed down flat with a very fine jeweler's file. (See pages 221, 225). **Keep oil away** from the points.

Common contact-breaker troubles are: insufficient lubrication causing wear; loose breaker bar; fiber bumper worn.

Spark Plugs for Magneto Ignition

The spark plugs used should be those recommended by the manufacturer because, in some instances, the points of the plugs are of a higher resistance metal. The average gap for magneto ignition is .020″, or about 1/64″, and on battery and coil ignition, .025″ to .030″.

The spark-plug gap recommended by some of the magneto manufacturers is as follows:

Berling	.030″
Bosch	.016″ to .020″ ("NU4" is .016″)
Dixie,	.025″[1]
Eisemann,	.025″
K.W	1/64″
Remy (low t.)	.025″
Remy (high t.)	.030″ or 1/32″

SETTING TIME OF SPARK OF MAGNETO

There are three general positions of the piston for setting the time for the spark with the magneto:

1. Top of compression stroke.
2. After top of compression stroke.
3. Before top of compression stroke.

A variable spark is where the breaker can be shifted to advance or retard the time of spark.

A fixed spark is where the breaker (or interrupter) is set or fixed at one position and cannot be varied (see page 289).

In setting a magneto of the fixed-spark type, the instructions for moving the breaker housing to the extreme advance or retard position are to be disregarded. The magneto should be set so that the spark occurs at the most advantageous point in the cylinder. This should be decided upon by the engine manufacturer, but where such information is not available, the spark should occur at top-center.

In setting a magneto of the variable-spark type, one of three methods can be used:

(1) By setting the piston on top of the compression stroke and setting the magneto breaker retarded. In this instance the most advantageous position of the piston for the spark to occur, when the breaker is fully advanced, is determined by how much advance the magneto is capable of giving. A high-speed engine requires more advance than a slow-speed engine. Magnetos vary from 22° to 35° or more. However, this is the average and general setting. This is termed "setting piston on top and ignition retarded."

(2) Sometimes, on truck and tractor engines and others, the spark is made to occur when the piston is slightly down after the compression stroke, and the breaker is retarded. This would not permit advancing the spark so far ahead of the stroke—unless a magneto with a greater range was used, but this is done on slow-speed engines and where very slow running or idling is desired.

(3) Setting the piston before the top of the compression stroke and advancing the breaker would be termed "setting ignition advanced." The point to determine here, as to where to set the piston, depends entirely upon where you wish the spark to occur when the breaker is fully retarded. For instance, suppose the magneto range of advance was 35° and you wished the spark to occur on top of compression stroke: simply set piston 35° before top, with the magneto breaker full advanced. This would mean the same thing as setting the piston on top with the magneto retarded.

Setting the High-Tension Magneto "Retarded on Top"

The average plan for setting a magneto: Where the magneto has been removed from the engine and its connections were not previously marked, it can be retimed as follows:

1. Place No. 1 piston on top of compression stroke. To find compression stroke, see pages 307, 70.
2. Uncouple magneto from its drive shaft. If the magneto cannot be uncoupled, then time from magneto gear and gear driving it, by taking them out of mesh.
3. Retard the breaker box (also called interrupter) (**F**) (Fig. 5), by turning it in the direction of rotation of the armature shaft, as far as it will go.
4. Turn the armature in the direction of rotation until the distributor arm (**DA**) is on segment (**S**) of No. 1 spark-plug cable connection; then turn the armature one way or the other slightly, until the interrupter arm (**A**) is just starting to separate the platinum point connection (**P**) with (**K**), which of course is caused by cam action, as shown. In other words, just when the points start to separate is the time to set the magneto.
5. Couple the magneto shaft, or mesh the gears driving the magneto, at this point, being careful not to move either the armature or piston.
6. Now see that the wire cables from the distributor are properly connected, as explained on page 295. In this instance, by looking at the distributor connections and noting direction in which rotor (**DA**) turns, the firing order would be 1, 3, 4, 2.

---

[1] See Index for "Conversion of thousandths of an inch in decimals to fractions of an inch."

[1] .025″ on four and six-cylinder engines, and .020″ on eight-cylinder engines.

The foregoing setting is for retarded position of interrupter and piston on top. This setting would allow the spark to occur considerably before the piston reached top of stroke when the interrupter was advanced, which is usually the case with high-speed engines, and the average and usual setting.

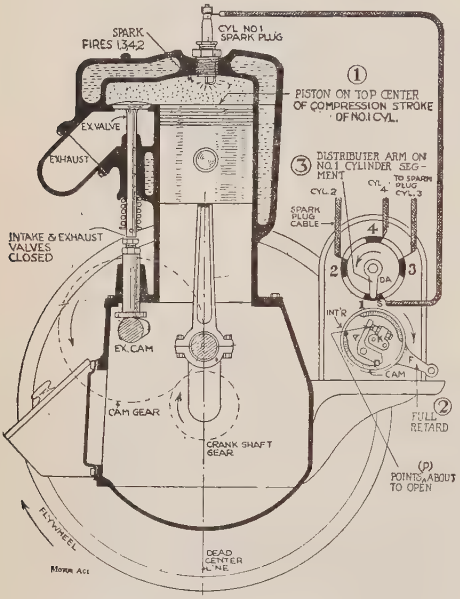

Fig. 5. Diagram showing how a high-tension magneto is usually timed; interrupter housing (F) is retarded and the piston is placed on top center of the compression stroke.

No hard-and-fast rule can be given in the absence of specific instructions of the manufacturer, as to the best piston positions corresponding to full advance and retardation; but, in general, a trial setting on the average plan (as in Fig. 5) might be tried, in which the gear wheels are meshed so that, with the contact-breaker fully retarded, the piston is on top of the compression stroke.

If it is found that the contact-breaker cannot be properly retarded at slow speeds, without the engine tending to knock, another setting must be made, and the piston moved farther on the firing stroke.

After a few trials and after carefully noting the pull of the engine, the best setting for the particular conditions will be attained.

The "breaking" distance between the platinum points should be .015″ to .020″. The amount of range provided for advancing and retarding is greater on some magnetos than on others; an average range is from 22° to 35°.

Setting Magneto "Retarded—After Top"

If a manufacturer's instruction said, "Place piston, say, ⅛″ down after center of compression stroke with breaker box retarded," then this would not permit advancing the spark so far ahead of the stroke. In some instances, this is done on slow-speed engines and where very slow running or idling is desired, as on truck and tractor engines.

Note. The armature turns in the opposite direction to the distributor. Therefore always note the direction in which the distributor turns before connecting cables to plugs. To tell how an engine fires, see pages 79, 78.

The breaker box (F) is stationary. The arms (**A**) and (**K**) revolve with the armature (Fig. 5).

Usually when viewing the magneto from the front of the engine, the magneto would be facing in the opposite direction to that shown in Fig. 5, i.e., towards the flywheel, as the rear end of a magneto is usually driven from the front of the engine.

When the breaker points are just breaking, the armature cheek, breaking from the pole, is in correct position, as it was set at the factory; this is true, likewise, of the speed of the distributor to the armature.

How the Instructions for Setting a Magneto Vary

(1) **Set by marks on flywheel.** Usually designated on the flywheel by a mark (C) or (F). This mark is placed in line with a punch mark on the cylinder which indicates that piston No. 1 is on compression stroke and the magneto is to be set advanced or retarded as instructions may be given, at this point.

(2) **Set by inches.** Should the time for the spark to occur be given in inches, for example, "time for spark to occur is full advanced position measured 3½″ on flywheel, before upper dead center," as is the case in the instructions given to set the valves on the Simplex engine, which is 4⅜″ bore, 6¼″ stroke, and 18¾″ flywheel:

To do this, set the spark lever or breaker on the magneto at "full advance" position. Then turn the flywheel until the top center of compression stroke is reached. At this point a center mark on the flywheel is in line with a center mark on the inspection hole. To have the spark occur 3½″, as measured on the flywheel, would mean to turn the flywheel back or before top of compression stroke until this center line was 3½″ away from the center line on the inspection hole. This would be the position for the spark to occur in.

The armature of the magneto would then be uncoupled, the breaker advanced, and the armature turned slightly until points were just starting to separate. The coupling would then be tightened. This setting would cause the spark to occur 21° before top of compression stroke, with breaker housing advanced. (The value of degrees relative to that of inches was found by referring to the table on page 299.)

(3) **By measurement of armature from pole piece,** as in Figs. 7 and 7A (page 288). Note (e), which is the distance the armature is to be set with piston on top and breaker points separating (see "Synchronizing distributor with armature").

(4) **By sight hole,** as in Fig. 6 (page 299).

(5) **By degrees:** Should the firing position be given in degrees, the movement of the piston, measured in inches corresponding with any given number of degrees of the crank shaft (where the relation of the crank shaft throw to the length of the connecting rod is as 1:4.5),[1] may be determined by reference to diagram, page 299.

Example: Suppose you were instructed to set the spark 34° before top of compression stroke—"advanced," on an engine with 5½″ stroke.

(a) Turn to table on page 299; find 5½″ at bottom. Next find 34° to right. Follow instructions for finding result given in chart. The distance in inches at which to place the piston would be midway between ¼″ and ⅜″ from top.

(b) With this information you would then proceed to place the piston, say, within 5/16″ of top of compression stroke.

(c) The interrupter housing would then be full advanced and the armature turned in direction of rotation until the cam just started to separate the interrupter points.

---

[1] See footnote, page 299.

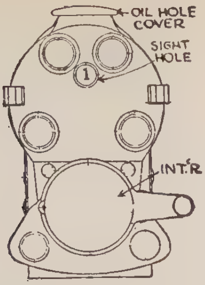

Fig. 6. Magneto setting by sight hole.

In some magnetos, "ZR" Bosch, for instance, the magneto can be set by observing the sight hole.

The piston is placed to firing position, for full advance position. This point is determined by the engine manufacturer.

The armature is then rotated until the figure 1 can be seen in the window in the face of the distributor plate, which indicates that the distributor rotor is on No. 1 segment to fire No. 1 spark plug. The cover of the oil well is then raised, and the armature turned a few degrees in one direction or the other until the red mark on one of the distributor gear teeth is brought into register with red marks on the side of the window. The magneto is then turned for full advance position, and the gear or coupling is secured to the armature shaft.

Setting Magneto by Degrees

A diagram for determining the advance in "inches," or a fraction thereof, to set the piston when the stroke is known and when the time to set the spark is expressed in "degrees," is shown in Fig. 7.

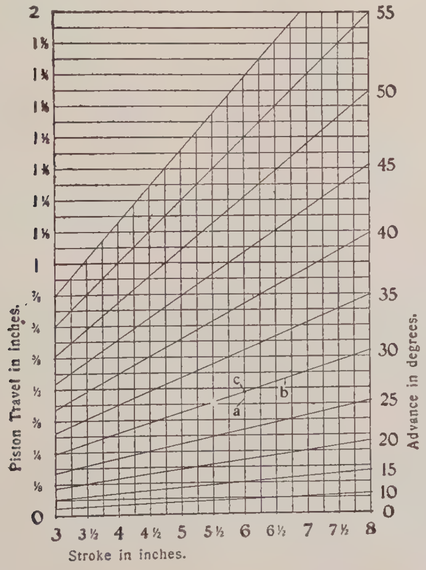

Fig. 7

The relation of the piston travel to the rotation of the crank shaft depends on the stroke and the length of the connecting rod.

The piston travel of an engine[1] is easily determined, and the determining of the rotation of the crank shaft in degrees, corresponding to any desired piston travel, may be ascertained from the accompanying diagram. In this diagram the relation between the crank and the connecting-rod length is as 1:4.5 (see footnote).

In the diagram the vertical lines numbered at the bottom give the stroke of the engine in inches, the rotation of the crank shaft in degrees being indicated by the slanting lines and the figures at the right.

The figures on the left and the horizontal lines indicate the piston travel in inches.

As an example in the use of the diagram: It may be desired to find the piston travel for an advance of 30° on a motor of 6″ stroke. The vertical line for the desired stroke may be identified by the figures at the bottom of the diagram; and this vertical line may be followed upward until it cuts the diagonal line indicating the desired number of degrees, which is 30° in the present case.

The horizontal line nearest this point should be followed to the left, until it meets the diagonal line, and this should be followed to the left-hand side. In the present instance it will be seen to indicate about ¼″. This gives the advance in inches, corresponding to 30°.

Timing the Bosch Dual Magneto

This system is explained on pages 267 to 269. Note that there is a **battery interrupter** and a **magneto interrupter** (see Fig. 11, page 267). Although both are in the same housing on the front of the magneto, but one setting—that of setting the magneto interrupter—is necessary.

The battery interrupter is so arranged that it will then interrupt or break its circuit approximately 10° later than the magneto interrupter; this feature gives the full timing range of the magneto. For instance, if the timing lever is fully retarded and the magneto interrupter is set to break when the piston is on top of compression stroke, the battery interrupter, with the switch in battery position, would break slightly after top, or 10° later. Therefore set the magneto interrupter just the same as you would set the Bosch independent type of magneto.

Timing the Bosch Independent Type

Place the piston on top of the compression stroke with the interrupter retarded as explained on page 297.

The magneto points on the dual system should be adjusted to open about 0.35 millimeters, or slightly under 1/64″, and the **interrupter points** full 1/64″. **The spark-plug points** should have a gap of about 1/64″ to .025″.

Timing the Remy Magneto, Model "RL"

Model "RL" is to be timed to the engine by the break of the contact points. When the piston is on exact dead firing center, the cam house must be in full retard position, and the platinum points must just be separating.

The high-tension cable from this cylinder, which is in exact dead firing center, should then be connected to the distributor terminal, to which the distributor segment, which is opposite, corresponds.

The remaining distributor terminals should then be connected up in the proper firing order of the engine.

The position of the "inductor" or "rotor" type of armature is just the same as on a "shuttle" type armature; the interrupter should just be breaking when the "rotor" is just leaving the vertical position.

Sectional cuts explaining the Remy magneto, with its inductor type of armature, are shown on page 247. Set the breaker points at .025″ gap.

Timing the Eisemann Magneto, Dual System

To set this type, turn the engine by hand until the piston of No. 1 cylinder is on the dead center (compression stroke). Place the timing lever of the magneto to fully retarded position, then turn the armature of the magneto until No. 1 appears at the glass dial of the distributor plate. Make sure that the platinum contacts of the magneto are just opening. Fix the driving medium in this position.

In order to insure absolute safety when cranking on the battery, the contact-breaker of the battery system is arranged so that it will open 10° later than the magneto contact-breaker.

---

[1] 1:4.5 is a ratio equation and means, as 1 is to 4 5/10, or, in other words, the connecting rod is 4½ times longer than the crank throw.

Timing the Splitdorf Low-Tension Magneto

Set the piston on top of compression stroke with the interrupter retarded.

Now revolve the armature shaft in its direction of rotation until the oval breaker cam comes in contact with the breaker bar and just begins to separate the platinum contacts. Set the coupling or gear at this point.

Berling High-Tension Magneto

The model "E-41" four-cylinder engine magneto is shown in Fig. 8.

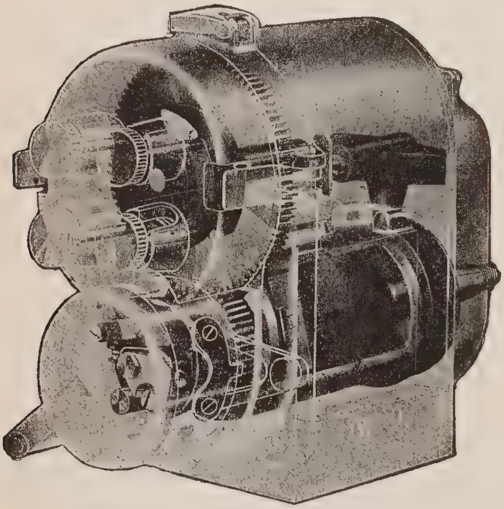

Fig. 8. A phantom view of the "E-41" Berling high-tension magneto. A "gap-distributor" is used. Usual setting; retarded, piston on top. Interrupter adjustment, .015" to .019"; plug .031". (Ericsson Mfg. Co., Buffalo, N.Y.)

Simms Magneto

A special feature of the Simms magneto is the design of the pole pieces which have extensions on the edges following the direction of rotation of the armature. These extended edges keep the edges of the armature shuttle within influence of the pole in all positions from full advance to full retard. That is to say, that at the moment of breaking the current the edge of the shuttle is never widely separated from the edge of the pole piece. Therefore the current is generated at low or high speeds without much loss of intensity.

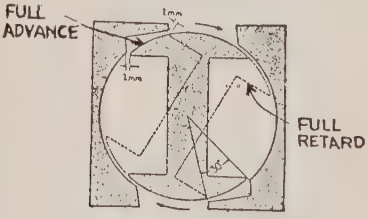

Fig. 9. Special pole piece used on Simms magneto to give equal spark intensity at all speeds.

Checking Ignition Timing of Magneto

When the gears which drive magneto or timer are disengaged, be sure they are marked as indicated in Figs. 10 and 11. When connecting high-tension wires, first learn the firing order, and then connect as explained on page 295. Remember, the distributor on a magneto revolves in a direction opposite to that of the armature. For instance, see Fig. 10: crank gear (C) revolves to the left (view supposed to be from rear of engine); idle gear to right; magneto gear to left, and distributor to right.

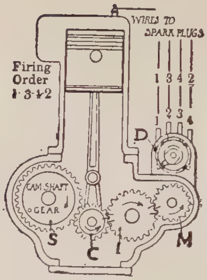

Fig. 10. Rear view of engine.

In Fig. 10 the rotor of distributor (D) turns in a clockwise (right-hand) direction, so that it next will make contact with the stationary segment No. 2. As the engine fires 1, 3, 4, 2, the cable No. 2 should lead to No. 3 cylinder, No. 3 to No. 4 cylinder and cable No. 4 to No. 2 cylinder.

Re-Meshing Timing Gears

To assemble gears if removed (Fig. 11): Turn flywheel until Nos. 1 and 4 pistons are at top-dead-center, with No. 1 ready to fire (top of compression stroke). Key the crank-shaft gear (C) and cam-shaft gear (S) to shafts so that Fig. 1 on each will mesh. Then replace idler gear (I) so that Fig. 2 on it will mesh with Fig. 2 on the crank-shaft gear. Then mesh Fig. 3 on the magneto gear (M), with Fig. 3 on the idler gear.

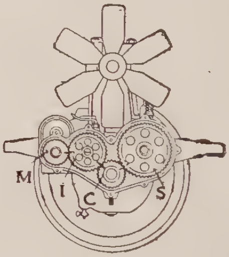

Fig. 11. Showing front view of engine.

Synchronizing Distributor with Armature

Synchronizing the interrupter points, cam, and distributor: If the magneto has been entirely disassembled, proceed as follows:

Bosch "DU4" as an example: (1) place the distributor brush on the segment—just starting; (2) place armature in direction of rotation 3/32" from pole shoe—just breaking; (3) breaker to start opening must be advanced.

Bosch "DU4," model 5: (1) place the brush in the center of the segment; (2) armature 1/16" from pole shoe; (3) breaker points will start to open at full retard.

Bosch dual system: (1) place the brush 1/16" on the segment; (2) armature breaks from pole 1/64"; (3) breaker points will separate at full advanced position.

K. W. High-Tension Magneto Circuit

This is the inductor type of magneto explained on page 246.

The rotor, with paddles (A) (B), revolves between the poles of the magnets (not shown here), and the magnetic lines-of-force pass through the rotor in the direction shown by the small arrows, then in the reverse direction, and so on.

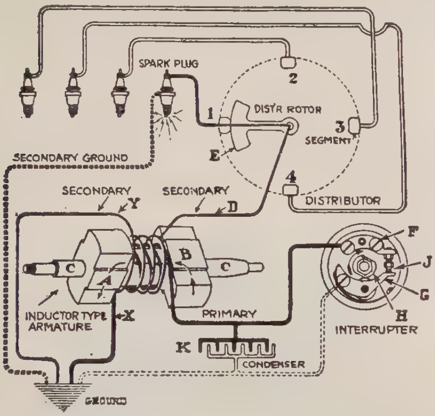

Fig. 12. Diagram of operation of the K-W magneto.

This reversing and moving of the magnetic lines causes current to be generated in the primary coil or winding (X). The current passes through the circuit-breaker arms (F) and (G) and through the metal of the engine (ground) back to the coil.

When this current in the coil (X) gets to the proper point, the cam on the end of the shaft (H) presses down the roller in the little arm (G) and pulls apart the breaker points (J), thus breaking the current in the primary circuit.

The stoppage of current in the primary coil (X) instantly causes a high-tension current to be induced in the secondary or outside coil (Y).

This high-tension current is carried up and delivered to the distributing arm (E).

This distributor arm (E) is for the purpose of distributing high tension to the different terminals 1, 2, 3, 4, which are in turn connected to the spark plugs in the cylinders in the order in which they fire. This arm (E) is so timed that it reaches one of these terminals just as the breaker points open in a primary circuit, that is, just as the high-tension current is being generated.

This distributor arm is shown delivering current through terminal No. 1 to spark plug No. 1, whence the current jumps across the gap to ground (that is through the metal of the engine), back to the end of the secondary coil.

SETTING TIME OF SPARK—MISCELLANEOUS IGNITION SYSTEMS

The timing of ignition is merely a procedure where the lever controlling the advance and retard of the spark is usually set retarded, advanced, or midway between full retard and full advance when the piston is either on top, before top, or after top of compression stroke.

In order to understand clearly the meaning of "advance and retard," see Figs. 1 and 2.

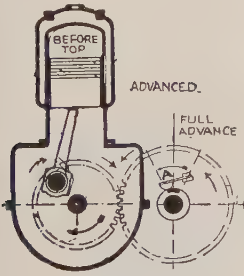

Fig. 1

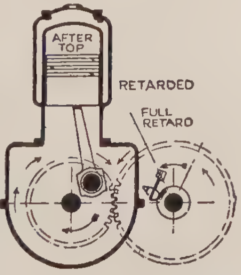

Fig. 2

The illustrations are exaggerated as to the actual distance at which the piston is placed before or after top of dead center. An **ignition commutator** is illustrated to explain the principle, but the principle applies to a magneto breaker-box, battery, and to a coil system of interrupter, or to any type of contact-breaker for an ignition system.

Note in Fig. 1 that the commutator arm (A) is at **full advanced position.** Thus the time of the spark, or when contact is made in this instance (contact would be broken if an interrupter was used instead of a commutator), would occur a considerable time before the piston was at top of its compression stroke. Thus the spark would occur at full advanced position.

Note in Fig. 2 that the commutator arm (A) is moved in the direction of rotation to a **full retarded position.** Therefore the contact would be made later than in Fig. 1, or retarded, or after the piston was over the top dead center of compression stroke and part of the way down on power stroke.

On a magneto or coil-and-battery system of ignition, the interrupter housing is advanced and retarded in the same manner, except that the points of the interrupter are made to open at a certain time instead of contact being made, as with a commutator.

Thus **the object of setting the ignition** is to set the contact-breaker so that the spark occurs either in an advanced position when (or before) the piston is on top of the compression stroke, or in a retarded position when piston is past the top of dead center of the compression stroke.

For instance, if the contact-breaker was set at full **retard position** when the piston was on top of its compression stroke, this would allow for a wide range of advance before top.

On many engines and ignition systems this practice is followed out, but on others, the contact-breaker housing is set at a **full advanced position** at a certain point before the piston is at the top of its compression stroke, as indicated by a mark on the fly wheel. For example, let us take the timing of ignition on the Studebaker "Light-six," using either a Wagner or Remy coil and battery ignition system. The instructions follow.

Timing the Spark on Studebaker "Light-Six" Coil and Battery Ignition System

This car uses an automatic and manual advance of the spark, and either the Wagner or Remy coil and battery ignition system is used.

Unless the engine has been completely overhauled, it will not ordinarily be necessary to readjust the timing of the spark. But if it has been necessary in making repairs to disturb the relation between the cam-shaft sprocket and the distributor shaft, the following instructions should be carefully followed.

Remove No. 1 spark plug and crank the engine by hand until the piston in No. 1 cylinder has begun its compression stroke. The beginning of the compression stroke may be detected by holding the thumb over the spark-plug hole until compression is felt.

The upper-dead-center position is indicated when mark "UP-D-C-1" on the fly wheel is opposite the pointed projection on the rear of the Bendix starter housing. Before this mark "UP-D-C-1" comes to the pointer you will notice a line marked "AD-SP" which indicates the manual advance spark position. When this line reaches the pointer, stop turning the engine and proceed as follows:

Place the spark lever at **full advance position.** The timer control lever should then be in its extreme forward position. Remove the distributor cover without disconnecting wires and lift off the revolving segment.

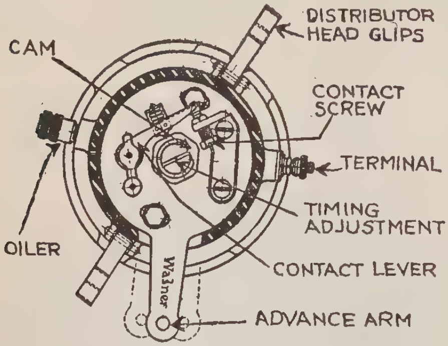

Fig. 3. Top view of the Wagner interrupter (Studebaker).

On cars with Wagner equipment, loosen the screw which holds the cam on the taper shaft. Pry the cam from its seat on the shaft, by using a screwdriver (Fig. 3). Turn the cam in a counter-clockwise direction, or to the left, until it reaches a position such that, when all parts are assembled, the edge of the revolving segment comes directly under the No. 1 distributor terminal and the breaker points are just in the act of breaking. Tighten the lock screw to hold the cam in this position and replace the revolving segment and distributor cover.

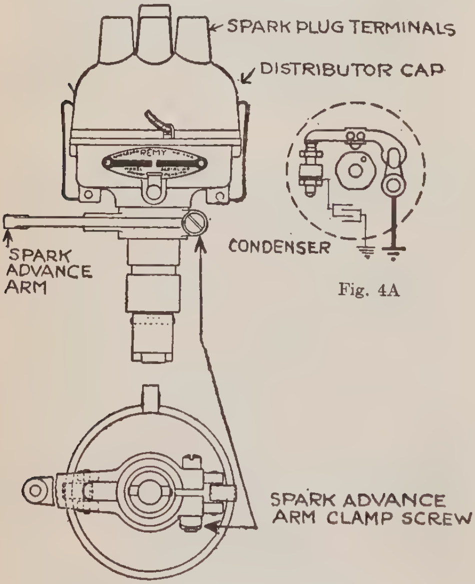

Fig. 4A

Fig. 4. Side view of the Remy interrupter and distributor.

Fig. 4A. Top view of Remy interrupter (contact-breaker) as used on the Studebaker.

To time spark on cars with Remy equipment get mark "AD-SP" opposite the pointer when No. 1 piston is coming up on compression and see that the distributor is assembled to drive so that the distributor segment will point directly to the rear. Then loosen clamp screw (Fig. 4) and make an accurate adjustment by rotating the distributor housing about the cam, with the advance arm at extreme forward position so that the points are just in the act of breaking the segment directly under No. 1 distributor terminal. Tighten the clamp screw to hold the housing in this position. Replace the revolving segment and distributor cover.

To test accuracy of adjustment, make sure that electrical connections from battery to coil and distributor are complete. Disconnect from the coil the high-tension cable leading to the center terminal of the distributor. Place the point of a wooden-handled screwdriver on a convenient part of the engine and have it held so that the metal part of the screwdriver is about ⅛" from the high-tension terminal of the coil. Fully advance the spark lever on the steering wheel and turn on the ignition switch. Crank the engine over slowly by hand until the spark jumps from the coil terminal to the screwdriver. The mark "AD-SP" should now be directly opposite the pointer.

The adjustment of the spark-control rod will govern the retarded adjustment. This should be adjusted so that it will move the distributor arm against the stop for advanced and retarded positions.

Timing the Spark on Mitchell "F"

The ignition system used on this six-cylinder model of car is the Remy. The instructions are as follows:

Ignition timing: With the circuit-breaker in full retard position, the circuit-breaker contact points should just start to separate or open when the engine is turned past dead center.

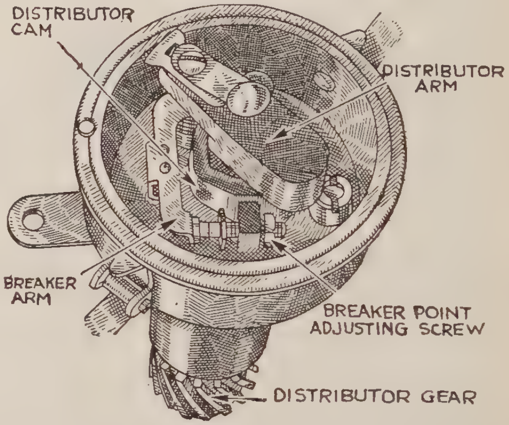

Fig. 5. Top view of Remy interrupter (contact-breaker) as used on the Mitchell "F".

If it should ever be necessary to retime the ignition distributor, proceed as follows: Open all compression cocks and turn the engine by hand till the intake valve of cylinder No. 1 (next to the radiator) opens and closes, and till the mark "D.C. 1-6" on the fly wheel is in top center position. When this has been done the piston of cylinder No. 1 is just starting down on its working stroke.

Next place the spark lever in **full retard position.** Remove the distributor segment by pulling it up off from the shaft, disclosing the nut that locks the cam. Unscrew and remove this nut. Loosen the cam from its snug fit on the taper of the shaft by prying up, rapping it at the same time. Use care not to mar the smooth surface of the cam.

Reset the cam by moving it in the direction in which it rotates until the circuit-breaker contact points just start to separate, and the cam is in such a position that when the segment and cap are replaced, the metal blade of the segment will be nearest the extension in the distributor cap connected to the spark plug in No. 1 cylinder. Rap the cam down in this position, and tighten the nut. The next distributor-cap terminal in a counter-clockwise direction from the terminal connected to cylinder No. 1 is to be connected to the spark plug of cylinder No. 5, the next to No. 3, the next to No. 6, the next to No. 2, and the next and last to No. 4.

Spark plugs: Failure of spark is sometimes due to the gap in the spark plug becoming clogged with carbon or oil. This gap should measure .022".

Too large a gap may cause missing on a hard pull or when accelerating at very low speeds. With **too small a gap,** the engine may operate unevenly at idling speeds and miss at higher speeds. With spark plugs having more than one gap, the shortest gap should be as stated.

Timing the Spark on Essex Model "A"

Timing the ignition: The ignition system is carefully timed when the car leaves the factory, and, under ordinary conditions, will not require any attention; but should it become necessary to re-time the ignition for any reason, it can be done as follows:

1. Place the spark lever on the steering-wheel sector in the **fully advanced position.**
2. Turn the engine with a hand crank until No. 1 piston starts to come up on the compression stroke. The marking of the fly wheel should then be observed through the hole in the fly-wheel housing on the right-hand side of the engine until the marking "D.C. 1-4" appears at the pointer on the fly-wheel housing.
3. Loosen the timing adjustment screw in the center of the distributor shaft and turn the breaker cam so that the rotor button will be in a position under No. 1 high-tension terminal, or that which leads to No. 1 cylinder, when the distributor

head is down in place. Locate the breaker cam carefully in this position so that when the slack in the distributor driving gears is rocked forward, the contacts will be opened by the breaker cam, and when the slack in the gears is rocked backwards, the contacts will just close.

4. Tighten the adjustment screw, securing and replacing the rotor and distributor head.

Adjusting spark plugs: The gauge on the distributor wrench marked "Spark Plug" should be used for adjusting the spark plugs. This gauge is approximately thirty thousandths of an inch thick (.030"). On spark plugs having more than one gap, all but one gap should be made very wide, and the closest gap should be adjusted to this gauge. An exceptionally wide **adjustment** may cause missing at the higher speeds. **Too close an adjustment** will cause the ignition to be very poor at very low speeds and when idling.

See Index for Delco ignition and Essex wiring diagrams.

On the Cole, "870 Series" car, using Delco ignition, the spark lever is fully advanced, and the piston is placed within 1½" of the top of the compression stroke.

Timing the Spark on the Maxwell "25"

This car uses type "CC" Atwater-Kent ignition system.

Procedure: Turn the crank shaft with a hand crank until No. 1 piston is 1/32" past top dead center, or 1¼" past on the fly wheel, on compression or firing stroke. Then turn the vertical shaft until the distributor arm is under the terminal on the cover leading to No. 1 cylinder. Assemble the unit to the engine.

Loosen the screw which locks the advance and retard on the timer to the timer head. Turn the timer head in whichever direction is necessary so that the points just start to open when the cam is revolved, in clockwise direction. Holding the timer head in this position, push advance and retard lever in the retard position, and tighten the lock screw. Replace the distributor cover and connect the terminals in proper firing order of the engine, viz., from left to right, or clockwise, No. 1, 3, 4, 2.

The breaker points should be set to open between .006" and .008", or about twice the thickness of this paper.

Timing the Spark on the Chevrolet "490"

Remove the distributor cover and the distributor arm, and with a special wrench supplied with the car, remove the lock nut holding the igniter cam to the shaft (Fig. 6); slip the hooked end of the wrench under the cam (Fig. 7) and pry it loose from the shaft (the igniter shaft is tapered and the cam is held to this taper by friction so that it should not require a great effort to loosen it).

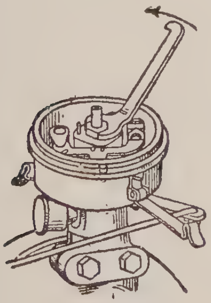

Fig. 6

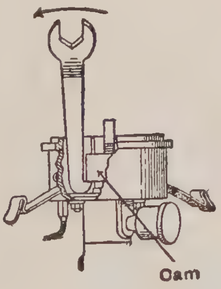

Fig. 7

Fig. 6. Remove lock nut.

Fig. 7. Slip hooked end of wrench under cam and loosen from tapered shaft as shown.

Insert the starting crank and turn until the intake valve on No. 1 cylinder begins to open; remove the spark plug on that cylinder and insert a screwdriver or rod; continue to turn the engine until the piston has traveled downward and has again returned to its uppermost position. By holding the screwdriver or rod firmly, the position of the piston at which no further upward movement takes place can readily be determined. The piston is then on "top dead center" of the compression stroke, and the gases have been compressed ready for firing.

Next turn the cam on the igniter, so that the driving pin assumes the position shown in Fig. 8, then turn the cam in the direction of the arrow until the two contact points begin to open. By the term "begin to open" we mean that point at which the two contact surfaces no longer touch each other.

The lock nut can then be slipped on the shaft and can be securely tightened against the cam; however, in doing this use care not to disturb the position of the cam. The distributor arm and cap can now be put in place and the car operated.

The sequence of firing is 1, 2, 4, 3, the No. 1 wire being the one immediately above the small slot on the edge of the distributor case. This slot fits over the locating pin on the rim of the igniter body. The rotation of the igniter is called "clockwise," that is, it turns in the same direction as the hands of a clock; therefore in the same direction will come the No. 2 wire, then No. 4, and lastly No. 3.

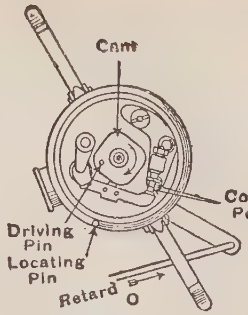

Fig. 8. Rotate the cam so that the driving pin assumes position shown. Retard the spark. Then turn the cam in the direction of the arrow until contact points begin to open when No. 1 cylinder is on top dead center of compression stroke. Replace the lock nut and tighten securely.

Timing the Spark on the Lexington Series "S" Model Six-Cylinder Engine

The Connecticut closed-circuit ignition system is used as an illustration.

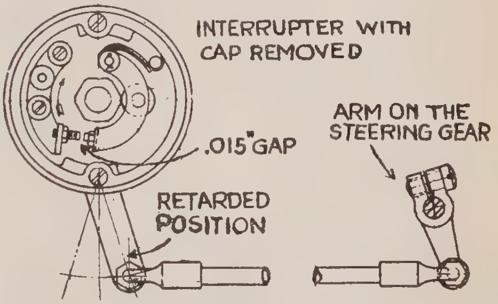

Fig. 9. Top view of the Connecticut interrupter (contact-breaker) as used on the Lexington "S."

To time the ignition, open the pet cock on No. 1 cylinder (next to the radiator), by means of the starting crank; turn the motor slowly until you get compression, determined by holding the finger on the pet cock. Be sure not to pass upper dead center. This is determined by the mark on the flywheel, "D, C-1 and 6," seen through the opening on the top flywheel housing exposing the pointer or indicator.

Retard the spark lever on the steering column fully (Fig. 9); remove the distributor cap; note the position of the breaker points. They should be just ready to open or separate. By advancing the spark lever on the steering column slightly, a spark should jump if the current is turned on.

Note that the spark is set to occur on top dead center of the compression stroke with the spark lever in full retarded position.

The breaker-point adjustment should be .015" air-gap when the cam separates the points fully.

The spark-plug point gap should be .020".

Other Ignition Timing Information

By referring to the Index for Delco, Atwater-Kent, Connecticut, Remy, and other systems of ignition, detailed explanations of each can be found, as well as of other cars.

See page 220 relative to the "Timing of Delco ignition."

Timing the Ignition of a Vibrator-Coil and Commutator Ignition System

Before passing from the subject of ignition timing, it is well to mention the timing of the high-tension vibrator-coil system, as also the "make-and-break" low-tension ignition.

The old-style coil ignition system, with "vibrators" and "commutators," requires a greater advance than magneto ignition. The reason for this is the time required for contact of the commutator, contact of the vibrator, and a possible loss of time for the vibrator to start operating.

Owing to the lag and inertia of a coil trembler, **considerable range of advance is required** to obtain the spark at the most effective position of the piston.

The usual method is to **place the spark lever midway between advance and retard** position, so that it will have half of the motion to advance on, and half to retard on (see Fig. 10).

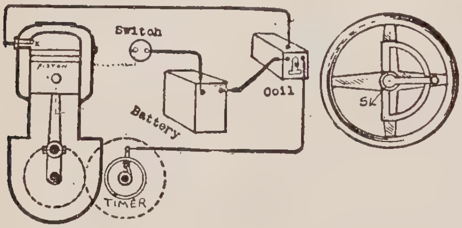

Fig. 10. (1) place piston on top of compression stroke; (2) place spark lever in center position of quadrant (SL); (3) set contact on commutator so that it will make contact with No. 1 cylinder. This will allow for a range of advance and retard in either direction from the center.

Timing Ignition of the Ford

The Ford ignition timing is explained in the Ford instruction.

Timing "Make-and-Break" Ignition

Timing the low-tension magneto[1], with make-and-break type of igniter: The armature of the magneto must be positively driven off the engine by means of a chain or of gear wheels. On engines with cranks at 180°, where the ignition has to take place at 90° relative to the cam shaft, the armature has to be driven at crank-shaft speed.

In the low-tension "make-and-break" system, the contact-breaker is not fitted on the magneto; a connection from the outer end of the armature winding joins up to the terminal of the hammer-break device inside the cylinder.

The general practice, when timing (see Fig. 11), is to arrange for the mechanism of the break to "trip" when the piston is just completing the compression stroke, or a little earlier, say ⅛" (or an amount determined by experiment to give the best results), the armature being, as in the case of the high-tension system, in "maximum" position.

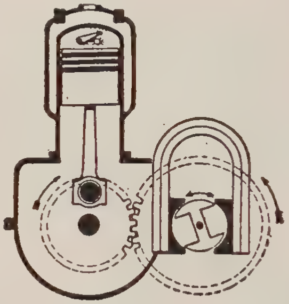

Fig. 11. Illustrates the principle of timing a low-tension magneto using a "make-and-break" ignition. The armature is in one of the maximum positions just as the piston is completing the compression stroke, and the "break" or "igniter" mechanism has just tripped or broken the circuit. This system is seldom used.

SPARK CONTROL AND OVERHEATING

As few motorists really understand just how the power efficiency of an engine is affected by the spark timing (which is generally under the control of the operator), the following may be of interest:

When a combustible mixture has been compressed in a cylinder by the rising piston, and the spark occurs, a very small portion of the mixture in the immediate vicinity of the spark is ignited; and if the mixture is of the proper proportions and suitably compressed, the flame propagation throughout the entire combustion chamber will be rapid.

This is as it should be. When combustion takes place, intensely heated gases are formed, which in their effort to occupy a larger volume of space exert great pressure on the walls of the combustion chamber and upon the piston head.

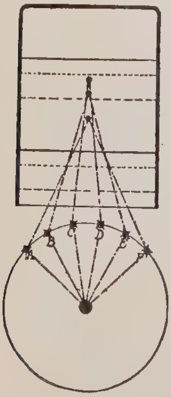

Fig. 1

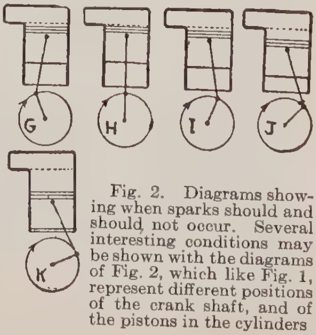

Fig. 2. Diagrams showing when sparks should and should not occur. Several interesting conditions may be shown with the diagrams of Fig. 2, which like Fig. 1, represent different positions of the crank shaft, and of the pistons in the cylinders

As a gas or gaseous mixture is compressed, it becomes heated, and the greater the pressure, the greater the heat.

If a mixture is of proper proportions, the greater the pressure, the more readily will it ignite, and the greater the speed of flame propagation or combustion.

On the other hand, as the pressure of a combustible mixture is reduced, it loses its heat, and its speed of ignition and combustion is also reduced.

Thus it must be understood that to get the utmost efficiency out of a combustible charge **it must be ignited at or near the point of maximum compression.**

Let it be assumed that a car is being driven at a speed of about 30 miles per hour, and that the engine is necessarily turning over at a speed of about 1,200 revolutions per minute, with the spark lever advanced so that sparks occur when the piston is ascending as at (G) (Figs. 1 and 2).

Ignition, we will assume, is complete at (**H**), and combustion at (I), at which point the maximum pressure of the expanding gases is being exerted. Under these conditions the engine runs smoothly and cool.

Now, by retarding the spark and advancing the throttle lever, it is found that the speed of 30 miles an hour can still be maintained.

The engine is generating the same amount of power, but with the spark retarded and the throttle advanced; but after about 30 minutes' running the radiator begins to steam, and we see that the engine is overheated. What is the cause?

---

[1] When setting the time of the spark on a **stationary engine,** the spark is set to occur, when retarded, slightly after the compression stroke to prevent kicking back. This type of engine is usually equipped with a "make-and-break" igniter system.

It is this: The spark is retarded, so that now it occurs when the piston is at (I); compression is already reduced, so that ignition is slower and is not complete until the piston is at (J), and combustion is still incomplete at (**K**).

The explosive mixture is now richer in fuel, so that more heat is given off than under the first-mentioned condition; therefore the expansive force is greater than before, so that the speed of the engine is the same. But note the area of wall surface of the cylinder at (**K**), which now is exposed to this more intense heat.

The water in the jackets has not only to take care of the heat absorbed by the walls of the combustion chamber, but also of an excessive amount absorbed by the cylinder walls.

Range of Spark Advance and Retard

Fig. 1 is a diagram showing the range of spark advance and retard, representing different positions of a crank shaft and the relation of the piston in the cylinder at these different positions.

Referring to this diagram, we find that if an engine is running at an extremely high rate of speed the spark might be advanced so as to occur in the cylinder when the throw of the crank shaft is ascending and at the point (**A**); thus combustion might be complete or so nearly complete, by the time the throw reached the point (**D**), that a very strong pressure would be exerted upon the piston, which is as it should be.

If the engine were being subjected to an extremely hard pull, as in ascending a hill on high gear, so that its speed is considerably reduced, and ignition were to take place at (**A**), combustion might be complete at (**B**) or (**C**), and the pressure or power-impulse on the piston head would tend to turn the crank shaft in a reverse direction.

If the car were traveling at a very low speed, or if there were not sufficient momentum in the flywheel or the car itself, the engine would be stalled, or killed, as the expression is.

Of course, if the car or engine were traveling at a sufficiently high rate of speed to carry the crank and piston over this dead center, a large percentage of the power would be applied in the right direction, but considerable would nevertheless be lost; there would be what is known as an "ignition knock," and the strain on the bearings would be quite severe.

On the other hand, if the engine has been slowed down considerably under a hard pull and the ignition is retarded so as to occur at about (**C**) or (**D**), combustion might be complete at about (**E**) or (**F**), or perhaps even a little farther down where the leverage on the crank shaft is greatest, and thus the greatest amount of the downward pressure on the piston is utilized.

It must be remembered that the greatest power is dependent upon the momentum or torque of the flywheel.

An engine always should be run with the spark advanced as far as possible without causing it to knock or lose power, and it will overheat if caused to run for any great length of time with a retarded spark.

Verifying the Ignition Timing

It occasionally happens that cars turned out of the factory hurriedly, to meet pressure of orders, are not as well adjusted in the setting of the ignition timing as they might be, with the result that the car may fail to idle properly, due to the setting being slightly too far advanced when the contact-breaker is retarded.

On magneto ignition it was a common practice to set for either "slow idling," or "for speed" or just between. In other words, if slow idling was desired, then extreme high speed was sacrificed. On the other hand, if very high speed was desired, the engine would not idle properly. Thus an average setting was made by meshing the timing gears driving the magneto.

Testing Ignition Advance

If the ignition is suspected of being set too far advanced, and idling speed is desired, then test as follows:

(1) Place No. 1 piston on top of compression, or its firing stroke. This can be found by following out the wires and noting when the cylinder to be tested will fire.

(2) Place breaker-box in "retarded" position.

(3) Note if the contact-points are just separating when the piston is on top. If so, the setting is about right for the magneto.

If, however, the points have already separated, then it is likely there is too much "advance," the amount being determined by the distance the spark occurred before top.

If a vibrator coil system, then the contact on the segment ought to be made when the piston is, say, ⅛" over the top of compression stroke with retard-spark lever.

If a change is made in the setting, then a trial should be made with the engine running, and a note should be made as to how the speed responds to the advance-and-retard movement. Variation in the setting should be made if found necessary.

QUESTIONS AND ANSWERS RELATIVE TO THE ADVANCE AND RETARD OF SPARK, EXPLAINING WHY THE ADVANCE OF SPARK INCREASES THE SPEED OF ENGINE

Question 1: How can the spark be made to vary as to the time at which it takes place?

Answer: By movement of the hand-spark lever on the steerng wheel, as in Fig. 4, page 287, which connects with the circuit-breaker housing on the magneto, or, if a coil and battery system, by connection with the advance arm of the interrupter housing and distributor (Figs. 3 and 4, page 302).

Movement of the interrupter housing in the direction of rotation of the cam causes the break to occur later, or retarded; movement in the opposite direction to that of rotation causes the spark to occur earlier, or advanced. See also Figs. 3 and 4 on this page, showing a commutator as used on a vibrator-coil ignition system.

Note in Fig. 3 that the contact arm (instead of a cam) is moved in the direction of rotation of the rotating segment with which it makes contact; thus, the spark occurs late. In Fig. 4,

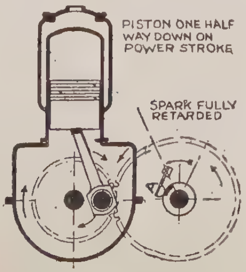

Fig. 3

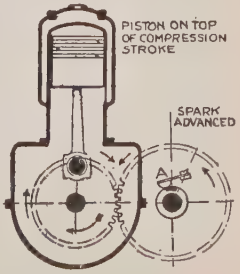

Fig. 4

the arm is shown moved back, or in the opposite direction to that of the rotation of the segment; therefore the spark will occur earlier.

Where an automatic advance of the spark is provided, as explained on page 203, the same action takes place but by means of a governor instead of by the hand-spark lever.

Question 2: Suppose the throttle is open, and the engine is speeded up, and the spark lever is not advanced but left at full retard position, what happens?

Answer: The gas would not be compressed as tight because the piston would be part way down on its power stroke, as seen in Fig. 3, with the result that there would be very little force exerted on the head of the piston. The engine would waste part of its power stroke and would not be as powerful as if the spark was properly timed or advanced. Excessive heat would also result, because the gas would continue to burn, not only during the rest of the power stroke, but also during a part of the exhaust stroke. For instance, with a retarded spark and an opened throttle, if the exhaust manifold was removed, a long red flame would be emitted from the exhaust ports; whereas, if the spark was properly advanced, there should be no flame at all, as the gas is supposed to ignite and cool before it passes through the exhaust valves. When running with a retarded spark a greater throttle opening is needed to develop the same power or speed. Thus a retarded spark generates greater heat and greater gasoline consumption.

Question 3: Why does advancing the time for the spark to occur increase the speed of the engine? For instance, suppose the engine is running with a certain throttle opening and the spark is advanced, the speed of the engine increases. Why is this?

Answer: The reason why **the advance of the spark causes an increase of speed** in the engine with the throttle open is principally the fact that when the spark is retarded, the power stroke is much shorter. In other words, suppose that the piston is half-way down on power stroke before the retarded spark occurs, as in Fig. 3. Note that when it sparks the gas at this position, the space between the head of the piston and the head of the combustion chamber is so great that there is not much force exerted on the head of the piston when the spark occurs; whereas, if the spark occurs advanced, or when the piston is near the top of the compression stroke, as in Fig. 4, the compression of gas is greater, and hence greater force is exerted on the head of the piston when the spark occurs advanced. Consequently more speed results.

In other words, with a retarded spark the piston travels well down on its power stroke without doing any work, whereas, with an advanced spark the piston works all the way down.

Question 4: What occurs if the spark is advanced when the engine runs slowly?

Answer: There will then be a fierce struggle inside the engine: the piston fighting to complete the compression stroke, and the explosion, which has occurred too soon, trying to force it back again. And which wins? If the engine is working fairly briskly, the piston overcomes the explosion; otherwise the explosion drives back the piston, and stops the engine. This is why, when an engine is cranked, it frequently "kicks back"; the spark has been advanced too far, and the piston can not overcome the early explosion. In order words, the spark occurs and combustion takes place before the piston reaches the top of stroke. Fig. 4 shows the spark advanced so that it occurs on the top of the stroke. It is not full advanced; if it were, the spark would occur before the piston reached the top. See pages 291 and 292.

Question 5: How can I tell when the spark is too much advanced?

Answer: There will be a sound in the engine as of a hammer striking the top of the piston. The engine will be said to "knock;" and the more the spark is advanced, the louder will be the knock. This is termed an "ignition," or "spark knock."

Question 6: And what should make it knock? Does the piston strike the top of cylinder?

Answer: We have already pointed out that this is impossible, as the length of the stroke is invariable; neither does it appear that it is caused by a general looseness throughout the parts of the engine, since new engines knock in this instance as much as old ones.

The ignition knock thus produced is caused by a "piston slap." When the piston is going up on the compression stroke, it is riding hard against one side of the cylinder, and as it passes over dead center the piston jumps to the other side of the cylinder wall, owing to the compression pressure, or compressed charge, which would be from 62 to 125 lbs. to the square inch. Such a charge would produce no noise in an engine with properly fitted pistons. However, if this compressed charge should be ignited considerably before top dead center, by the time top dead center was reached, which is the position where the piston "slaps," or is transferred from one wall of the cylinder to the opposite wall, the pressure would probably be 300 lbs. or 400 lbs. to the square inch, which would cause a very decided noise in the piston. See page 292 explaining the relation of the speed of the engine to the spark.

An engine should not be slowed by retarding the spark. If it has been noticed by the reader during the last few paragraphs that it is possible to slow an engine by retarding the spark, let him at once understand that this is the last method by which it ought ever to be done. It is not only unscientific, but is also wasteful of fuel, causes unnecessary work for the engine, and results in rapid pitting of the exhaust valves, the gases passing through them in an incandescent form. Engines even of the same make may vary as to the exact position of the spark lever. Thus the best plan is to experiment as to what position of spark makes the engine run best.

The correct method of slowing down or increasing the engine speed is to shut or open the throttle valve, which is situated between the carburetor and the inlet valve, by which the amount of fuel supplied to the engine may be regulated (see Fig. 11, page 33). Then as the engine varies its speed slower or faster, the spark should be retarded or advanced accordingly.

The rule therefore is to **let the engine speed follow the throttle and make the spark follow the engine speed;** or, to put it in another way, in order to drive economically, keep the throttle valve closed as much as possible and the spark advanced as far as possible, short of knocking or of a tendency to knock.

Retarding the spark too much produces heat. See page 304: "Spark control and overheating."

AVERAGE ADJUSTMENT OF LEADING IGNITION SYSTEMS. INTERRUPTER AND SPARK-PLUG CLEARANCE

MAKE OF IGNITION SYSTEM	MODEL OF IGNITION SYSTEM	CLEARANCE INTERRUPTER	TIMING POSITION	SPARK PLUG GAP

Ford	**Clearance between magnets and magneto coils. .031 or 1/32"**			1/32"

The air-gap clearances and position in which to place the spark lever (advanced or retarded), given on the left may vary on different engines and with different models or types of ignition systems or magnetos, as made by the different manufacturers mentioned. But in the absence of definite instructions by the manufacturer, the clearances and position of the spark lever are near enough to produce fairly good results. See page 220 for Delco average timing instructions; and page 208 for Remy instructions.

Average ignition timing: After placing the piston on top and retarding the timer housing, the interrupter points should just be opening, if a "closed-circuit" type of timer, or just closing if an "open-circuit" type of timer. It is difficult to see this; therefore a good plan is to use a 6-volt lamp in the low-tension circuit (between battery and timer). In this way one can tell when the circuit is closed or opened at the timer points, by the light going out or on (see page 221). See Index for Atwater-Kent, Connecticut, Remy, and Delco timing instructions.

---

†On 4, 6, and 12-cylinder engines the spark-plug gap is .025" and 8-cylinder engines .020". On 4, 6, and 8-cylinder engines place the piston 1/16" before top with interrupter retarded. On 12-cylinder engines place the piston on top with the interrupter retarded.

†† Eisemann new-style spring contact breaker requires .012"; others .016".

T, means to place piston at top of stroke.

R, means interrupter is retarded.

**NU4 Bosch spark-plug gap is .016".

FINDING POSITION OF PISTON

In the preceding pages we have discussed placing the piston on top of the compression stroke. How to tell when the piston is on top of the compression stroke is explained on page 70, but the following pointers will no doubt be of interest.

There are two possible firing orders on a four-cylinder engine, that is 1, 2, 4, 3, and 1, 3, 4, 2. In either case, cylinders 1 and 4 fire one revolution or half a cycle apart, so that at the instant that No. 1 cylinder needs the spark, the exhaust valve of No. 4 cylinder is just closing.

Refer to Fig. 1, and note that the cylinders are numbered, beginning at the radiator. The last valve away from the radiator is usually the No. 4 exhaust valve. In order to tell when it just closes, it is well to slide a piece of paper (P) between the valve stem and the tappet or push rod, and then to crank the engine over by hand, until the tappet is seen to rise and pinch the paper and lift the valve.

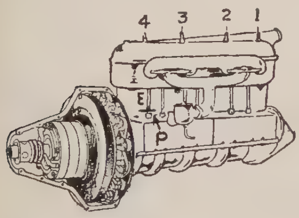

Fig. 1

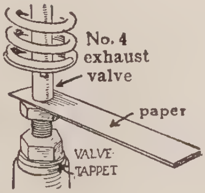

Fig. 1A

Continue to crank the engine, with one hand held on the piece of paper. At the instant that the paper **just gets loose, the spark for No. 1 cylinder should occur.**

In magnetos and most battery systems this will be the instant at which the interrupter points just begin to open, and in a Ford system using vibrating coils it will be the instant at which the timer just begins to make contact (see the Ford instruction or the discussion of "Valve timing"), which can most easily be determined by the use of batteries, and by listening for the first buzz of the coil.

In six-cylinder engines there are two common firing orders, as follows: 1, 5, 3, 6, 2, 4, and 1, 4, 2, 6, 3, 5; in each of these it will be noticed that cylinders No. 1 and No. 6 are half a cycle apart, just as No. 1 and No. 4 were half a cycle apart in the four-cylinder engine. We can then use the same rule for the six-cylinder engine as for the four, except that we look at the No. 6 exhaust valve, which is still the last valve down the line, the one farthest from the radiator.

It sometimes happens that the valves are inaccessible, as, for instance, in a sleeve-valve engine, in which case it is necessary to check by the compression, in order to get the proper top dead-center position, and then to check the exact piston position by feeling with a piece of wire inserted at the spark-plug opening.

If the firing order is not known, it can be determined by the order in which the valves lift or by opening the pet cocks and putting wads of paper in them. If the engine is now cranked by hand, the wads will blow out in the same order in which the engine fires.

To determine the end of the compression stroke, in any cylinder (Overland is taken as an example): turn the crank until the exhaust valve in that cylinder, which is the one directly beneath the priming cup, has just reached its seat; and then turn the flywheel approximately one revolution, stopping when the mark "1-4 UP" (or "2-3 UP") is at its highest position and in line with the guide mark on the back end of the crank case. Another method is to turn the engine while the hand is held over the open priming cup and identify the compression stroke by the escape of air. See also Index under "Finding position of piston."

INSTRUCTION No. 29

CARE AND REPAIR OF THE MAGNETO

Care of the Magneto

Distributor parts: The distributor plate should be removed occasionally for inspection as to the presence of the carbon dust that wears off from the carbon brushes. This dust may form a connection between the distributor segments, and as a consequence may cause a spark to occur in the wrong cylinder. Carbon dust that has collected on the distributor should be wiped out with a cloth, the cloth being moistened with gasoline in case the carbon has become caked. After cleaning with gasoline, the inside of the plate should be given a very light film of oil to prevent excessive wear of the brush and the distributor plate.

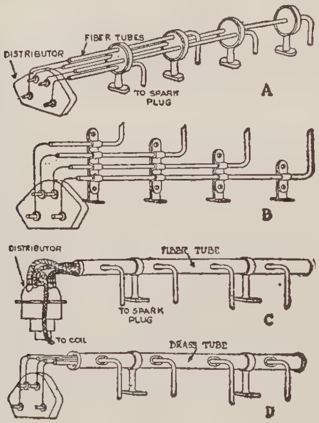

Fig. 1. **A**, method by which the wires can be separated from one another to avoid static effects; **B**, another method of separating wires to avoid static effects; **C**, with this arrangement static effects are sometimes felt; **D**, running wires through brass tubing does not avoid static effects.

Cables: Use only the best insulated wire for all electrical connections and especially those leading to the plugs. The wires running from the distributor to the spark plug are called secondary cables, and should be protected from static[1] electricity. (See Fig. 1; **A** and **B** are best arrangements.)

Terminals: Scrape off about 3/16″ of the insulation from both ends of the cable; clean the copper wire, and screw it into the tube of the terminal (it will not do to push it in only), in order to connect the two parts thoroughly. Spread out inside the tube the portion of the wire which has been stripped of its insulation, and screw in the little screw supplied for the purpose.

Many a case of ignition trouble has been hard to locate due solely to one of the strands of wire short-circuiting. Therefore, if special connections are provided, use them; otherwise solder the ends.

Interrupter Adjustments

Among the most important parts of the magneto is the interrupter and it is advisable to inspect it from time to time. An inspection of the interrupter requires the removal of the cover which is usually secured to the interrupter housing by means of a spring ring that permits it to be snapped on and off. The interrupter lever should be moved for assurance that it is free on its pivot, and a test should be made of the distance between the platinum points.

Adjustment: When the lever is depressed by one of the steel segments or the cam, the distance between the platinum points should be about .015″ to .020″ or about 1/64″. This distance may usually be adjusted by the movement of a platinum-pointed screw.

Should it be necessary to replace one of the platinum points, or to attach a spare part, the interrupter may be more completely exposed by turning the lock ring a quarter of a turn to the right or to the left, and removing it and the interrupter housing. The interrupter itself may be removed by unscrewing the interrupter screw.

When replacing the interrupter, care must be taken that the key on the interrupter disk fits exactly into the keyway on the armature shaft, and care must also be exercised when replacing the interrupter housing, to make sure that it is placed back in exactly the same position as it was in when it was taken off.

The platinum points on the interrupter "pit" in time, but not so badly as the points on a vibrator coil. The alternating current of a magneto does not cause pitting of the points as much as the direct current. However, in time the points are bound to become worn and new ones must be fitted, or the old ones dressed down. (See Index under "Dressing platinum points.")

A defective condenser will cause excess sparking at the interrupter points. See Index under "Condenser."

The Safety Spark Gap

In order to protect the insulation of the armature and all other parts from injury due to excessive voltage, a safety spark gap is provided, to permit the passage of the current to ground without injury. The current will pass across the safety spark gap in case a high-tension cable is disconnected, if the spark gap is too great, or if for any other reason the spark-plug circuit is open. Discharge should not be permitted to pass through the safety spark gap for any great length of time, however. This should be particularly guarded against if the engine is operated on a second or auxiliary ignition system. When the engine is operated on such a system, the magneto should be grounded in order to prevent the production of high-voltage current. See Index under "Safety spark gap."

---

[1] Static electrical discharge means jumping of high-tension current from one wire to another when the wires are together, even though fairly well insulated.

Oiling the Magneto

The over-oiling of the magneto should be guarded against in order to prevent the entrance of oil to the interrupter parts. Each of the oil holes is to be given a few drops of fine machine oil every two weeks, or every 1,000 miles. The interrupter is designed to work without lubrication, and the presence of oil on the platinum points will give unsatisfactory results, inasmuch as it will cause sparking at the points and possible misfiring.

Vaseline is suitable for lubricating the ball bearings, but never use oil on the interrupter in such a manner as to permit it to reach the platinum points.

Cutting Off the Magneto Ignition

To cut off the ignition, the **primary current must be "grounded,"** which will prevent the breaking of the circuit by the opening of the interrupter, and consequently prevent the production of the secondary current. The primary current may be grounded by making a connection between the grounding nut and the engine ground, this circuit usually including a switch. One terminal of the switch is connected to the engine or frame, the other terminal leading to the grounding terminal. When the switch is open the magneto will produce a spark, but the closing of the switch will ground the primary circuit and will prevent the production of the ignition spark.

MAGNETO IGNITION TROUBLES

In case of defective ignition it must be determined whether the fault is in the magneto or in the plugs. Generally, when only one cylinder misses, the fault is in the plug.

Defects of Spark Plugs

(1) **Short-circuit at the spark gap,** due to small metallic beads which are melted by the heat of the intense spark and form a conducting connection between the electrodes. This defect is easily ascertained, and may be remedied by removing the metallic beads.

(2) **If the gap between the spark-plug electrodes (point) is too great,** the spark will jump across the safety gap on the magneto. In such a case, when the plug is unscrewed from the cylinder the spark will jump across the electrodes of the plug, and not across the safety spark gap. This does not signify that the distance between the electrodes is correct, for it must be borne in mind that open air has a lower resistance than the compressed air or gas existing in an engine cylinder. The distance between the electrodes when under compression in the cylinders must, therefore, be less than is required in the open air. The correct gap should be approximately 1/64″ or .020″.

(3) **Fouling of the plug:** If fouling should occur, the parts exposed to the burning gases may very readily be cleaned by removing the plugs from the cylinder. This exposes the plug core, and it may be cleaned with gasoline.

The spark plug used with a magneto should have the point set closer than with a battery and coil ignition, because, when the magneto runs slow, the current is not as strong as when running fast. With a battery as a source of supply, the current is constant at all times.

The spark-plug cables must be tested, and special attention should be paid to ascertaining that the insulation is not injured in any way. The metal terminals of the cables must not come in contact with any metal parts of the engine or with any metal parts of the magneto, except the proper binding posts.

Diagnosing Magneto Troubles

(1) Engine balks—no spark.

(2) Misses at low speeds.

(3) Misses at high speeds.

(1) **Engine balking** may be due to broken connections, short-circuit in primary circuit, or between coil and distributor brush. Timing may be wrong or breaker points too far apart.

(2) **Missing at low speeds** may be due to spark-plug gaps too far apart, or too close; breaker points too far apart; loose connections or short-circuits; weak magnets.

(3) **Missing at high speeds** may be due to breaker points set too close; breaker arm not working freely, loose connections, or short circuit.

If ignition fails suddenly: A sudden failure of ignition **indicates a short-circuit** in the low-tension cable, either through a defect in the cable, through a faulty connection of the switch, or through the presence of dirt or moisture. This may be tested by removing the grounding cable from the binding post on the magneto and endeavoring to start the engine on the magneto. If the engine runs with this wire disconnected, but stops when the wire is connected, it may be taken for granted that there is a fault in the insulation or some other defect through which the low-tension current escapes to "ground." It is also advisable to examine the carbon distributor brush to ascertain if it is in good condition. This brush may be exposed by removing the distributor plate.

Irregular firing: Irregular firing is usually caused by the **improper working of the interrupter,** and this part should be examined. It should be seen to that the interrupter lever moves freely on its pivot, and that the center screw is properly tightened; see also that the steel segments or cams, as well as the two platinum screws, are properly secured in position. Furthermore, the platinum points should be inspected for the correctness of their adjustment, and they should be so set that they are about 1/64″ apart when the interrupter lever is depressed by one of the segments. The platinum points should be clean, flat, and true to one another, and any oil, grease, or dirt that is deposited on them should be removed. If they are uneven or in bad condition—but only then— they should be trued by means of a fine flat file. If the interrupter lever does not move freely on its pivot (as is occasionally the case, particularly with new magnetos), the hole through the fiber bushing that forms the bearing should be reamed out. This work should be very carefully performed, however, and excessive reaming must be guarded against.

Starting the engine: To start the engine it is sufficient to give a sudden pull to the starting handle at the moment when a spark is to take place in one of the cylinders. If the engine does not start off at once, this may be caused by either or all of the following: (1) by the setting not being done in a proper way; (2) by the points of the plugs being too far apart; (3) by the cables being faulty, or the connections being badly made. Very often the carburetion is faulty.

In any case, care should be taken, when stopping the engine, to short-circuit the magneto, and to cut off the supply of gasoline (by closing throttle) when the engine has ceased running. In this way the cylinders are prevented from being filled with air. If the cylinders contain gasoline, the starting of the engine is always easy. If on the contrary, the supply of gasoline (throttle) is cut off while the engine is running, the cylinders get filled with air, and on restarting it has to be driven out and replaced by gasoline.

Coil: If on turning the magneto no high-tension current is produced, it may be that the coil is damaged (this applies to a low-tension magneto with a separate coil, or with the secondary winding on the high-tension armature), and should be returned to manufacturers in order to have it repaired or replaced.

Magnets: Remagnetizing will not be necessary unless the magnets have lost their magnetism through having been taken off and left, for a long period, without their bases having first been bridged by a piece of iron; or unless, before taking out the armature, no piece of iron or steel has been placed on the pole pieces. This piece of iron or steel should remain there until the armature is replaced. It often happens that on remounting the magnets, a mistake is made in placing them in the wrong order, whereby their magnetic power is completely neutralized.

When it becomes necessary to take the magneto apart, you will do well to draw a chalk line across one side of all the magnets. Be careful that the same marks stamped on the magnets appear all on the same side. All north poles are to be replaced on one side, and all south poles on the other.

Difficult starting is in many cases caused by the fact that upon stopping the engine, the supply of gasoline is cut off, while the ignition only should be stopped. In this way the cylinders are filled with air only, without any gasoline, and no explosions are possible. After opening the throttle about one-quarter of the way, draw in a "mixture" of air and gas; then the engine will start.

By cutting out the ignition only, there will be gasoline vapor in the cylinders instead of air, and the engine can be set in motion by a half-turn of the starting handle, i.e., by a sudden pull at the moment of highest compression.

Springs: Examine from time to time whether the safety contact spring sliding in front of the cam presses sufficiently against the cam; as soon as the steel bosses are rather worn, the spring should be replaced by a new one. By putting some oil now and then upon the steel parts, too rapid wear will be prevented.

Carbon brushes: The low-tension carbon brush, as well as the high-tension distributor, will wear off in the course of time and have to be replaced by new ones, i.e., in the first case, as soon as the spring presses down on the metal holder of the carbon, and in the second, as soon as the spring of the carbon comes out of its case.

When the magneto armature rubs against the pole-piece, it is probably due to worn bearings or to a broken ball, to loose screws on the armature head, or to gears meshed tight causing undue wear on one end of the shaft.

Magneto Trouble Indications—Condensed

Failure of magneto to give the proper spark may be due to:

Armature: weak current; open primary; open secondary; shorted primary or secondary.

Condenser: short-circuited; open circuit (see Index).

High-tension circuit: brush on collector spool cracked or punctured; loose connection to collector spool; defective distributor brush.

Spark plugs: improper gap; fouled.

Magnets: weak; reversed.

Contact breaker: points worn; points too close or too far apart; weak spring.

Assembly: gear bearing worn or dry; armature rubbing on pole pieces and end play in armature, due to loose screws in armature head or worn bearings.

Procedure of Diagnosis

If missing continues to occur and the cause cannot be located, then **begin the diagnosis as follows;** being sure that the—

(1) Spark-plug gaps are correct—about .020″ gap.
(2) Magnets are not weak.
(3) Interrupter points are clean and the correct distance apart—about 1/64″.
(4) Connections from magneto and switch are tight.
(5) Magneto is properly set.
(6) Carburetor adjustment is correct.
(7) Armature is in perfect alignment.

Determine whether missing occurs when running slow or fast.

First Determine if Trouble Is Due to Magneto

This should be done by first **running the engine on the battery and coil system of ignition;** then switch on to the magneto side. If the engine begins to miss, yet runs on the battery side, this will indicate that the trouble is in the magneto.

Quite often, however, this test is made when the engine is running slow. If the engine misses only on slow speed, try setting the plug points closer together and adjust the interrupter or clean the interrupter points. Look for a loose wire or strand of wire short-circuiting. If everything else, including carburetion, is apparently in proper order, and the engine runs on the coil and battery, but misses on the magneto, then the trouble is likely to be due to weak magnets or to punctured or short-circuited insulation.

Before deciding that it is the magneto winding giving the trouble, be sure magnets are strong. See test below, and **test the magneto,** as directed in pages 311 to 315.

To Test Magneto on Engine

First test to find out **which cylinders are missing,** as directed on page 238. If all miss, then the trouble is probably in the magneto or the carburetion. If missing is found in one regularly, the trouble is then probably due to the spark plug or wiring.

Run the engine slowly; advance and retard the spark; note if there is any missing; **then speed the engine up** and advance and retard, and notice if there is still any missing. This will enable you to determine if missing is on low or high speed.

If the engine is running and the spark jumps ⅜″, and is blue and has volume, and spreads when blowing on it, then it is not likely that the magneto winding is defective. If it will not jump this far regularly, and is thin and yellow, and the cause is not elsewhere, then test the armature winding, as directed on pages 313, 314.

Note. The magneto could continue to give a weak spark, even though the winding was defective, as only part of the winding may be cut out.

MAGNETO MAGNETS AND REMAGNETIZING

Magnets Made of Steel

The magnets used on both low and high-tension machines are of special tungsten steel made as hard as it is possible to obtain them, so hard that a sharp file cannot make any impression on the metal. Much depends on the class of steel used—a special grade known as magnet steel is now being adopted. The retention of magnetism by steel is a very curious and interesting property. It resides only on the surface of the steel and it is found that a much stronger magnet is obtained, weight for weight, by making it in sections, one placed over the other, than in using a massive single magnet. Magnetos have two magnets placed side by side; some have a single large magnet—they were formerly two—made of superimposed parts.

Soft steel is easier to magnetize than hard steel, but the former loses its magnetization quickly if subjected to vibration. The hard steel magnet loses its magnetism very slowly, although the magneto has, as a matter of course, to withstand much vibration from the engine, etc.

Weak Magnets

After the magneto has been in use for approximately two years, the magnets may have become weakened. The length of time a magneto retains its magnetism is governed by the quality of steel used in the magnets.

Misfiring will be the result of weak magnets. There are other conditions, however, to determine before blaming the magnets. For instance, the missing may occur from spark-plug points not being set equal distances apart.

The best remedy for trouble from this source is obtained by having the magnets of the magneto recharged; but temporary relief often may be obtained by adjusting the points of the spark plugs so that all are brought a little closer together, and all equally distant apart; that is, the gap between the points should be the same on all plugs. If the gaps are not all the same, then the plug with the widest gap generally will be the first to misfire, as a result of weak magnets.

When running a car slowly on the high-speed gear, the engine may be turning over so slowly that the magneto will not generate the required current and misfiring accompanied by a jerky action of the car will take place. When this occurs, one should either shift to a lower gear, or switch over to the battery. The better plan is to shift to the lower gear, if in congested traffic when the car speed cannot be increased; for by so doing one speeds up the engine and magneto; more current is generated; a hotter spark results, and missing is eliminated.

Remagnetizing Magnets[1]

In charging by the use of an electro-magnet, one of which is shown in Fig. 1, unlike poles must be placed together. That is, the north or N pole of the magnet should be in contact with the S or south pole of the electro-magnet, and the south pole of the magnet with the north of the charging device. The electro-magnet has polarity because the fields are wound in opposite directions. It is easily determined whether the magnet is in its proper position, even if the poles are not marked. Since like poles repel and unlike attract each other, when the magnet is placed in contact with the electro-magnet cores they should hold fast. If there is a repulsion, then the magnet should be reversed.

After charging has been completed and the magnets are assembled on the magneto, it is necessary that **like poles be in contact.** That is, if the magneto has three magnets the north poles of these must be in contact, as shown in Fig. 2. Often some figure is painted upon the magnets, such as is shown, and when this figure is made by the assembly of the magnets, the poles are properly facing. It is best then to determine the proper polarity by the attraction and repulsion methods; like poles repel each other, and unlike poles attract each other.

Another method to find N and S poles: The S pole of the magnet will attract the N pole end (**N**) of the compass needle (see Fig. 3).

Keeper: When magnets are disassembled, place an iron bar (called the "keeper") across the ends to retain magnetism. This should be done instantly on removing magnets, and after remagnetizing.

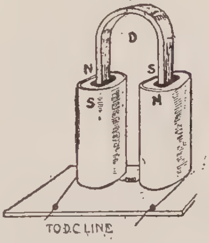

Fig. 1

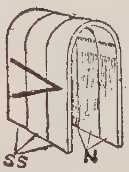

Fig. 2

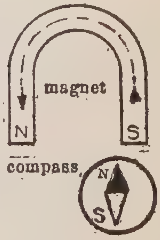

Fig. 3

To test if magnets need recharging: A good way to test, is to place a steel bar or a pair of pliers across the bottoms or the sides of the magnets on the magneto. If they pull fairly strong, you may know that they are in fairly good condition. You can ascertain whether or not they are pulling fairly strong by testing some other magneto which you know is all right. In doing this, however, turn the armature so that the points are just separating.

Another method is to turn over the armature of the magneto by hand, as shown in Fig. 3A, and when the armature gets to a certain position resistance will be felt. This resistance is due to the breaking of the lines-of-force by the armature. Since weak magnets produce a weak field, little resistance will be felt in cases of weak magnets. The magnitude of the resistance will not be known to the repairman unless he has tried previously to turn the armature when the magnets were in good condition, or unless he tries another magneto and compares the results.

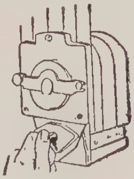

Fig. 3A

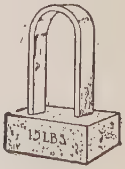

Fig. 3B

Another test is to test the magnet's capacity for lifting 15 lbs. as shown in Fig. 3B. On small magnets 10 lbs. would suffice.

---

[1] A. L. Dyke, Granite Bldg., St. Louis, Mo., is in a position to remagnetize magnets and to repair magnetos, coils, etc.

A good plan is to test the ability of a new magnet of the same size, etc., to lift, and to **compare** the results with those of the one just charged, or which you know is charged.

How Poor Compression Weakens Magneto Magnets

If the engine has good compression, the piston will stop on quarter and not dead center. Result, a free path for magnetic lines-of-force forming virtually a complete magnetic circuit, as in Fig. 4.

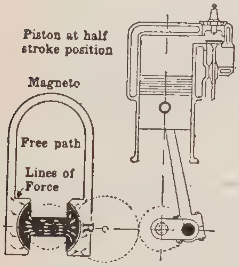

Fig. 4

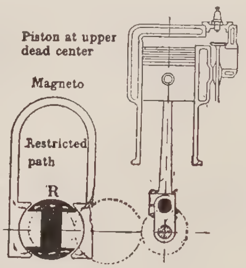

Fig. 5

Fig. 4. Left, position of magneto armature with piston of engine at midstroke showing free path for magnetic lines-of-force between poles of magnet.

Fig. 5. Right, position of magnetic armature with piston at upper dead center showing restricted path of lines-of-force through armature.

If the engine has poor compression, even in one cylinder, the piston will stop on dead center. (Fig. 5). Result, the path for the magnetic lines from one pole-piece to the other is very poor and the result is the same as when a horseshoe magnet is allowed to lie around without its keeper—the magnets will gradually lose their magnetism (from *Motor World,* by Thurston W. Turner).

One Reason Why a Magneto Fails to Spark at Times

A high-tension magneto secondary winding insulation may in time become hardened and leaky from heat, caused by the strain of running with too wide a spark plug and safety gap.

A wide-open throttle increases compression, and the plug gap offers resistance which increases the voltage in the winding, with the result that the spark jumps the insulation internally instead of at the plug gap.

When running on a level with an almost closed throttle, compression is less, with the result that the spark, although weak, may jump the plug gap. This accounts for a magneto armature requiring rewinding, yet producing a spark at times.

Remagnetizing Magneto Magnets

The device[1] shown in Fig. 6 is an electromagnet designed to remagnetize the permanent magnets which are used on magnetos.

A fully charged **6-volt storage battery** of the lighting or starting type should be connected to the terminals of the Magnetizer, using short heavy wires.

On closing the switch on the base of the device, a current of 25 or 30 amperes will flow, and the Magnetizer becomes a powerful electromagnet of such strength that a magnet placed across its poles will be magnetized to its maximum strength.

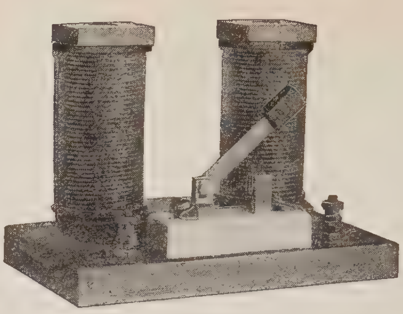

Fig. 6. Electromagnet[1] for remagnetizing magneto magnets of all kinds. For remagnetizing Ford magnets without removing from car, the attachments shown in Fig. 8 are provided.

In order properly to remagnetize magneto magnets it is necessary to remove the magnets from the magneto. Before doing so, one side of the magneto, that is, the pole-piece and the legs of the magnets on one side, should be chalk-marked. The magnets should be magnetized so that the chalk-marked poles have the same polarity. This is done by chalk-marking one pole of the Magnetizer and placing the chalk-marked pole of the magnet to be charged, on the marked pole of the Magnetizer.

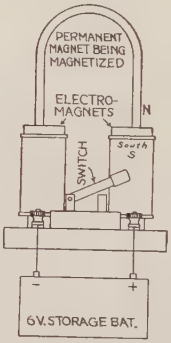

Fig. 7

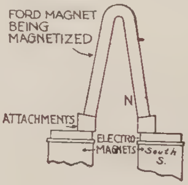

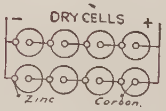

Fig. 8 (upper)
Fig. 9 (lower)

The magnets are placed, one unit or section at a time, so as to span the poles of the Magnetizer, as shown in Fig. 7. Switch the current on and off several times. The current need only flow a few seconds at a time. While the current is flowing, the permanent magnet to be charged should be rapped a few times with a piece of wood. This will assist the magnet to absorb the magnetism easier. It is well to place a piece of soft iron as a keeper across the poles of the magnet before removing it from the Magnetizer so as to preserve the full strength of the magnet until it is put on the magneto. When sliding the magnet on the magneto, the soft iron "keeper" will slide up and may then be removed. See that the magneto is put together exactly as before.

Do not allow the current to flow longer than a short time, as it will cause the coils to heat and will also drain the battery. The Magnetizer may be used on a **12-volt battery or two 6-volt batteries in series.** This will cause it to be twice as strong as if used on a 6-volt battery. It is then suitable for very large magnets.

It is possible to use **dry cells** in case a storage battery is not available. Six or eight fresh cells should be used and connected in two groups in parallel, the groups to be connected in series. See Fig. 9.

If it is desired to magnetize the magnets with a certain polarity, it is necessary to observe the following:

The polarity of the Magnetizer will be as shown in Fig. 7, provided it is connected so that the plus (+) terminal of the battery is connected to the right-hand terminal of the Magnetizer when facing the side with the switch. Place the marked or north pole (N) of the permanent magnet on the south pole (S) of the Magnetizer. When magnetizing this way the marked leg of the permanent magnet will then be the north pole.

The polarity of a magnet is easily determined with a magnetic compass. The north (N) pole of the magnet attracts the (S) pole end of the compass needle. The north pole of a magnet is sometimes called the plus or positive pole. Like poles repel each other; unlike poles attract.

---

[1] Can be secured of A. L. Dyke, Electrical Dept., Granite Bldg., St. Louis, Mo. Price $8.50 (add $1 if Ford attachments are desired).

Remagnetizing Ford Magnets

The magnets in a Ford magneto may be charged as described above, but by attaching the special pole pieces, as shown in Fig. 8, it is not necessary to remove the flywheel from the engine. Remove the transmission-case cover so that the ends of the magnets are available.

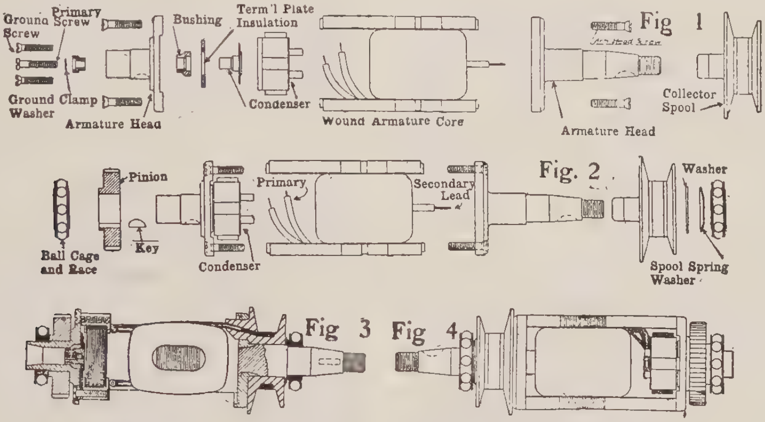
With the aid of a small magnetic compass, the north poles of each one of the magnets should be chalk-marked. Also chalk-mark the south pole of the Magnetizer.

Now place the pole tips of the Magnetizer so as to touch the ends of one of the magnets, taking care that the chalked end of the Magnetizer touches the chalked end of the magnet. By turning the flywheel over, each magnet should be magnetized, one at a time.

It is advisable to check up the polarity of all the magnets with the compass, when they are charged.

DISASSEMBLY, ASSEMBLY, AND TESTING OF A MAGNETO (BERLING AS AN EXAMPLE)

The parts of the armature on the type "E" and "F" Berling magneto are disassembled as shown in Figs. 1 to 4. The interrupter, which was first removed, and the magnets, distributor, etc., are not shown. On most magnetos there is but one primary connection to the condenser, the other primary terminal being grounded, also one terminal of the condenser. Here the primary leads are connected to the condenser and one terminal of the condenser is grounded, which gives the same results. The primary leads are soldered to the condenser.



Figs. 1 to 4. Parts of the Berling "E" and "F" high-tension magneto.

Fig. 2 shows the armature parts being assembled.

Figs. 3 and 4 show a sectional and top view of the completed armature.

It is not advisable to take the magneto apart, unless you know it is defective. Before taking apart read pages 309 and 310 carefully.

To Disassemble the Magneto

Remove interrupter, distributor block, gear housing, magneto and bearings. This will leave the armature as shown in Fig. 5. Be sure and place a "keeper" on the magnets the instant they are removed, as directed on page 311.

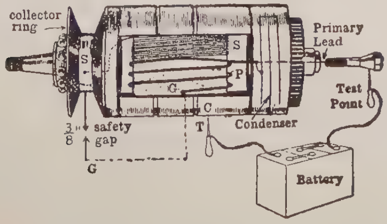


Fig. 5. Testing a magneto armature.

To Test Armature Primary Winding

Use a 6-volt battery[1] and test points, as shown in Fig. 5. Connect one test point with the primary lead, and touch the other test point (T) to the armature core at (C) for an instant. The current then travels through the primary winding and condenser, and is induced into the secondary winding.

If a spark occurs at the test point, and at the same time it jumps the secondary gap of 3/8", then we know the armature has tested out properly.

If there is no spark at all, then we know that there is an open circuit in the primary winding.

If there is a heavy spark at the test point when touching the core, then there is a short-circuit in the condenser or primary winding, and it is necessary to disassemble the armature. This, of course, would mean a dead short-circuit on the battery.

To Disassemble Armature

Remove the screws, armature heads, collector spool, etc., as shown in Fig. 2.

To Test Secondary Winding

A single wound primary coil with a vibrator and condenser fitted internally can be used for this test. A Pfanstiehl[2] coil, is excellent for this purpose; or a Heinze coil unit as used on a model "N" Ford, with the secondary winding short-circuited, could also be used.

Only the primary winding in connection with the vibrator is necessary, as the secondary winding on the armature is used instead; hence the reason for shorting the secondary terminals.

---

[1] Secondary is grounded. On some magnetos it connects to two collector rings.

[2] This coil can be supplied by A. L. Dyke (Elect. Dept.), Granite Bldg., St. Louis; price $7.50.

If the secondary winding is in order, then on touching test point (T) to the armature core (Fig. 6), the spark will jump the ⅜″ gap.

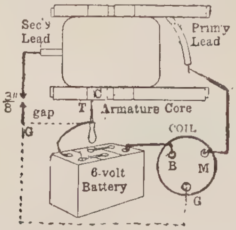

Fig. 6. Testing secondary winding of armature with a battery and a coil.

If the secondary winding is short-circuited, the secondary spark on this test will arc from secondary winding to armature core, but will not jump the gap.

If the secondary winding is open, a spark could occur, as it could jump the open gap internally, but it would be weak.

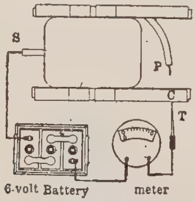

Fig. 7. Testing the secondary winding of an armature with a battery and voltmeter.

To tell positively if a secondary winding is open, about the only plan is to put a very low-reading sensitive voltmeter, connected with a 6-volt storage battery, across the winding, as shown in Fig. 7. If the circuit is open, the meter needle will not move at all. If it moves at all, this circuit is in good order.

Note. Never run current through armature when magnets are on the magneto; it may be run through in the wrong direction and tend to demagnetize them.

Magneto Spark-Plug Gap

The correct gap is .020″ to .031″. If too wide, starting will be hard, and there is a danger of breaking down the high-tension insulation of the winding. If too close, the points are more likely to become shorted, due to carbon collecting on the gap points.

Compression of an engine determines the type of magneto to be used. For instance, if the magneto is used on a high-compression engine, then the points must be closer than on a low-compression engine. If, however, the magneto is made of sufficient capacity for the high-compression engine, then the gap could be normal, or .020″ to .025″.

Contact Breaker Tests

Usual troubles are: dirty points; platinum worn off; arcing at points; gap too far apart or not far enough; points not genuine platinum.

To test platinum points, use nitric acid. If it eats the points, they are not genuine platinum. The best test is to use a jeweler's stone test (ask any jeweler). Platinum or platinum-iridium is generally used for points on magnetos, and tungsten (which is very hard) for points on battery and coil-system interrupters. See also Index under "Platinum points."

MAGNETO TESTING APPARATUS

When considerable testing is done, a countershaft with pulleys, and used in connection with a 1/6 h.p. electric motor, can be used to run the magneto at various speeds to test the length of gap and volume of spark at various speeds (see Fig. 8).

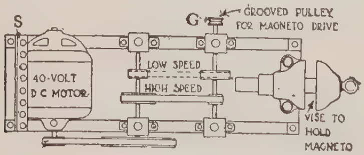

Fig. 8. Counter-shaft, pulleys, vise and motor for driving magneto for testing.

An adjustable gap arrangement can easily be made as shown in Fig. 9. Note that the length of the gap can be adjusted.

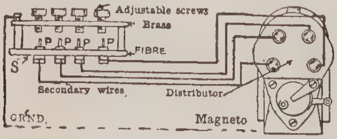

Fig. 9. An adjustable secondary spark gap for testing the secondary winding of magneto.

To test the magneto, place it in the vise (Fig. 8). Connect the secondary terminals to the stationary points (P) (Fig. 9). Place a grooved pulley on the taper shaft of the magneto and connect it with grooved pulley (G) (Fig. 8) on the second countershaft by means of a round belt. Then run the magneto and test as directed on page 315.

If the spark does not test out satisfactorily, then disassemble magneto and test armature and condenser as directed on pages 313, 314, and 315.

To Test Condenser

All high-tension magnetos and high-tension coils are provided with condensers.

A condenser usually consists of 161 layers of mica insulation material, between which sheets of tinfoil are laid so that each layer of tinfoil is electrically insulated from its neighbor (see page 191). In some coil condensers paraffined paper is used instead of mica, but this is not as efficient.

Condensers can be removed, but it is usually necessary to unsolder the primary armature winding connections to one of its terminals, the other condenser terminal being grounded to armature frame.

Usual troubles are due to the sheets of tinfoil becoming grounded, or to the fact that one of the connections is open. **Indication of a defective condenser** is excessive sparking at the contact-breaker points, which become pitted white.

How to test: Use 110-volt direct current with one or two lamps connected, as shown in Fig. 10. If

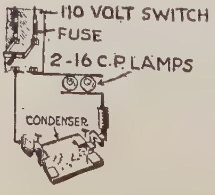

Fig. 10

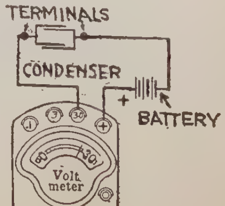

Fig. 11

the condenser is properly insulated and not grounded, the lamp will not light when the switch is closed. If it does light, then the condenser is grounded. If the ground cannot be removed, a new condenser is necessary.

Another test is shown in Fig. 11. Use a 30-volt range volt-meter and connect as shown. If the condenser is good, no indication will be obtained. If it is grounded, an indication will be obtained. See also Index under "Testing condenser."

A Home-Made Magneto Armature Tester

This device is similar to the one explained on page 230, for testing a high-tension coil.

To test a magneto armature, a hole, the diameter of the armature, is made in the sheet of copper, as shown in Fig. 12. The vibrator iron knob (V) on the spring (B) is placed close to the side of the iron core of the armature. This vibrator blade will vibrate when current is passed through the primary winding of the armature if the iron knob (V) is close to the iron armature core.

The primary winding of magneto is connected as shown. One end is grounded to the armature core; the other end connects with the vibrator blade at (**F**).

Note. The armature core should fit tight in the hole so that it will act as a ground.

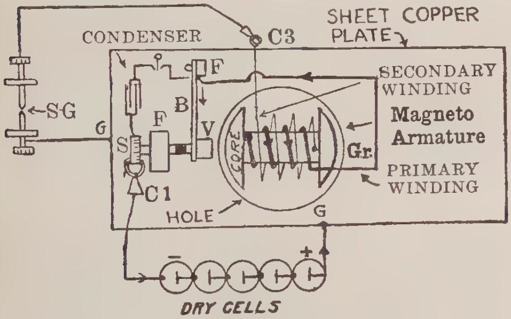

Fig 12. Magneto armature tester.

The primary circuit would then be from (+) of the dry cells to the ground plate (use six dry cells), through ground of primary winding on armature core, through primary winding to vibrator blade at (**F**), through points, to clamp (C1), to (−) terminal of battery, completing the primary circuit.

By adjusting the vibrator screw, the blade (**B**) will vibrate, thus causing a spark at the secondary spark gap (SG), which consists of fiber blocks with very fine brass wires sharply pointed and adjusted to a gap of about ¼″ or 5/16″.

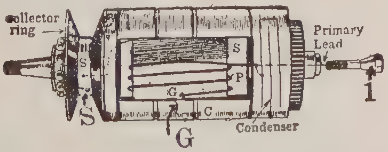

Fig. 13. Showing the winding and parts of a magneto armature.

The secondary winding is wrapped over the primary winding, as shown. One end is grounded to the iron core (usually grounded to the primary wire which is grounded to the iron core); the other end is connected with the insulated slip ring (S) (Fig. 13). Thus the secondary circuit would be from clamp (C3, Fig. 12) which would connect with the slip ring (S, Fig. 13) to the spark gap (SG), to ground (G) on the plate, to ground of the secondary on the armature.

A condenser is shown connected on the outfit to be used for testing purpose. This condenser can be taken from a magneto which is known to be in good condition, and should be so connected that it can be used by means of a plug switch.

The idea is to test the secondary spark, to see if it will produce a spark continuously—at least one hundred steady sparks without missing. The width of this gap at (SG) should be about 5/16″, or slightly less than the length the safety spark gap is set for on the magneto.

First test with the condenser which is used with the magneto armature, and note if there is sparking at the points of the vibrator interrupter; if so, try the good condenser on the outfit and see if the sparking disappears. If it does, the condenser in magneto is defective and can be tested separately with test points (pages 227, 230) to see if shorted. There should be no circuit between terminals of a good condenser. The condenser, of course, should be across the interrupter points, or the vibrator points.

If the condenser in the magneto is in such a position that it is not across the points, then test with condenser on the test outfit, and then unsolder the leads from the condenser on the magneto and test separately with a 110-volt test lamp similar to test on pages 314, 230. By reading the directions for testing a high-tension coil with a similar outfit, on page 230, the explanations will probably be clearer.

Other Methods of Testing a Magneto

Testing high-tension magneto: Oil the magneto; connect the distributor wires to the spark plugs and set the points at about a 3/16″ gap; then run the magneto 40 minutes at 1,500 r.p.m. with interrupter full advanced and for 10 minutes at 3,500 r.p.m. full advance, and 10 minutes at 150 r.p.m., noting that it runs equally well during last run in either advanced or retarded position.

During the runs the contact points should not spark or flame excessively. There should be no excessive noise or stray sparks about the magneto. The safety gap in the magneto should be 5/16″, and should not spark at any of the speeds mentioned, if the spark-plug gaps are not over 3/16″ during the test. The spark should jump the safety gap when the armature revolves at 60 r.p.m. with the spark plug or distributor wires removed.

One method of driving a magneto on a test is by an electric motor. Another method is from a line

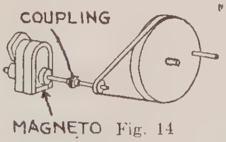

Fig. 14

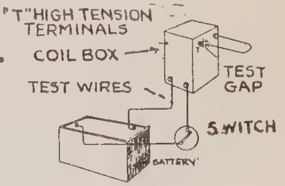

Fig. 15

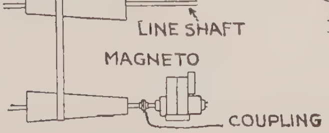

Fig. 16

Fig. 14. A method for determining the condition of the spark produced by driving the magneto at high speed.

Fig. 15. A battery, switch and test wires to test a coil.

Fig. 16. A variable-speed arrangement for driving a magneto from a line shaft.

shaft and a pulley (Figs. 14 and 16). Fig. 16 shows a variable-speed pulley arrangement. When testing a magneto or coil, run until heated up.

Be careful that the armature is in perfect alignment. If a ball is broken, the armature shaft will be out of line and permit the armature to rub against the pole-piece; or the armature heads may become loose, or the drive shaft may be worn unduly on one end of the armature by the gear driving it meshing too tight.

Usually, **the cause of the armature being out of alignment** is worn bearings, or a broken ball, or loose screws on the armature head.

Testing a High-Tension Coil Used with a Low-Tension Magneto

Connect the low-tension circuit of the coil with a good battery of the same voltage as is used on the car, and provide a spark gap of suitable size on the high-tension side.

For 60 lb. compression the gap should be ¼″ in the atmosphere and for 90 lb., ½″. Fig. 15 shows the conventional arrangement which may be used when the coil is not on the magneto armature.

The coil primary circuit is closed and then quickly opened, and if the coil is in good condition a spark should occur at the high-tension gap (Fig. 15).

There is no necessity for removing the coil box from the car to do this work if the test wires are long enough to be attached with the coil in place.

Unless the internal wiring of the coil is known, some experimenting will be required in order to connect up with the right terminal. Probably the simplest method of procedure is to note the terminals to which the low and high-tension wires are attached, and to attach the test wires accordingly.

Testing a Dixie Magneto

The windings of a Dixie magneto armature can be tested by disconnecting the primary winding from the stationary insulated contact point (S) and connecting this primary lead (W) to one terminal of a 6-volt battery. (This primary lead is clearly shown in Fig. 26, page 276). The other terminal of the battery should then be connected to the stationary contact point (S), the circuit then being as shown in Fig. 17. Then turn the armature so that the contact points will open and close, and watch to see if the spark jumps the safety-gap. The safety-gap points should be set about 5/16″ apart. In such a case, the winding is probably in good order.

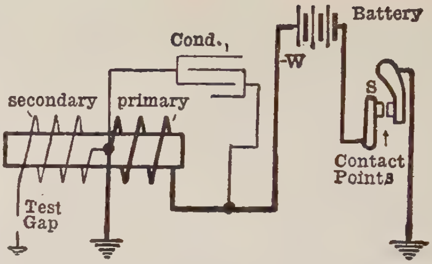

Fig. 17. Testing a Dixie magneto. The same principle applies to the armature type of magneto.

A good plan is to test a winding that you know is in proper condition, and to compare the suspected defective one with the spark of a good one.

The test described above may also be used on the armature type of magneto, the principle being the same, that is, to connect the battery between the primary winding and the **insulated** contact point.

If the points rotate, do not give the armature many revolutions, as the battery leads will wrap around it.

Changing Direction of Rotation

If the direction of rotation of a standard revolving armature-type of magneto armature is changed, a contact-breaker, housing and a cam must be obtained for the opposite rotation.

It will also be necessary to change the meshing of the armature gear and distributor gear teeth, so that the spark will occur at the proper plugs according to the firing order.

Magneto Gear Tool

A specially made tool for removing magneto gears is shown in Fig. 18 at (W). The prongs of the fork are tapered. By using two such tools, the gears can easily be removed without damage.

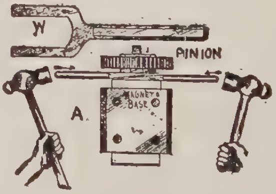

Fig. 18. Magneto gear tool.

INSTRUCTION No. 30

ENGINE STARTERS: Ignition; Priming; Compressed Air; Gasoline and Air; Electric

Ignition Starting

The first form of self-starter was the ignition starter. It is still used, but to no great extent, in connection with the priming systems and gas systems of starting, as explained on page 268. A special form of switch, is sometimes provided which causes a spark in all cylinders simultaneously.

It is possible to start any engine occasionally on the switch, if the cylinder in which the spark is made at the time happens to have a charge of gas and the ignition is a battery and vibrator-coil system, either as an auxiliary or regular system. If, however, the magneto system and breaker are used in connection with a non-vibrating coil, then the chance of obtaining the spark is not so good. The breaker points will not permit the opening and closing of the circuit when the engine is idle.

Therefore a special connection is usually provided on the non-vibrator type of coil in the form of a button switch. This applies to engines of four or more cylinders. The principle: there is always a certain amount of unexploded gas remaining in one of the cylinders when the engine stops, especially if the driver has taken the precaution to open his throttle before the engine stops. Therefore, if a spark occurs in the cylinder, this unexploded gas will combust and give enough momentum to start the engine.

As stated, if a coil system is used, the switch can be thrown on and a quick movement of the spark lever for its full length will cause contact to be made on the timer or commutator, thereby causing a spark in one of the cylinders.

Naturally the cylinders must be in good condition. The piston rings must be tight so that the compression will not be lost by leakage. When stopping the engine the throttle ought to be opened part way, so as to admit a full charge of gas to the cylinders, to make starting easier. The engine must be speeded up, but by holding the clutch out.

Priming Starter

The priming method of starting was the next method. Instead of depending on the pistons to draw in a charge of gas, a special pump was devised as in Fig. 1. This pump forced a charge of carbureted gas into the cylinder, as explained below.

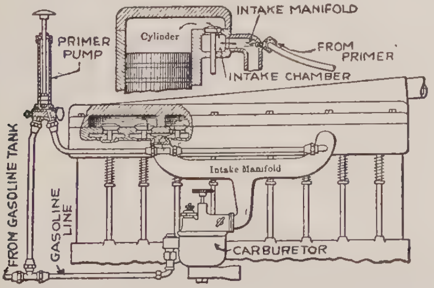

Fig. 1. A primer starter. Cylinder primers are all operated very much along the same lines, the fuel being injected into either the cylinders themselves through special priming cocks or into the intake manifold. A hand-operated pump is usually used to draw the gasoline from the supply tank to the feed pipe. The gasoline is brought into the primer cylinder from the carburetor supply pipe. It is then forced into the intake manifold through a special form of spray nozzle. An upward stroke of the handle fills the primer cylinder, and a downward stroke forces it into the valve chambers of the engine. With all priming systems it is necessary to have a spark at the correct time. See Index under "Starting on the switch."

Gas Starter

The acetylene gas idea of starting developed from both of these systems. The Prest-O-Lite Co. worked out a very satisfactory system for starting, as explained in Fig. 2. This system also employed a special electric connection for igniting the gas.

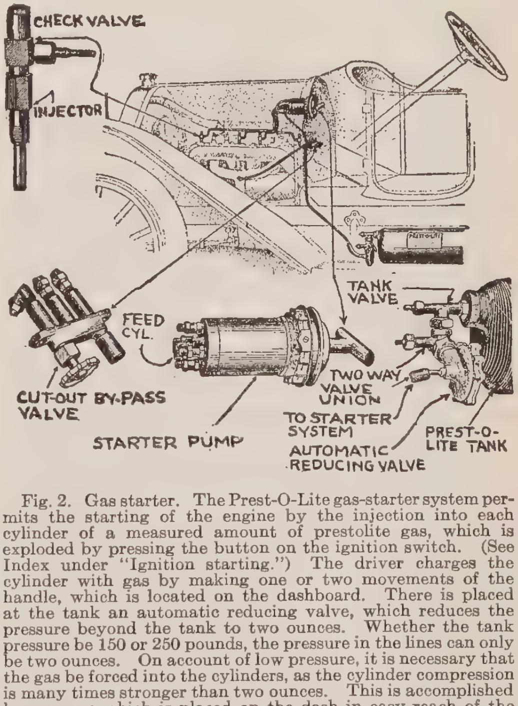

Fig. 2. Gas starter. The Prest-O-Lite gas-starter system permits the starting of the engine by the injection into each cylinder of a measured amount of prestolite gas, which is exploded by pressing the button on the ignition switch. (See Index under "Ignition starting.") The driver charges the cylinder with gas by making one or two movements of the handle, which is located on the dashboard. There is placed at the tank an automatic reducing valve, which reduces the pressure beyond the tank to two ounces. Whether the tank pressure be 150 or 250 pounds, the pressure in the lines can only be two ounces. On account of low pressure, it is necessary that the gas be forced into the cylinders, as the cylinder compression is many times stronger than two ounces. This is accomplished by a pump which is placed on the dash in easy reach of the driver. In cold weather the driver can press a by-pass valve button and cause the gas to pass from the tank directly to the intake manifold. (Prest-O-Lite Co., Indianapolis, Ind.)

Compressed-Air Starter

The compressed-air system was first used by taking pressure from the exhaust, storing it in a tank, and then distributing it to the cylinders. The compressed-air starter is divided in two classes: (1) the type which uses a pump, operated mechanically from the engine to store fresh air in the air tank (Fig. 3); (2) in the other type, the exhaust gases are stored in a tank.

This last-mentioned method was a type of starter formerly used on the Winton several years ago. Part of the exhaust gases from the engine was stored up in a tank, during the exhaust stroke. This gas was then used to force the piston (which was ready to commence its power stroke) down. Fig. 3 shows the method, using a mechanically driven air pump to store fresh air in a tank under pressure.

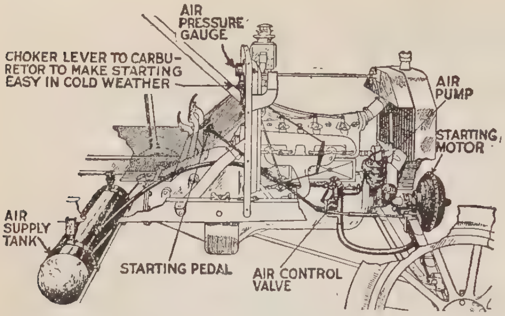

Fig. 3. Compressed-air starter. The Stewart starter for the Ford cranks the engine from the front end of the crank shaft in exactly the same manner it would be cranked by hand. To start the engine, it is only necessary to press the pedal which is installed on the footboard.

The starter motor, or cranking unit, is an air-tight chamber, circular in form and replaces the crank handle. Passing through this is a shaft which engages the engine shaft, the same as the crank handle formerly did. Within the cylinder is a stationary head; also a revolving valve.

This valve is attached to a collar through which the starter shaft passes. In operation, the charge of air is admitted into the starter motor at a point between the stationary head and the revolving valve. This air pressure forces the revolving valve to make almost one complete revolution.

Inside of the collar, attached to the revolving valve is a pawl which engages the grooves or teeth in the starter shaft. A "driving" clutch is attached to the end of this starter shaft.

A "driven" clutch is installed on the end of the engine crank shaft. The "driving" clutch engages with the "driven" clutch in the same manner as formerly, when the car was started by the old crank handle. (Stewart-Warner Speedometer Corp'n., Chicago, Ill.)

Gasoline and Air Starter

The Christensen gasoline and air starter (Fig. 4) is used on aeronautical engines, such as the Thomas, Sturtevant, Roberts, Duesenberg, Hall-Scott, Curtiss, Wisconsin, and others; also on motor boats, trucks, tractors, and automobiles.

Principle: This starter does not crank the engine, but starts it as follows: The engine, when running, uses gasoline and air, properly mixed, as its fuel. When not running it cannot be started ordinarily only by cranking by hand or some other starter. The Christensen starter supplies this mixture to the engine in ready-made form, under compression, to each of the cylinders in firing order so that the engine is started on the first touch of the button.

The parts are shown in Fig. 4 and consist of **the compressor; a clutch** for engaging and disengaging the starter; **a carburetor chamber** (independent of the engine carburetor) and **a distributor,** timed with the firing order of the engine; **a control valve,** which is used for starting the engine and for engaging the air compressor; **a tank** for holding the air, and **a gauge** telling how much air the tank contains.

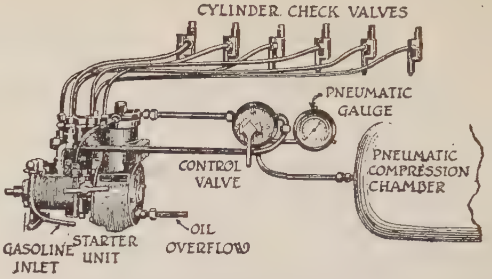

Fig. 4. Gasoline and air starter.

Into each engine cylinder a **starter check valve** is screwed (usually in the priming cup opening), and a pipe runs from the check valves to the distributor.

Method of attaching: The starter unit is usually driven by Oldham coupling from the crank shaft or cam shaft, and is mounted in the most convenient place. (The Christensen Engineering Co., Milwaukee, Wisconsin.)

Mechanical Starter

The mechanical starter is made in many and varied forms, one being shown in Fig. 5.

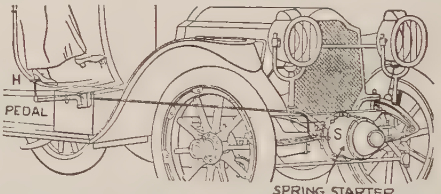

Fig. 5. A mechanical starter. This device (S) is attached to the front of the car in place of the ordinary starting crank. It is about the size of an ordinary automobile headlight, and looks like one reversed. There are two powerful springs in the device which are released by a very slight pressure on a pedal (H) which is located near the driver's seat. (American Ever-Ready Works, Long Island City, N.Y.)

Electric Starter

The electric starting motor has many advantages over other systems, in that the motor is easily applied and manipulated. The source of electric supply is derived from a storage battery which is kept recharged by an electric generator (dynamo).

Summary

Thus, we have the several types of self-starters classified as follows: Ignition or switch starter; primer and ignition; acetylene gas; compressed air; gasoline and air; mechanical, and electric.

Electric Starter Most Used

The electric starter is the system in general use and will be treated in the next instruction.

INSTRUCTION No. 31

THE ELECTRIC STARTING MOTOR: Principle of an Electric Motor; Windings

The electric starting motor is an electric device or motor for turning over the crank shaft of a gasoline engine. The electric motor is a device for transforming electric power into mechanical power. The electric motor receives its electric current for its motion from an electric storage battery.

The storage battery receives its charging current from an outside source, or an electric generator, usually run from the gasoline engine. Quite often this generator (also called a dynamo) is made a part of the starting motor, as will be explained under "Generators."

APPLICATION OF THE ELECTRIC STARTING MOTOR TO THE ENGINE

By referring to Fig. 1, different methods employed for cranking or starting the engine by means of the electric starting motor will be noted. We might classify the methods under two headings as follows:

1. **Flywheel** application (**A** and **B**, Fig. 1).
2. **Crank-shaft** application (**C**, **D**, **E**, and **F**, Fig. 1).

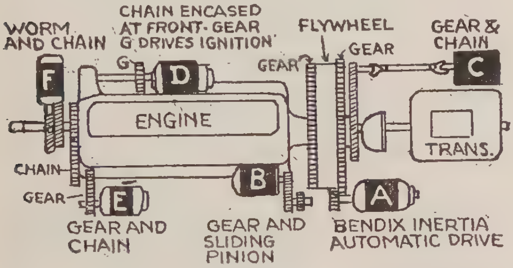

Fig. 1. Various methods of applying the starting motor to an engine. The application shown in **A** is used most.

The flywheel drive methods can be classified as "mechanical" and "automatic." For instance, (**A**) (Fig. 1) the teeth of the pinion or gear on the end of the motor armature shaft automatically engages with the teeth of the flywheel and automatically disengages after the engine is started. This method is known as the "Eclipse-Bendix inertia gear drive," and is illustrated in Fig. 2.

Eclipse-Bendix "Automatic" Inertia Gear-Drive Application to Flywheel

The Bendix "automatic" shifting pinion, as used on a large percentage of the different makes of electric starting motors, also called the "inertia" gear shift, is pictured in Fig. 2. This illustration is not exactly as the device appears today, but explains the principle clearly.

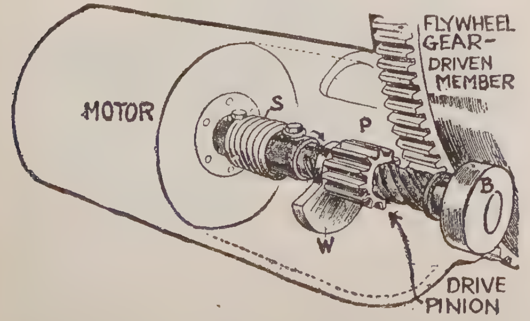

Fig. 2. The Bendix inertia gear drive is the type in general use. Note that the drive pinion automatically engages the driven gear on the flywheel.

The armature shaft has a screwed extension provided with an outer bearing (**B**), and carries the pinion (**P**).

A weight (**W**) is solidly attached to the pinion, and the latter is loose enough on the shaft always to occupy the position shown, with the weight underneath when the shaft is idle. The leading screw has a triple thread.

On starting the motor, the inertia of the weight (W) causes it and the pinion to be carried quickly along the shaft into mesh with the teeth on the flywheel, where it remains performing the operation of cranking until the engine commences to fire, when the direction of the drive is reversed, coming from flywheel to pinion, and throwing out pinion.

The spring (**S**) is provided simply to ease the shock of starting by permitting a slight play between the motor shaft and the screwed extension. The teeth of both flywheel and pinion are beveled on the entering side for easy engagement.

The action is easy to understand. But a query will naturally arise as to what would happen if the starting switch is not released and the motor continues spinning. It would seem that the pinion would return and either get into mesh or continue chattering at the edges of the teeth. Neither happens. The pinion simply continues to rotate out of mesh until the switch is released. This is due to a secondary function of the weight (**W**). Immediately the pinion is thrown out from the flywheel the speed of the motor is such as to cause a binding of the pinion on its shaft, due to the one-sided position of the weight. The action involved is that of the center of gravity of the weight attempting to get into the central plane of rotation of the pinion, and the slight necessary looseness of pinion on shaft allows a temporary binding as a result.

This type of gearing would be termed a "single reduction" of gearing.

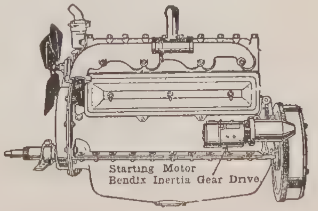

Fig. 3. Illustration showing how the starting motor using the Bendix inertia gear drive is connected to the engine (Studebaker "Light-six," as an example).

Bendix Construction

A modern construction of the **Bendix automatic gear shift** is shown in Fig. 4.

The gear (A) shifts, which meshes with flywheel gear (D). The action is as follows: When the starting button of the switch is pressed down, the connections are made between the storage battery and the electric motor, which causes the armature to rotate rapidly. This causes gear (A) to travel towards the motor on the coarse-threaded sleeve (B) and to mesh with gear (D) on the flywheel. (B) is connected to the armature shaft through spring (C), which allows a certain amount of flexibility and prevents too sudden application of the gears.

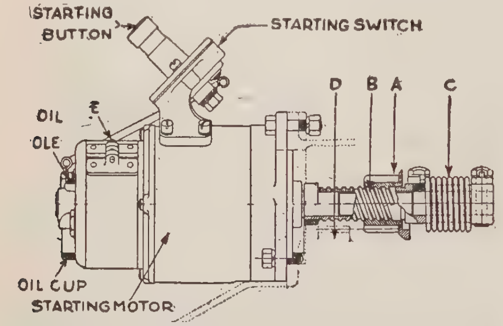

Fig. 4. Bendix drive as used on the starting motor of the King car.

As soon as gear (A) is fully engaged with flywheel gear (D), it comes up against a stop and is locked firmly to sleeve (B), thus rotating with the starting motor armature shaft and allowing the starting motor to crank the engine.

When the engine starts under its own power and the starting button is released, the small inertia gear (A) is thrown out of mesh with the flywheel gear (D), and the starting motor comes to rest.

Note. In the Bendix type of drive shown in Fig. 3, the spring is positioned at the inner end of the sleeve and gear (A) travels in the opposite direction. The principle however is exactly the same. In this construction, the counter-weight on gear (A) is in the form of a flange.

Pointers on the Care and Repair of the Bendix Drive

In case the starting motor fails to start the engine when the starter button is pressed, the following suggestions will be found helpful in tracing the trouble: (1) ignition switch in "off" position; (2) throttle closed; (3) carburetor not choked; (4) loose ignition wire connections; (5) interrupter breaker points out of adjustment; (6) no gasoline in main tank; (7) no gasoline in gravity tank. Remove the carburetor float chamber cover, and if no gasoline is present, see that the shut-off cock underneath the gravity tank is open. If there is gasoline in the main tank, and none in the gravity tank, see "Gasoline feed" instructions for remedy.

If the starting motor runs, but does not crank the engine: This trouble is likely to occur only in extremely cold weather when the oil congeals, causing the starter inertia gear to stick, and not to move into mesh with the flywheel gear. A slight tapping on the starting motor housing will usually overcome the difficulty, but if this fails, start the engine with the hand crank and when the motor is warmed up, it will operate properly.

If the starting motor does not run, this might be caused by any of the following: (1) loose connections at either starting switch, starting motor or battery; (2) battery discharged (test solution with hydrometer); (3) dirty starting motor commutator; (4) worn or loose brushes.

If the pinion goes into mesh with a "bang" and there is considerable noise while cranking, it is evident that the clamping bolts (R) (Fig. 5) have loosened. Be particular to line up the motor properly before drawing them up. By turning the threaded sleeve (B) with the fingers, the pinion (A) can be moved into mesh. Unless it meshes easily, it is not in line.

Starting switch: Good contact and a quick release are important. Examine the spring occasionally, as it must be in good order to prevent damage to the gear teeth. Keep the clamping bolts (that hold down the motor) drawn up snug at all times, otherwise the motor will shift out of line.

Occasionally a Bendix drive gear will stick in mesh, and will not release after the engine has started. This is often caused by improper alignment of a starting motor. In this case, or if the gear meshes harshly, or spins considerably without meshing, proceed as follows: (1) remove bolt (R), spring (C) and threaded sleeve (B); (2) wind a strip of emery cloth around a stick and clean inside of sleeve (B); (3) clean armature shaft; (4) apply small amount of light graphite grease to inside of sleeve (B) and replace parts; (5) do not grease any other part of this drive mechanism, as the action of the starter depends upon the inertia weight on gear (A), and this action is hindered if grease or dirt is on the threads of (B); (6) see that the starting motor is in perfect alignment. If not, place 1/64" shims under it.

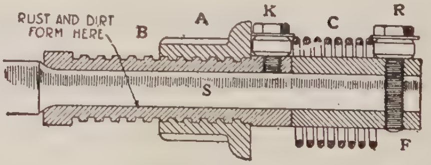

Fig. 5. Parts of the Bendix drive where trouble may likely occur.

Bendix drive troubles may develop from rust and dirt collecting on the inner drive shaft and sleeve (Fig. 5). This should be cleaned out by means of emery paper, being careful to see that no trace of emery is left.

Ratio of Gearing

Ratio of gearing using the Bendix drive: On the Ford, as an example, using this system, there are 10 teeth on the starting motor pinion and 120 teeth on the flywheel gear; thus the starting motor turns twelve times as fast.

On the King car (Fig. 4), there are 12 teeth on the pinion and 126 on the flywheel gear. The ratio is therefore 10½ to 1. The starting motor cranks the engine at a speed of about 150 to 200 r.p.m.

Care of Starting Motor

Lubrication: The bearing at the commutator (rear) end is fitted with a wick oil cup underneath the bearing. The wick dips into the lubricant and the upper end rests against the armature shaft, so that the oil is constantly fed to the bearing. The wick should be cleaned with gasoline and the oil cup filled with non-fluid oil or vaseline once every 3,000 miles. The oil hole is on top of the bearing bracket.

Commutator: The commutator and brushes can be exposed by unscrewing the screw in (**E**) and removing the band cover. Do not touch the commutator so long as the motor starts properly. If it becomes dirty, clean with a piece of canvas moistened with gasoline; if rough, polish with No. 00 sand paper while revolving. See Index, under "Care of starting motor."

BOSCH AUTOMATIC ELECTRO-MAGNETIC PINION SHIFT

Another "automatic" method of a flywheel drive application of the starting motor is where the gear or pinion on the end of the motor armature shaft is shifted electrically. This system, now known as the "Bosch," was formerly known as the "Rushmore," and is termed a "displacement type of armature" because the armature shifts endwise.

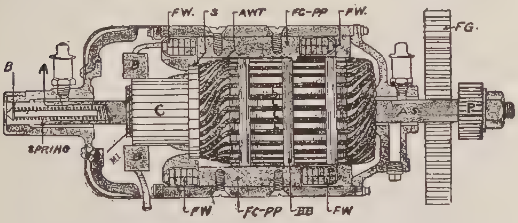

Fig. 11. **C**, commutator; **B**, brushes; **L**, laminated iron core; **AWT** armature winding terminals; **BB**, brass bands around armature to hold coils in place; **F, C,** and **PP,** field core, or pole pieces; **F, W,** field winding; **A, S,** armature shaft; **S,** segment of commutator, where armature coils connect; **MI,** mica insulation between the copper commutator segments; **P,** drive gear or shaft pinion; **FG,** flywheel driven gear.

Displacement Type of Armature

The armature is so arranged that it can be shifted endwise in its bearings, parallel to its axis.

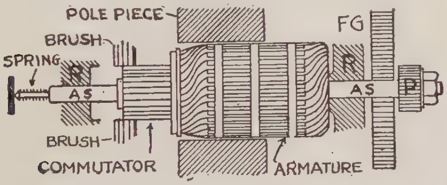

Fig. 12. Motor armature in non-operating position.

In the normal or non-operating position (Fig. 12), the armature is held out of electrical center, or out of line with the pole pieces, by means of a spiral spring in the commutator end of the armature shaft; therefore, when in the normal position (Fig. 12), the pinion (**P**) on the driving shaft of the starting motor is kept out of mesh with the gear ring (**FG**) on the flywheel of the engine.

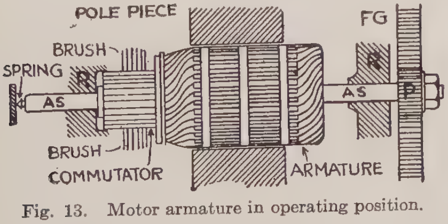

Fig. 13. Motor armature in operating position.

Fig. 13 shows **the motor armature in operating position.** Note that the armature has been pulled to the left under the center of the pole pieces and the gear (**P**) on the end of the armature shaft is now in mesh with flywheel gear (**FG**). Also note that the spring at the left end is now full up into the hollow armature shaft. In this position the gear (**P**) revolves the flywheel gear (**FG**), thus cranking the engine.

Other starting motor armatures, unless of a "displacement type," do not shift; instead, a Bendix drive, or other means for connecting the motor drive gear (**P**) with the flywheel gear (**FG**) is used.

Principle of Operation

The principle of the Bosch starting motor is as follows: Switch arm (**R**) is pressed down slowly by foot pedal (**D**), until connection is made across (**A**) to (**B**). Note that the current from the battery must then pass through resistance (**E**). The amount of current is thus limited. A small portion of the current will then flow through armature (**A**), while the greater portion flows through the motor field coils around pole pieces (**PP**), forming a strong electro-magnet of the field pole pieces (**PP**).

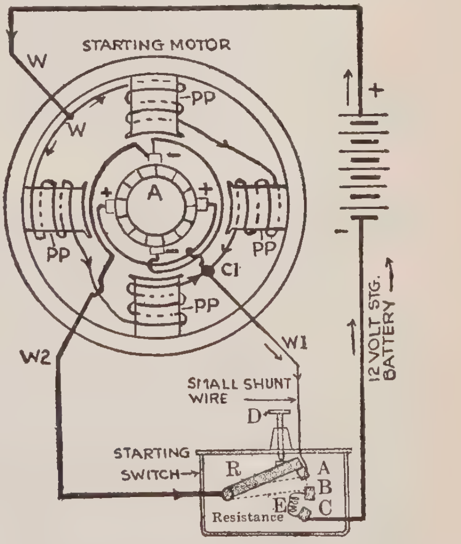

Fig. 14. Principle of operation of the Bosch electro-magnetic pinion shift.

The result is that the **armature is magnetically drawn endwise** against the tension of the spring (Fig. 13) into the magnetic center of the motor, or, in other words, into its working position between the pole pieces.

The passing of the small amount of current through the armature causes the armature to rotate slowly, and as the rotary motion occurs simultaneously with the shifting of the armature endwise, the meshing of the motor pinion (**P**) with the gear ring on the engine flywheel (**FG**) is accomplished quickly and positively.

Immediately after connection is made at (**A**) and (**B**) (Fig. 14), the switch pedal (**D**) is pressed down until (**R**) is in contact with (**C**); therefore the resistance (**E**) and the connection (**A**) and (**B**) and shunt wire or cable (**W1**) are cut out of the circuit and a straight "series-parallel" motor connection through the motor field windings is thus established. This allows the entire current to pass through the motor field windings and the armature windings.

The circuit would then be from (+) terminal of battery to terminal (W) on the motor, which connects with the field windings. The current divides, part going through two field coils in series on one side and through the two field coils on the other side, then from (C1) to (+) brushes on the armature, through the armature coils, out (−) brushes, to switch arm (R), to (C), to (−) terminal of battery, thus completing the circuit.

As soon as the engine starts, the starting motor is relieved of its load, and the current passing through it drops rapidly in volume, this being a characteristic of all series-starting motors. In consequence, the strength of the field magnets is lessened to a point where the spiral spring in the end of the armature shaft overcomes the magnetic attraction holding the armature, and returns it to the original or non-operating position. It is this action that automatically and positively throws the armature shaft pinion (P) out of mesh with the flywheel gear (FG).

Thereafter, until the starting switch is released, any current which continues to pass through the armature will merely cause the latter to revolve freely but without meshing with the flywheel, due to the fact that the amount of current utilized when the motor is running free and the shunt wire (W1) is out of the circuit, is not sufficient to overcome the tension of the spiral spring. The switch should be released quickly.

The system described was formerly used on the Marmon car.

WESTINGHOUSE STARTING MOTOR WITH AUTOMATIC ELECTRO-MAGNETIC PINION SHIFT

The Westinghouse starting motor with an electro-magnetic pinion shift was formerly used on the Pierce-Arrow, Locomobile, Mercer, Cunningham, and McFarlan, and is still used on some cars in connection with a magnetic starting switch.

The internal construction varies slightly on the systems used on the cars just mentioned, but the principle is similar on all.

As an example we will use the system (Fig. 16) as used on the 1919–20 Locomobile.

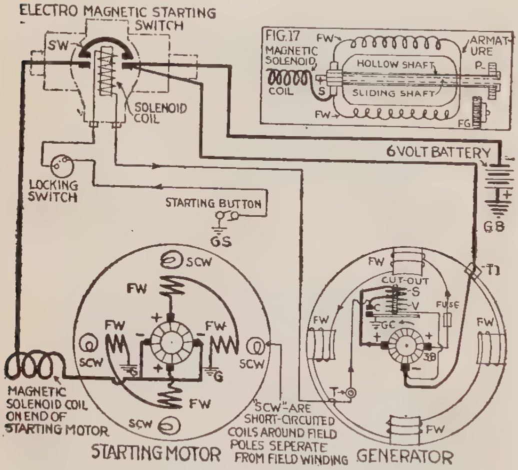

Fig. 16 (lower). Fig. 17 (upper right)

The starting motor is a series-wound, round-frame type, with four poles and with four brushes. It develops 0.7 h.p. at 5.25 volts. It turns the Loco "38" engine crank over at about 125 r.p.m., and the "48" model engine at 115 r.p.m.

On each field pole there is a short-circuited coil (SCW) for the purpose of preventing the starting motor from turning too rapidly as the first rush of current passes through the motor. It acts somewhat like an electric brake for a short period of time. These coils reduce the inductive effect temporarily around the field cores, so that the starting motor does not revolve fast, but permits a current of high value to build up in the magnetic solenoid. This short-circuit coil only affects the magnetism of the field cores temporarily, and the current soon builds up around the field windings (FW); thus the motor picks up speed.

The magnetic solenoid is mounted on the commutator end of the motor (Fig. 17). The armature is on a hollow shaft. On one end of the hollow shaft is the shifting pinion (P) which is splined to it, and thus can slide on this hollow shaft. A sliding rod runs through the armature hollow shaft which is attached to the pinion (P), and it is this sliding shaft which is drawn endwise into the magnetic solenoid, thus shifting the pinion (P) in mesh with the flywheel gear (FG).

It will thus be observed that the difference between this system and the Bosch (Rushmore) system (page 321) lies in the fact that instead of the entire armature being shifted, as in the Bosch "displacement type armature," to cause the pinion (P) to mesh with the flywheel gear (FG), the sliding or shifting rod (S, Fig. 17) is moved in the hollow shaft of the armature in the Westinghouse (Figs. 16 and 17).

When the engine starts on its own power, the starting motor is relieved of its load, or, in other words, the series-wound motor draws more and more current, the heavier the load; the lighter the load, the less current it draws. Therefore as the load has been relieved, when the engine starts to run itself, the current passing through the solenoid and field windings is reduced to such a point that the solenoid loses its magnetic pull and the spring (not shown) forces the sliding shaft (S) and gear (P) out of mesh with the flywheel gear (GP).

A return spring, not shown, forces the shifting rod back so that the gear (P) is out of mesh with the flywheel gear (GP) when the motor is not running.

When the starting switch is closed (which could be a foot pedal, but in this example is an electromagnetic switch, explained farther on), the circuit is from (+) ground (GB) of the battery, to ground (G) of the field coils (FW), to (+) brushes, through the armature, to (−) brushes, through the magnetic solenoid, through the switch, to (−) terminal of the battery.

The electromagnetic starting switch: This type of starting switch takes the place of a foot pedal and is operated by a push button placed on the gang switch on the dash.

Circuit: When starting, the push button (Fig. 16) is depressed. The circuit is from (+) of battery ground (GB), through the frame of the car to ground (GS) on the push button, through the locking switch, through a solenoid winding or coil of the magnetic switch, to generator terminal (T), to cut-out point (C), through cut-out series winding (S), to (+) generator brush, through the armature of the generator, through (−) brush, to terminal (T1), to contact on the electromagnetic switch, to (−) terminal of the battery.

When the engine commences to fire and to speed up, the voltage of the generator builds up.

Cut-out voltage coil circuit: The voltage is built up in the voltage coil (V) of the cut-out. The circuit is from (+) brush, through the series cut-out coil (S), through the voltage coil (V), to (−) brush. This causes the cut-out points (C) to close. Therefore the closing of the cut-out points (C) causes the circuit from the generator (+) brush to become grounded. Thus the electromagnetic starting switch has its solenoid coil grounded at (GC) and also at the push button (GS), with the result that its circuit is opened because its coil is demagnetized and the switch (SW) opens (by a spring not shown), thus opening the circuit between the starting motor and battery. This switch cannot be closed as long as the generator is running fast enough to maintain a voltage sufficient to close the cut-out points.

The generator: In this example a third-brush regulated generator is shown. The field poles are built up, or magnetized, by the (+) current from the armature passing through the third brush, to the four shunt field windings, to terminal (T1), thence to (−) main brush.

Charging circuit: When the generator runs at a speed corresponding to eight miles per hour car speed on high gear, the generator is generating sufficient voltage to close the cut-out points (C); therefore the generator will charge the battery.

The circuit is from (+) main brush, through the series cut-out coil (S), through the closed points (C—now shown open), through the frame of the cut-out, to ground (GC), to (+) ground of battery (GB), to the connection on the magnetic starting switch, to the generator terminal (T1), to (−) main brush.

MECHANICAL GEAR-SHIFT APPLICATION TO THE FLYWHEEL

A mechanical gear-shift arrangement for engaging the shifting gear or pinion (J) with flywheel gear (FG) is shown in Fig. 18, an **early Westinghouse system.**

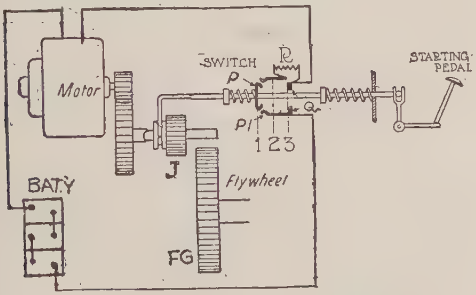

Fig. 18. **A mechanical gear-shift arrangement** for starting the engine with a starting motor and reduction gear drive.

The switch is operated by a foot pedal, which closes the electric circuit to the starting motor and shifts sliding gear (J) in mesh with flywheel gear (FG).

When the switch is at position 1 (Fig. 18), the starting motor switch is off and starting motor idle.

The starting pedal is depressed slowly, forming position 2. This causes contact to be made at (P) with (P1), at which time resistance (R) is in the circuit causing the armature to rotate slowly. This slow rotation allows pinion (J) to mesh easily with the flywheel.

In position 3, **the starting pedal is depressed fully.** This causes (P) to make contact with (Q), at which point the resistance (R) is cut out and the full voltage is applied to the starting motor terminals in order to crank the engine.

After the engine is started, the starting pedal is released and the spring de-meshes the pinion (J) from flywheel gear (FG), and the switch cuts-out and assumes position (1).

Gear Reduction

The connection of gears between the starting motor and flywheel can be either a **single reduction,** as shown in Fig. 19, or a **double reduction, Fig. 19A.** The single and Bendix drive are used most.

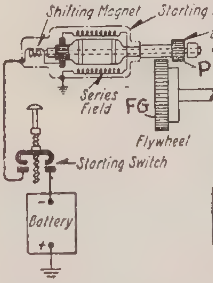

Fig. 19

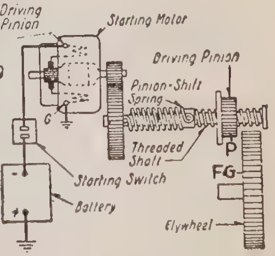

Fig. 19A

THE BIJUR DOUBLE-GEARED TYPE OF DRIVE—FLYWHEEL APPLICATION

This type of geared drive shift is the standard, as used on the Packard "Twin-six." It was also used on the Nash cars for 1916, 1917, and 1918.

The Bijur double-geared pinion shift (Fig. 20) for starting motors driving through the flywheel is similar in some respects to the Bendix (page 319), and can be attached to the armature shaft (A) of any starting motor with the shaft machined to fit it.

Names of parts: A, armature shaft; B, drive shaft; D, driving gear; E, clutch; H, sleeve; L, clutch spring; M, pinion which meshes with flywheel gear or pinion; O, light spring; X, pinion on end of armature shaft.

To start the engine: The driving gear (D) rotates the drive shaft (B) through the clutch mechanism (E and F). This causes pinion (M) to screw itself

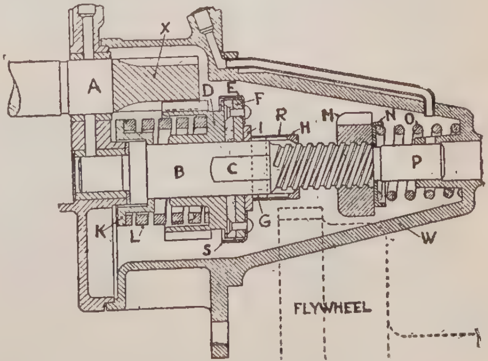

Fig. 20. The Bijur double-geared pinion shift.

to the left along the shaft (**P**), and after meshing with the teeth of flywheel (**M**), it continues to travel in mesh until (**M**) comes in contact with sleeve (**H**). It then pushes (**H**), the whole clutch assembly, and driving gear (**D**) in the same direction and compresses the clutch spring (**L**).

When the members are in this position there is sufficient pressure between the face of the driving gear (**D**) and the clutch member (**E**) to cause the clutch to transmit to the drive shaft the power required for cranking. This it continues to do until the engine begins firing.

When the engine starts the pinion (**M**) is rotated faster by the flywheel than by the electric motor. It therefore screws itself to the right and out of mesh with the flywheel teeth. On coming out of mesh the pinion is cushioned by the spring (**O**).

CRANK-SHAFT APPLICATION OF STARTING MOTOR

The starting motor can be connected with the crank shaft by means of gears or chains.

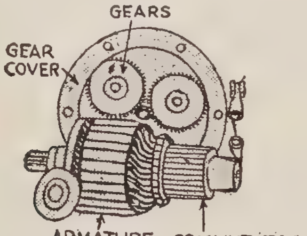

Fig. 21

When connected with the crank shaft by gears, there is usually a reduction of gears encased in the motor housing, as shown in Fig. 21, which permits a reduction of speed, as the starting motor speed is too great for connecting direct to the crank shaft.

Fig. 22. Showing application of starting motor to crank shaft by gears. Note that the clutch is in gear (B). The gears are all out of mesh after the motor serves its purpose. (Westinghouse method formerly used on the Davis car.)

An application of a starting motor and generator, where the starting motor drives through a chain and sprocket and the generator is driven through a chain by means of a sprocket and an over-running clutch, is shown in Fig. 23.

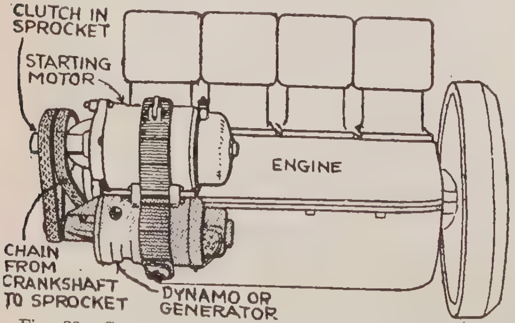

Fig. 23. Starting motor driving the crank shaft by means of a chain through a clutch in the sprocket.

Note that the clutch is in sprocket. Both chain and sprocket run with the engine, but the clutch in sprocket cuts out the motor after the engine is started. (This system was formerly placed by the Gray & Davis Co. on the 1914 Overland.)

The starting motor is started by current from a storage battery, thus starting the engine by means of a silent chain connected with a sprocket on the crank shaft of the engine. After the engine is started, the sprocket to which the starting motor chain is connected is then operated by the crank shaft of the engine. The action of the roller clutch permits the two sprockets to run free of the starting motor; thus the generator is operated from the crank shaft without operating the starting motor.

Just how this clutch permits this action is explained as follows.

Action of the Roller Clutch

The roller type of clutch is a popular type of clutch and its action should be studied carefully. In fact, this type of clutch is now used on a popular make of motor-generator, the Delco, as explained farther on; but it is used in a different manner from that shown with this Gray & Davis system.

Fig. 23C. Gear **B** attached to starting motor armature shaft. Part shown by Fig. 23B fits over gear **B** and attaches to motor housing.

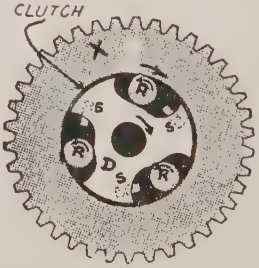

Fig. 23D

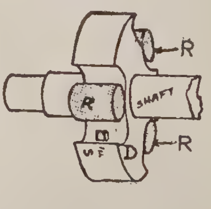

Fig. 23E

Figs. 23D (left) and 23E (right). Showing parts of the roller clutch.

A reference to Figs. 23A to 23E shows that the starting motor is geared, by means of reduction gears (A) and (B), to clutch member (D).

When starting the motor, the armature shaft is made to revolve by current from the battery; then (D) becomes the driving member and turns in direction shown by arrow point (D, Fig. 23D), causing rollers (R) to roll outward and clutch against the inner surface of sprocket (X), thus transmitting the power through (D) to (R), to gear (X), then by the silent chain to the crank shaft of the engine.

After the engine is thus started and the motor switch is off, then the engine drives sprocket (X), which becomes the driving member instead of (D). This reversed action causes rollers (R) to roll in an opposite direction and against spring stops (S), thereby releasing the clutching action to the inside of (X). The result is, the double sprocket over-rides clutch (D). Therefore when the engine is running, clutch (D) and gears (A) and (B) and the starting motor are idle.

Starting Motor Direct on Crank Shaft

On some cars, the starting motor is mounted directly on the crank shaft by having the armature built into the flywheel. This eliminates the necessity of gears or chains. The motor is a slow-speed machine.

An example of this construction is the U.S.L., as used on the Jeffrey (see Index under "U.S.L. motor-generator").

TYPES OF STARTING MOTOR SWITCHES

A foot-operated starting switch for the automatic "pinion shift" drive such as the "Bendix," is shown in Fig. 24. Contact is closed at (a) and (d) when (B) is depressed.

The foot-operated starting-motor switch is the one in general use, and while the construction may vary, the principle is much the same as in Fig. 24.

An electromagnetically-operated switch (Fig. 25) is used in connection with the "electrically operated automatic pinion shift" as shown on page 322. The operation of this switch is controlled by the push-button switch (Fig. 25A), mounted on the dash.

On many of the Delco systems the starting switch is eliminated by raising the starting motor brushes at the same time the gears are meshed with the flywheel (explained farther on, under the instruction on the Delco system).

Fig. 25. Electro-magnetically operated starting switch automatic pinion shift.

Fig. 25A. Push-button switch for magnetically operated starting switch.

RELATION OF THE STORAGE BATTERY TO THE STARTING MOTOR

The electric current is supplied to the starting motor from a storage battery. The voltage is usually 6 volts, but some systems use 12 or 18 volts, others 24 volts.

Direct electric current only, is used for starting motors.

The voltage of the storage battery can be ascertained, by counting the number of cells. For instance, if there are three cells, then the battery is a six-volt battery. If there are six cells, it is a twelve-volt battery. Each cell gives two volts—no matter how large or how small.

The amperage, or quantity of current consumed by a starting motor varies according to the condition of the engine. If it is cold and the oil is congealed, it will require more power to turn the crank shaft of the engine over, than if it is warm and flexible. The average length of time the starting switch is down is about 10 seconds. Therefore, with this great quantity of current being drawn from the battery, large heavy plates as well as large connections from one cell to the other are necessary. Large wire or cable for conducting the current to the motor is also necessary.

The average cranking current is 250 to 300 amperes when starting a cold stiff engine, and about 150 to 200 amperes when starting a warm flexible engine, for, say, one-half of a second, then 120 to 150 amperes after the engine flywheel is in motion. The voltage of a charged battery, when being used for starting, drops to approximately 5.4 volts. (This subject is further treated under the heading, "Storage batteries.")

The overload on the battery, it will be noted, is considerable. In fact, it is a temporary dead short-circuit for an instant, but, being only momentary, a good battery will stand it.

Charging the Battery

A starting and lighting storage battery, could be charged by removing it from the car and taking it to a charging station. But if this were done, owing to the great amount of current used, the size of the battery required, in order to last for a satisfactory period of time, would necessitate entirely too large a battery. Therefore a dynamo, also termed a "generator," is operated from the engine. When the engine is running the car at a speed of eight miles or more per hour, this generator generates electric current and charges the storage battery. The generator is treated in the next instruction.

Grounding the Battery

Sometimes the positive (+) terminal of the battery is grounded, and sometimes the negative (−) terminal is grounded. On many of the Westinghouse electric systems the (+) is grounded. On many of the Delco electric systems the (−) is grounded; that is, if the wiring system is a "single-wire grounded" system instead of a "two-wire insulated" system.

If the negative (−) terminal of the battery is grounded, then the negative (−) brushes of the motor and generator must also be grounded.

If the positive (+) terminal of the battery is grounded, then the positive (+) brushes of the motor and generator must be grounded.

STARTING MOTOR WINDINGS

The construction of a starting motor is similar to that of a generator, with the following exceptions:

The windings on the field poles are "series," or "series-parallel," wound instead of "shunt" wound, as on a generator. This gives greater **starting torque.**

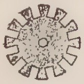

Fig. 1A

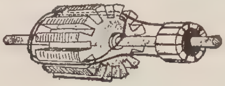

Fig. 1

The armature on a starting motor consists of many coils of very heavy wire, and is of a drum-wound type (Fig. 1). The core of the armature is made of laminated iron with slots for the coils (Fig. 1A). The armature winding on a two-pole starting motor is usually a "lap winding" with one coil per slot. The winding on a four-pole starting motor is usually a "wave winding."

The commutator has as many segments as there are coils. There is usually one coil for each slot on starting motors, and two coils per slot for generators.

The brushes rest on the commutator and conduct the current from the battery to the armature coils. The brushes are in series with the battery, field, and armature circuit.

Field poles: Starting motors usually have four poles and four brushes. A two-pole motor or generator is said to be of the "bi-polar" type, and a four-pole, of the "multi-polar" type.

When the multi-polar field is used the conductors on the armature, revolving between them, cut the magnetic lines-of-force many more times in one revolution, so that as the size of the machine increases the speed decreases—which is an advantage.

A Remy four-pole round-frame type of starting motor, with "series" field winding is shown in Fig. 2.

The circuit is from (+) of battery, through starting switch, through four field coils, to (+) brushes, through the armature, out (−) brushes, to (−) terminal of battery. This would be termed an "insulated," or "two-wire" circuit.

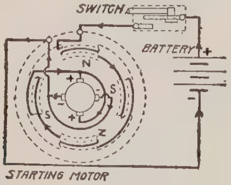

Fig. 2

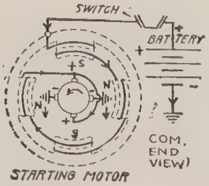

Fig. 3

Practically the same circuit is shown in Fig. 3 as in Fig. 2, except that the return circuit from (−) brushes to (−) grounded terminal of the battery is through a grounded return through the frame of the car.

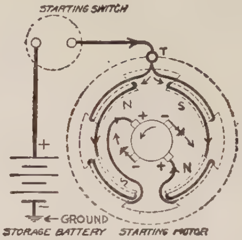

Fig. 4

A Remy four-pole starting motor is shown in Fig. 4, with a "series-parallel" field winding. The circuit is from (+) of the battery, through the starting switch, to (+) field terminal (T) on the generator. The current divides here; part going through the two-field coils on the left and right respectively, to (+) brushes, through the armature, out (−) brushes, to ground through the frame of the motor and car, to (−) terminal of the battery.

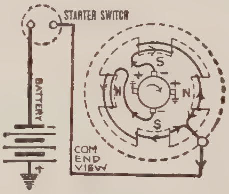

Fig. 5

The same "series-parallel" field winding is used in Fig. 5, but in this example, the (+) of battery is grounded instead of the (−). **The circuit is then** from (+) ground of battery, to grounded (+) brushes, through the armature, out (−) brushes, through the two-field coils on left and right, to the starting switch, to (−) terminal of the battery.

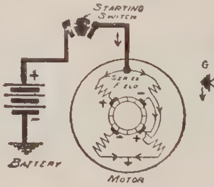

Fig. 6

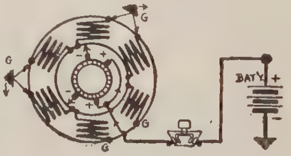

Fig. 7

A Delco four-pole round-frame type of "series-parallel" field winding is shown in Fig. 6. The circuit is from (+) of battery, through the starting switch, to the two-field coils, to (+) brushes, through armature, out (−) brushes, through the two-field coils, to ground to motor, through ground of the frame, to (−) grounded battery terminal.

A Simms six-pole round-frame type of "series-parallel" field winding is shown in Fig. 7. There are six field poles and six field windings and four brushes. One end of each field coil is grounded to the frame of the motor; the other ends connect to a (−) brush ring which connects to two (−) brushes.

The circuit: From (+) of battery, through the starting switch, through (+) brushes, through the armature, out (−) brushes to (−) brush ring, through the six-field windings in parallel, to ground (G), to the frame of the motor, to (−) grounded terminal of the battery. This is the type used on the 1920 Maxwell.

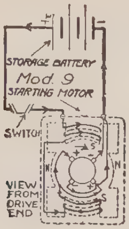

Fig. 8

A Remy rectangular frame "series" field-wound motor with two "active poles" with field windings on them and two "dead poles" without windings is shown in Fig. 8. Note the polarity of the poles.

The circuit: From (+) of battery, to the switch, to the top field coil, to the lower field coil, to (+) brushes, through the armature, out (−) brushes to (−) of battery.

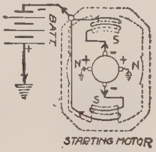

Fig. 9

A Remy rectangular frame motor "series-parallel" field wound is shown in Fig. 9.

The circuit: From (+) of battery, to ground, to (+) grounded brushes, through the armature, out (−) brushes, through the field coils, to (−) of battery; series-parallel circuit.

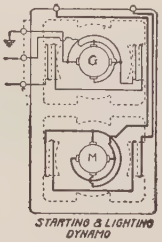

Fig. 10

A Remy "double-decker" motor and generator is shown in Fig. 10. The top circuit is that of a "shunt"-wound generator. The lower circuit is that of a starting motor "series" wound.

A motor-generator differs from Fig. 10, in that both the generator and motor field windings are on the same field poles, and only one armature is used. See Index under "Motor-generators."

Polarity of Field Poles

The polarity of the field poles of a motor is the same as that of the field poles of a generator. See Index.

PRINCIPLE OF A STARTING MOTOR

We will assume that there are two field poles wound as shown[1] in Fig. 14, so that the (+) current from the battery flows to series field winding (**F**), which would make a N pole of it, because the current from the battery flowing through the wire causes magnetic whirls in a direction which would make it a N pole (see Index under "Electro-magnets"). The battery (+) current is then to field winding (**F1**), which would make a S pole of it. Thus we have the main magnetic field flowing from N to S pole.

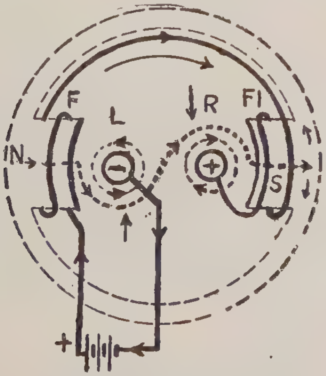

Fig. 14

The battery (+) **current** is then to field winding (**F**), to (**F1**), to armature coil (**R**), and the current is going in. Note that the magnetic whirl around this armature wire coil is the same direction at the top as the main magnetic field which is passing from the N to S pole, but at the bottom of (**R**), it is in the opposite direction.

After (+) battery current passes through this (**R**) side of the armature coil, it comes out at the wire (**L**) side, and the magnetic whirl at the top of (**L**) is in the opposite direction to the main magnetic field (from N to S pole), and at the bottom of wire (**L**), it is in the same direction.

Therefore we have two magnetic fields to deal with, one, the "armature magnetic field," which is set up around the armature wires (**L**) and (**R**), and the "main magnetic field," from the N to S pole.

Magnetic lines-of-force cannot flow in opposite directions in the same space at the same time. Thus the main magnetic field or lines-of-force from the N to S pole, pass under wire (**L**), and being in the same direction as the armature coil magnetic field lines under (**L**), they add to and strengthen the field below (**L**), and thus give a lifting effect to wire (**L**).

The main magnetic field then passes over wire (**R**), because the lines at the top of (**R**) are in the same direction, and thus the strength of the main magnetic field is added to that of the armature coil (**R**) field, giving a push-downward effect.

The lines-of-force can be considered as elastic bands that are always trying to shorten. Thus we see why the left side of the coil will be pushed upward and the right side will be pushed downward, which of course acts to produce rotation of the coil if it is pivoted and free to rotate. Thus in Fig. 14, we should have a clockwise rotation as indicated by the arrow.

---

[1] In this example we will omit the brushes and use only one coil of wire which is supposed to be wrapped around the armature, with end of coil (R) connecting with (+) brush, and the (L) end of the same coil with (−) brush. Also note that on Fig. 14 the (N) designating the North-pole end of the left field pole should be on the inner end instead of next to the frame, as the magnetic lines-of-force flow out of the N end, across the air gap, to the S pole end, through the frame, to the N pole end again. The magnetic circuit is treated farther on; see Index.

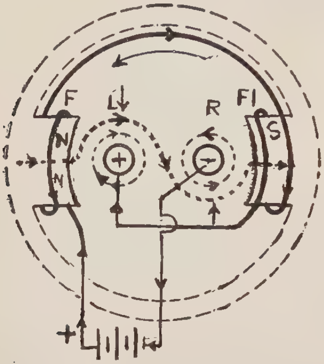

Fig. 15

Note that the wires are reversed from battery to armature coil in Fig. 15. Therefore the direction of the current flow from the battery in armature coil (**L** and **R**) is reversed, but not the main magnetic field. Thus the direction of rotation of the armature is reversed.

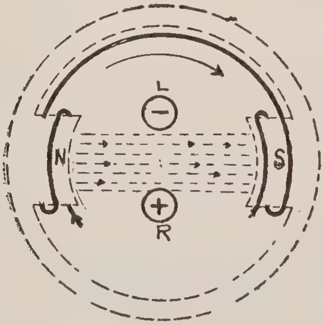

Fig. 16

If there was but one coil on the armature, as in Fig. 16, when (**L**) and (**R**) reached a vertical position, the main magnetic field or lines-of-force would pass directly across from the N to S poles, and if the coil should stop in this position there would be no effect of rotation, no matter how much current was in the coil, or how strong the magnetic field.

If two coils of wire (Fig. 17, **L** and **R** and **L1** and **R1**) are used, with their four terminals connected to a four-segment commutator (**17A**), then by placing the brushes (**B**− and **B**+) as shown, it is possible to obtain a continuous rotation. This is true because the sides of the coil (**L**) and (**R**) are in a horizontal position and are in the path of the main magnetic field and connected in the circuit by the brushes, whereas the sides of the coil (**L1**) and (**R1**) are in a vertical position and are disconnected from the circuit; but as rotation starts, then (**L**) and (**R**) would be disconnected from the brushes and (**L1**) and (**R1**) would be connected, thus establishing a continuous rotation.

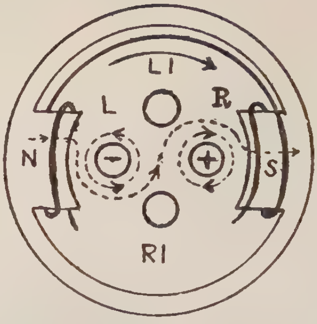

Fig. 17

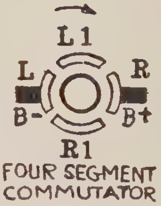

Fig. 17A

By using a number of coils and equally as many commutator segments the magnetic force acting on the coils will be more continuous.

This armature would be termed an "open-circuit" armature and would not be satisfactory for direct current, as only the coil connected by the brushes is in use.

A closed-circuit type of armature is more efficient, because all of the coils are used, one side being negative and the other side positive, or, in other words, the (+) brush would connect with the coils on one side of the armature and the (−) brush with the coils on the other side.

If a four-pole type, there would be four sections of coils connected to four brushes, two sections and two brushes being (+), and the other two sections and brushes being (−).

A generator can be operated as a motor, but is not as powerful because its field winding is of small wire and the same quantity of current would not pass through it as in a starting motor. It is wound for about 20 to 25 amperes.

A starting motor could be used as a generator, but would be of very low voltage, in fact impractical, because the wire is very large and intended for a very high quantity or rate of flow of current. It is wound for about 100 amperes or more.

To Reverse the Direction of Rotation of a Motor

From the explanations in connection with Figs. 14 and 15, it is seen that if the direction of either the magnetic flux or the current through the armature or field is reversed, the motor will revolve in the opposite direction. In order, then, to reverse the direction of rotation of a motor, we can **interchange** either the **field leads or the armature leads.**[1]

STARTING MOTOR BRUSHES

Thus two brushes are used on a two-pole motor or generator, and either four or two, on a four-pole.

If two brushes are used on a four-pole motor or generator, then they are placed 90° apart.[1] It is the usual practice however to use four brushes on a four-pole motor, owing to the heavy current they carry.

Brushes used on motors are made of a composition material something like carbon and graphite. Copper gauze brushes are also used on some of the starting motors, for reasons stated farther on. Generator brushes are made of carbon and have more resistance than motor brushes (see Index, under "Generator brushes").

---

[1] See also, Index under "Generator brushes."

[1] A. L. Dyke, St. Louis, Mo., is in a position to furnish books giving data for testing starting motors, generators, etc., of all makes. Write for circular.

Remy Instructions on Starting-Motor Brushes

Copper gauze brushes are used on starting motors because they give the lowest contact resistance on the commutator and allow the maximum current to flow through the motor at a given voltage. This permits the motor to develop its maximum torque. Two brushes on each motor are impregnated with petrolatum to provide lubrication. Under normal conditions this should be sufficient for the life of the car. Copper gauze brushes should be fitted to the commutator by tapping them lightly.

It sometimes happens that a motor is operated under adverse conditions; perhaps the brushes are not properly seated or the rocker ring is not set in the position which gives the best commutation. In any of these cases there will be excessive sparking at the brushes and the commutator will become hot. This will cause the lubricant to melt and run out of the brushes. When this occurs there will be a cutting and burning action that will materially shorten the life of both commutator and brushes.

In order to take care of these conditions it is advisable to use **brushes made of a mixture of copper and graphite.** These may reduce the maximum torque of the motor, but the difference is so slight that it can scarcely be noticed. They will give better commutation and are self-lubricating.

When new brushes are required at short intervals by a starting motor, examine it carefully to make sure that the trouble is not due to a shorted field or a damaged armature. Remember that any kind of trouble in a starting motor will usually cause damage to the commutator.

Copper-graphite brushes should be ground in with sandpaper in the same way that generator brushes are seated. The brushes should be located approximately on electrical neutral, which will be found at the center line of the poles. Moving the brushes in a direction opposite to the rotation of the armature will improve commutation, but will decrease the torque of the motor.

Never undercut the mica in starting motor commutators. (The subjects of undercutting mica and seating brushes, etc., are explained under a separate instruction farther on.)

Setting brushes on motors. Motor brushes should be set at the position of least sparking when the machine is carrying full load. This position will be located a short distance back (in the direction opposite to rotation and the reverse of the direction for generator brushes) from the neutral plane.

To set motor brushes in the correct position, place the machine on block test and apply a load approximately equal to that which it is normally required to carry. (This load will be about 40 lbs. on a pulley of 6″ diameter, or 10 ft. lbs. for starting motors; see Index under "Torque test of a starting motor.") The speed of a motor is greatest when the brushes are at the neutral plane and decreases as they are moved away from that position.

The voltage of a generator and speed of a motor can be changed considerably by moving the brushes, providing the machine is not so heavily loaded as to cause it to spark badly.

PARTS OF A STARTING MOTOR (N.E. USED ON THE REO AS EXAMPLE)

As an example of **the internal construction of a starting motor,** the North-East "model R" starting motor, as used on the Reo "models T6 and U6" car is shown.

The starting-motor internal construction, so far as the armature, the commutator,the brushes, etc., are concerned, is very much the same on all starting motors. Thus Fig. 18 will give a good general idea as to the location and name of parts. Note the heavy coarse winding on the armature and field coils, which is necessary in order to carry the heavy current.

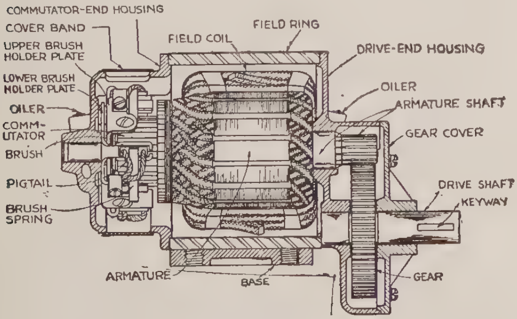

Fig. 18. Four-pole, straight series-wound starting motor

The drive method in general use is the "Bendix drive system," through the flywheel, as explained on page 319.

On the Reo starting motor (Figs. 18 and 18A), the drive method is through the transmission shaft, through the clutch to the flywheel. The gear-shift lever, of course, must be in neutral position.

The construction and action of the drive system used on the Reo is as follows:

The starting motor (Fig. 18) is mounted on the right-hand side of the transmission where it can be reached by raising the floor board. It cranks the engine through a chain drive operated in conjunction with a ratchet engagement (Fig. 18A) on the universal joint shaft.

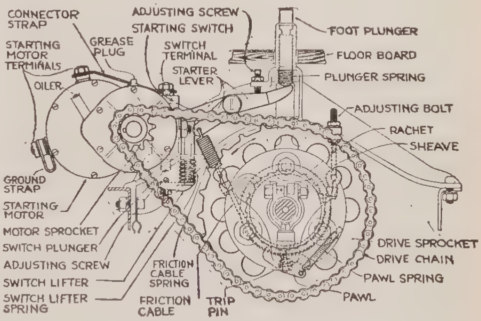

Fig. 18A

The ratchet is controlled by the starting switch pedal, so the motor is in action only during the actual period in which the starting switch is closed.

Under average conditions it will crank the engine at a crank-shaft speed of approximately 100 r.p.m., depending upon the condition of the battery. The cranking speed will of course be materially reduced in extremely cold weather, or in the case of a discharged battery.

Starting Action

To crank the engine by means of the starter, first make sure that the clutch pedal is in the driving position and the **gear-shifting lever is in neutral** (the starter cannot be operated with the gears in mesh), and **be sure to retard the spark lever fully.**

Next turn on the ignition and press down the starter push-rod. Hold the starting switch closed until the engine begins to run on its own power, and then release it at once. Finally, advance the spark to the running position and adjust the supply of gas as required.

Depressing the foot plunger (Fig. 18A) puts the starting ratchet into engagement and at the same time the switch is closed to complete the starting circuit.

The starting lever is forked, one arm operating the switch contactor and the other acting upon the friction cable.

When the starter push-rod is depressed by the driver's foot, the friction cable is thus tightened so as to retard the starter sheave. This allows the trip-pin to enter its slot in the sheave and cause the pawl to engage with the ratchet, whereupon the universal shaft and the starting sprocket are made to rotate as a unit. When the engine "picks up" and begins to run under its own power, the ratchet will be revolved faster than the sheave and sprocket, and the pawl will be thrown out of engagement. As soon as this occurs the starter push-rod should be released at once to remove the tension from the friction cable and also to open the switch contacts. This entirely disconnects the starting motor mechanically as well as electrically, and permits it to remain inoperative until the next time it is called upon to crank the engine.

The starter mechanism should be kept adjusted so that the friction cable has just enough tension to retard the sheave properly at starting and at the same time avoid holding the ratchet in partial engagement after the starter push-rod has been released. This adjustment is accomplished by modifying the tension on the friction cable by means of the nut and stud provided for the purpose. The need of adjustment will be evidenced by the starting motor tending to run without turning the universal shaft or by its starting the shaft with a severe pound, indicating that the pawl does not engage as quickly as it should.

The generator, a two-pole, third-brush regulated machine, and ignition are separate units. The generator is driven through a flexible coupling, similar to a magneto drive, on the left-hand side of the engine.

The ignition unit is mounted on the rear of the engine and is driven at cam-shaft speed from the cam shaft.

Delco Starting Motors

The Delco starting motor is treated under the Delco instruction.

STARTING-MOTOR TROUBLES

Starting-motor troubles, both "electrical" and "mechanical," are treated under "Digest of Troubles" (see Index). A few of the common starting motor troubles are given below.

If the starting motor fails to start, the trouble is usually due to one of the following causes:

1. **Battery almost or entirely exhausted,** the indications of which are that the lights burn dimly, especially when attempting to start the engine. Test battery for specific gravity and recharge from an outside source.

   Where a car is used a great deal in cases where frequent cranking is necessary, or where it is run at nights and very little in the day time, the probabilities are that the generator will not keep the battery fully charged. The generator should be adjusted for its highest charging rate under these conditions, and it may be necessary to have it recharged at an outside source occasionally, especially during cold weather when the engine is cold and stiff, since under these conditions it requires more current for the motor to start the engine.

2. **Loose connections or open circuit:** Loose connections would cause the motor not to operate at its full capacity, as the loose connection would cause resistance to the flow of current.

   Loose connections would include examination of such parts as the terminals of the battery, grounded battery terminal to the frame of the car, motor terminal, grounded connection inside of the motor where it terminates with a screw, and the switch connections.

   Loose connections at the brush terminals and brushes not seating properly, or worn short, are common troubles with starting motors which have been run for a long time.

   An open circuit would of course prevent the starting motor from operating at all.

3. **Starting switch not making proper contact:** The switch connections should be examined. When the switch connections are suspected, connect a jumper across the switch terminals. If the motor spins, the starting switch is defective inside. Should the motor fail to start, then you will know the trouble is elsewhere.

4. **Dirty or greasy commutator:** This would prevent the starting motor from working up to its capacity.

   See Index under "Commutator troubles." Oil or grease should never be put on the commutator.

5. **Inoperative motor:** Some of the causes would be, run-down battery, brushes not seating, open circuit at terminals or ground connections, or switch.

6. **The Bendix drive may be out of order.** See page 320.

Testing Starting Motors

Torque-test explanations and other tests can be found by referring to the Index.

INSTRUCTION No. 32

THE ELECTRIC GENERATOR: Construction and Principle; Armature Windings

PURPOSE OF THE GENERATOR

The purpose of the electric generator on an automobile **is to supply direct electric current for charging the storage battery,** for lights, for ignition, and also for the electric horn, when it is being run fast enough to generate sufficient voltage to close the cut-out points between the generator circuit and the battery circuit.

If the battery is a three-cell, six-volt battery, **the generator voltage** should be slightly more than the battery, or about 6.5 before the cut-out points would close. The generator generates this voltage, on an average, when the car is driven at about 8 miles or more per hour on high gear, and the current passes through the ammeter on the "charge" side.

When the generator is driven at speeds less than this, then the cut-out points remain open and the ignition, lights, and horn are dependent upon the battery for its electric supply. In this case the current passes through the ammeter on the "discharge" side.

The battery always supplies the electric current for the starting motor to crank the engine. The current is never taken from the generator for this purpose, for two reasons. One reason is that the engine is idle and not running when it is desirable to use the starting motor, and thus generator is not generating any current at all. The second reason is that the generator seldom delivers over 22 amperes at the most, whereas the starting motor requires from 120 to 250 or more amperes to start the engine.

The charging current from the generator to the battery is taken through the ammeter, but the current from the battery to the starting motor is never passed through the ammeter, because the ammeter on the cowl board seldom reads above 30 amperes, and thus would be burned out.

Water Analogy of the Electric System

In order to simplify the electric system on an automobile, a water analogy is given below.

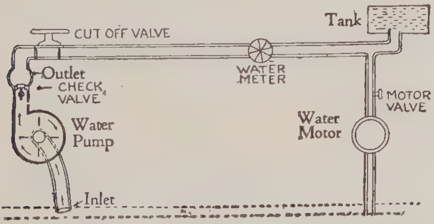

Fig. 1

The water pump (Fig. 1) is driven by some mechanical force and draws water from a source at the inlet. The water is forced through a check valve into and through the pipe, through the water meter to a tank. The check valve prevents the water flowing back to the water pump when it is not in operation, or when it is not running at sufficient speed to force water to the tank.

A water motor can be driven from the pressure of water from the tank.

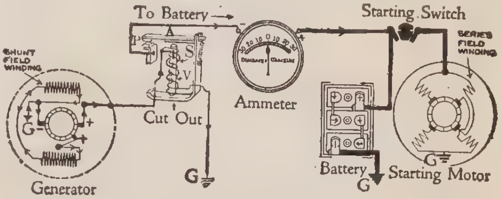

Fig. 2

The electric system (Fig. 2) is similar. The generator generates electricity from the magnetic lines-of-force at the field poles, around which are the shunt field windings; it then forces the electricity through the wires, through the cut-out (acting as a check valve), through the ammeter which shows the rate-of-flow of electricity in amperes, in the same manner that the water meter shows the rate-of-flow of water through the pipe, thence to the storage battery, which is similar to the tank.

The cut-out prevents the battery from discharging back into the generator.

The starting motor (like the water motor) can be operated by current from the battery (it cannot however be operated from the generator).

A point which must be considered, is **the speed of the pump.** If its speed was too great, it would produce a greater pressure, and consequently a greater rate-of-flow of water. This could be regulated with an automatic governor.

Just so with the generator. If the **speed of the generator** were increased, the e.m.f., or pressure, increases, and consequently the rate-of-flow of current in amperes is greater. The probabilities are that at very high speeds the voltage (e.m.f.) generated would be so great that the lights would be burned out. For this reason an action similar to a governor action is made use of on generators, in order to **regulate the output of the generator,** or to keep the voltage constant, or the amperage constant, or both, at various speeds of the generator, as it increases or decreases in speed, when the engine is speeded up or slowed down.

A mechanical governor was used on some of the early models of generators, but is now practically an obsolete method, and instead, a third-brush method is now more generally used, as will be explained farther on.

The regulation method as used in the generator (Fig. 2) is a third-brush method of regulating the output of the generator (see lower brush connecting with the field winding. This principle is explained farther on).

The subject of the regulation of a generator, or methods of governing the output at high speeds, is therefore one of considerable importance and will be treated farther on.

ELECTRICAL CIRCUITS; THEIR RELATION

Before proceeding farther, it is advisable that the reader clearly understand the circuits of the electrical system.

The circuit of a typical electric system is shown in Fig. 3. When starting to trace an electric system, always divide the system into the parts mentioned below.

When starting to trace one of the "eight" circuits, begin with the source of electric supply. For instance: the "generator field circuit," the "cut-out voltage circuit," the "battery charging circuit," would each begin with the (+) brush of the generator.

The "starting-motor circuit" would begin with the (+) terminal of the battery, and likewise the "ignition" and "horn" circuits, unless the engine was running at such a speed that the current for "ignition," "lights," and "horn" would be taken from the generator, in which instance, begin with the (+) brush of the generator.

The several circuits are:

1. Generator "field circuit."
2. Cut-out "shunt or voltage circuit."
3. Battery "charging circuit."
4. Battery "discharge circuit" back through cut-out.
5. Starting "motor circuit."
6. "Ignition circuit"; primary and secondary.
7. "Lighting circuit."
8. "Horn circuit" (not shown in Fig. 3).

Generator Circuits

Taking the generator field circuit first, always start with the (+) main brush of the generator. If the brushes are not marked (+) or (−), then look at the battery, as it usually indicates which terminal is grounded. And we know that the current from the generator to charge the battery must come from the (+) brush and pass into the (+) terminal of the battery, because direct electric current always flows from (+) or positive.

Therefore, if the (+) terminal of the battery is grounded, then the (+) brush of the generator must be grounded. In this example (Fig. 3), the (−) terminal of the battery is grounded at (G2); therefore the (−) brush of the generator is grounded at (G).

When tracing the field circuit, the regulation generator system is always included in this circuit. For instance, the generator in Fig. 3 uses a "third-brush regulation" system (explained farther on), and the third brush (lower brush on the right) always connects with one end of the field windings. The third brush may be connected with the (+) or (−) end. In this instance it is connected with the (−) end.

The field circuit therefore starts with the (+) main brush of the generator, through both shunt field windings (this is a two-pole generator), to the (−) third brush, through the armature to the (+) main brush (B). This completes the field circuit. The generator field winding is a shunt-wound generator.

Purpose and Principle of the Cut-Out

The cut-out shunt or voltage winding circuit is from the (+) main brush to the fine wire voltage winding (V), to ground (G1), to the frame of the generator or car, to the grounded (−) main brush (G).

This cut-out voltage winding (V) consists of very fine wire wrapped around a soft iron core (C). Its purpose is to magnetize the core (C) so that the core will draw the iron cut-out armature blade (A) to it, thus closing the points (P), so that the charging current can flow from the (+) brush of the generator to the (+) terminal of the battery.

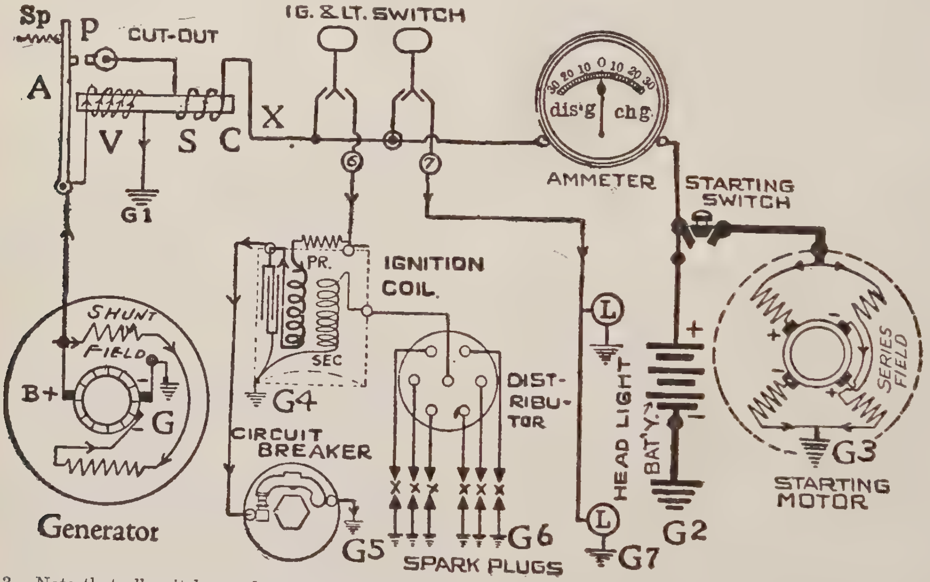

Fig. 3. Note that all switches and cut-out points (P) are open. The ammeter is at (O). Current is not flowing from the battery or generator. When current is being taken from the battery for ignition and lights, the ammeter needle goes to the "discharge" side. The ammeter is not connected with the starting motor circuit at all. When the generator is charging the battery, the current to the battery passes through the meter, and the needle goes to the "charge" side.

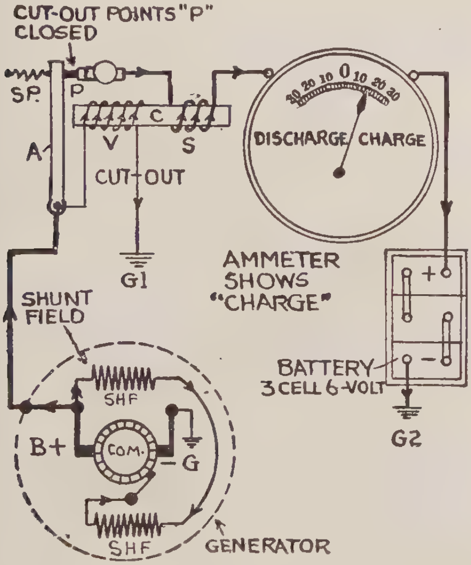
The cut-out voltage winding (V) is wound with such a size and number of layers and turns of wire, that it does not create enough magnetic force to draw the blade (A) against the tension of the spring (Sp.) until the generator speed is such that its voltage is higher than that of the battery, which is, in this example, about 6.5 volts.

Note that the current passes through this winding (V) whenever the generator is generating any current at all. Since the winding consists of very fine wire, however, the amperage is very slight.



CUT-OUT POINTS "P" CLOSED

AMMETER SHOWS "CHARGE"

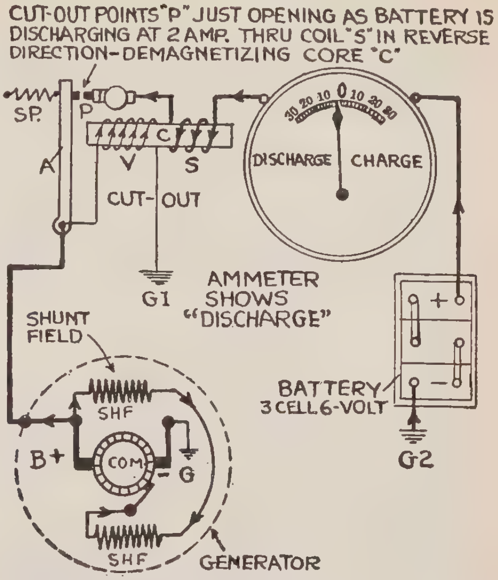
Fig. 4. Note that cut-out points (P) are now closed; therefore current from the generator is passing through ammeter to battery, and the needle is on the "charge" side of (O). About 10 to 15 amperes is usually the highest rate when the generator is running at 1,000 r.p.m. or more. 22 amperes is the extreme limit for which a generator can be adjusted, and with some generators 15 or 16 amperes is the limit.

Battery charging circuit: When points (P) on the cut-out are closed (Fig. 4), the path is from the (+) main brush (B) of the generator, through the closed points (P), through the series or current coil (S) of the cut-out, through the ammeter, which now shows the needle on the "charge" side of (O), to the (+) terminal of the battery, out to (−) terminal of the battery which is grounded (G2), to the (−) main grounded brush (G) of the generator.

Battery discharge circuit: If the generator speed drops to a point where the voltage of the generator is less than the voltage of the battery, the circuit would then be (see Fig. 5) from (+) of the battery, through the ammeter in a reverse direction to what it was in Fig. 4, thus causing the needle to go to the "discharge" side (showing about 2 amperes discharge), thence through series winding (S) of the cut-out in a reverse direction, through points (P), to the (+) main brush of the generator, through the armature to the (−) main brush, to ground (G), to the (−) grounded terminal of the battery (G2). The points (P) will instantly open when this circuit is completed.

The reason why the discharge through the series coil (S) of the cut-out is necessary, is to insure a quick demagnetization of the core (C).

Note in Fig. 4, that when current is flowing through the fine wire voltage winding (V) and the coarse series winding (S), the direction of the flow of current is in the same direction around the core. Thus a very strong magnetic pull is exerted by the core (C) with (A), and the polarity of one end of the core is N and the other end S.



CUT-OUT POINTS "P" JUST OPENING AS BATTERY IS DISCHARGING AT 2 AMP. THRU COIL "S" IN REVERSE DIRECTION-DEMAGNETIZING CORE "C"

AMMETER SHOWS "DISCHARGE"

Fig. 5. Generator speed is low, consequently the voltage of the generator has dropped to a lower voltage than the battery. The battery discharges for an instant through the ammeter and cut-out series coil (S) in opposite, or reverse direction, at about 2 amperes, thus demagnetizing core (C), and opening points (P). Note that the needle of the ammeter is on the "discharge" side of (O) during this operation. It will immediately go to (O) if the engine is stopped. If the engine is kept running (slowly) with ignition switch on, then the amount of current from the battery for ignition will be indicated on the "discharge" side. Or if the light switch is "on," the amount of current from the battery for the lights will be indicated on the "discharge" side. The generator, however, is cut out of the circuits at points (P).

When the current from the (+) terminal of the battery passes back through series coil (S) in a reverse direction, as shown in Fig. 5, this causes the series coil (S) to "buck," or oppose, the current flowing in the voltage coil winding from the generator, which is still flowing in its original direction. But, as the generator speed is low, the influence of the coil (V) is weak, with the result that coil (S) tends to change the polarity of the core (C), thus demagnetizing it, and causing a quick release of blade (A). For this reason the cut-out is often termed a "reverse current cut-out."

Starting-Motor Circuit

The starting motor circuit is never from the generator. The generator never delivers, at its highest output, over 22 amperes, and at times the starting motor requires from 150 amperes at normal conditions, up to 450 amperes or more if cold and stiff. This great overload on the battery is only momentary when first turning the engine over. After the engine turns over, the current is less, dropping to about 120 to 200 amperes.

Thus the starting motor never takes its current from the generator. The generator charges the battery and the battery supplies current for the starting motor.

Likewise the ammeter on the dash is never connected in the starting motor circuit, as it seldom reads higher than 30 amperes.

The starting motor circuit (Fig. 3) is from the (+) terminal of the battery, through the starting switch, through the "series-parallel" field windings, through the (+) brushes, through the armature, to the (−) brushes, to ground (G3), to (−) grounded terminal of the battery (G2).

Note that the field circuit of this starting motor is what is termed a "series-parallel" field circuit. There are four poles and four field windings. The current divides at the top and passes through two field coils, to the (+) brushes, through the armature to the (−) brushes, thence through the two lower field coils to ground (G3), to grounded (−) terminal of the battery (G2).

Ignition Circuit

Ignition: The ignition switch (6), which is shown open in Fig. 3, would first be closed. The circuit would then be from the (+) terminal of the battery (if the generator is running slow). In such cases, the ammeter would indicate a current "discharge" taken from the battery.

If the generator is running at a speed at which it is charging the battery, then the current for the primary ignition circuit would be taken from the generator, and the ammeter would be on the "charge" side.

The ignition primary circuit is, then, from the (+) terminal of the battery, or the (+) brush of the generator, to the closed ignition switch, to (6), to terminal on the coil, through the ignition resistance unit, through the primary winding (PR), to the coil terminal, to the insulated contact on contact-breaker, to the movable arm, to ground (G5), to the (−) ground of the battery (G2), or the generator (G).

The condenser is in the coil, and is connected across the grounded terminal (G5) and the insulated terminal of the contact-breaker.

The ignition secondary circuit is from the secondary winding of the coil (SEC), to the distributor, to the spark plugs, through the spark-plug gaps (X), to ground of the engine (G6), to ground of the coil (G4), to the secondary winding (SEC).

The lighting circuit is similar to the ignition circuit. The lighting circuit and ignition circuit almost always start at the (+) side of the ignition and lighting switch and circuits are traced from that point. The circuit would be (in Fig. 3) from the (+) terminal of the generator or battery, through the closed lighting switch, to (7), to the two lamps connected in "parallel," to ground, to (−) ground of the battery (G2), or (−) ground of the generator (G). See Index for "Wiring diagrams."

Floating a Storage Battery on the Line

This term refers to **the storage battery used in connection with a generator,** where the storage battery supplies current for lights, when the generator is running slow or not running at all, as explained heretofore.

The generator charges the battery and supplies current for lights when running at sufficient speed. If the speed of the engine is varied, the battery would be in use part of the time and part of the time the generator; the battery would then be "floating."

The "cut-out" would be changing from one to the other, owing to the variable speed of the engine.

Ammeter Indications

The ammeter is always placed in series with the circuit, and in Fig. 3 it would indicate on the "discharge" side of (O) when current is taken from the battery for ignition, lights, horn, or discharge back through the cut-out. When current is flowing from generator to battery, it would indicate on the "charge" side the amount of current flowing to the battery.

For instance, examples of the action of the ammeter will be given as follows:

If starting motor switch is closed: The ammeter would not be in this circuit at all, and is never placed in this circuit unless a "shunt" is used with it (explained farther on).

If the engine is idling, or not running at all, and lights and ignition switches are closed, and cut-out points (P) are open (Fig. 3): In this case the battery would be supplying the current and would be discharging. Thus current from the (+) terminal of the battery would flow through the ammeter to the ignition and light switches, through the circuits, to the (−) ground of the battery (G2), and in doing so, it would cause the ammeter needle to go to the left of (O), or the "discharge" side, and would indicate the amount of current being discharged or taken from the battery for ignition and lights. For instance, if the ignition consumed 2 amperes and the lights 5 amperes, the needle would indicate 7 amperes on the "discharge" side of (O).

Engine driving generator at a speed where generator is charging battery and cut-out points (P) are closed, and light switch open: We will assume that the maximum amount of current flowing to the battery from the generator is, at the rate of, say, 15 amperes. The battery would then be receiving a "charge" instead of "discharging"; thus the direction of the flow of current would be from the (+) brush of the generator, through the ammeter, to (+) of the battery in an opposite direction to what it did flow through the ammeter when discharging from the battery. Therefore, the ammeter needle would indicate on the "charge" side of (O) the amount of current flowing to the battery, or 15 amperes.

The ignition switch connection being at the left of the ammeter, the current required for ignition is, say, 2 amperes; therefore the actual amount of current taken from the generator would then be 17 amperes, but only 15 would show on the ammeter.

Note. All ammeters are constructed so that the (+) terminal of the ammeter is connected with the (+) terminal of the source being tested, and the needle will then move in one direction on the scale. If connections are reversed, the needle will read in the opposite direction. On ammeters used for testing purposes, the (O) (zero), is usually placed at the extreme left of the scale, and when connected properly the needle will pass to the right; if connected wrong it will pass to the left, thus indicating that the connections to the ammeter are not correct.

On dash ammeters, however, as shown in Figs. 3, 4, and 5, the (O) is placed in the center of the scale, so that it will indicate if a "charge" of current is going to the battery, or if the battery is being "discharged."

The "discharge" side on the dash-ammeter (Figs. 3, 4, and 5) is on the left, and the "charge" side is on the right of (O). This, however, varies, as some manufacturers reverse the order.

Engine driving generator at a speed where generator is charging battery, and cut-out points (P) are closed, and light switch is closed: In the previous example we assumed that the ignition switch was "on" and the light switch "open" and that 15 amperes was passing to the battery from the generator, after giving 2 amperes to the ignition, which would be indicated on the "charge" side of the ammeter. Therefore, if we throw "on" the light switch, and if the lights consumed, say, 5 amperes, then instead of the battery receiving 15 amperes, it would be cut down to 10 amperes. Thus 10 amperes would be indicated on the "charge" side as the amount of current flowing to the battery from the generator.

Take the case where the generator is running at sufficient speed to charge the battery, and cut-out points (P) are closed, and the ignition switch is closed but the light switch is open. Let us assume that the generator is running at sufficient speed to deliver 17 amperes. Then, the ignition switch being "on" and ignition consuming 2 amperes, 15 amperes would pass to the battery, and this would be indicated on the "charge" side of the ammeter.

If the light switch is now closed, and the lights take 5 amperes, then the rate of flow would be cut down to 10 amperes. Therefore 10 amperes would be indicated on the ammeter.

The point to grasp in connection with the foregoing explanations, is that when current is supplied from the battery, the more current that is taken from the battery for ignition, lights, etc., the greater the indications on the ammeter on the "discharge" side, because the battery is capable of giving a discharge supply, up to its capacity.

On the other hand, when current is taken from the generator, its output is limited by the speed of the generator, and if its maximum output is, say, 17 amperes, then as the different circuits are thrown "on," they reduce this maximum amount of current which would pass to the battery accordingly. Thus when lights are thrown "on," the "charge" side of the ammeter will indicate less current flowing to the battery.

The ammeter is placed, sometimes at one position and sometimes at another position, but is usually arranged so that as current is consumed from the battery for all purposes except the starting motor, it indicates the total amount on the "discharge" side of the ammeter and also shows the net amount of current flowing to the battery from the generator on the "charge" side. See Index for "Wiring diagrams"; see also the instruction on the Delco system for the location of the ammeter on various systems.

Suppose, however, that **the ammeter was placed at (X) on the left side of the ignition and the light switch.** What would the indications be?

Take the case where the **engine is idling and the cut-out points (P) are open,** with ignition and light switches closed. The "discharge" from the battery for both ignition and lights would not be indicated on the ammeter at all. The needle would stand at (O) because the circuit through the ammeter would be open at the cut-out points (P).

PRELIMINARY EXPLANATION OF THE CONSTRUCTION OF A GENERATOR

A round-frame, "bi-polar" (two field poles) **direct current** (dynamo) **generator** is shown in Fig. 6. The cut-out shown mounted on the generator is sometimes placed in the generator or on the inside of the dash.

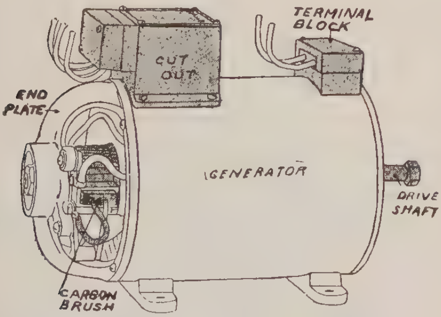


Fig. 6. A round frame bi-polar type of generator. Commutator and brush cover removed.

There are two "field poles" (PP) on the generator, shown in Fig. 7, and it is thus termed a "bi-polar" type. Around the field poles are windings. When the armature revolves, current flows through the field windings from the armature, and thus causes the field poles to become magnetized just like electro-magnets. Therefore the field poles (PP) are "electromagnetized."

When the field poles become magnetized, the lines-of-force pass from one pole to the other, and as the armature revolves between the poles, the lines-of-force are cut and current is generated.

The brush holders and brushes are mounted on the end of the generator, as shown in Fig. 8. The brushes rest on the commutator, as in Fig. 6.

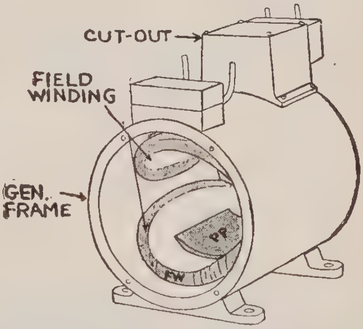

Fig. 7. End plate at drive end removed, showing field-coils or windings and one of the pole pieces (PP).

There are two carbon brushes on a bi-polar generator (placed 180° apart) and four brushes (or two brushes placed 90° apart) on a four-pole or "multi-polar" generator.

There are usually four field poles on a starting motor, due to the fact that considerable power is required and the pulling power of the "electro-magnetized" fields must be very strong.

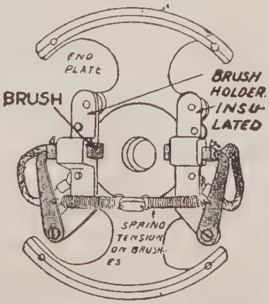

Fig. 8. The brush holder and brushes.

Armatures for generators are of "drum" type of construction. The "shuttle" type armature, as used on the magneto, cannot be used with a generator, as it generates and delivers "alternating" current, whereas only "direct" current can be used to charge a storage battery.

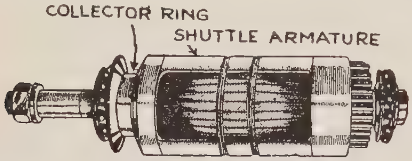

Fig. 9. A "shuttle" type of armature used on magnetos, which generates "alternating" current. Note that instead of a commutator, there is a "collector ring." Not suitable for a generator for charging a storage battery, used only on magnetos.

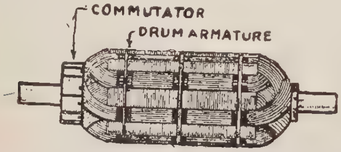

Fig. 10. A "drum" type of armature used on "direct" current generators which is suitable for charging batteries. All generators produce alternating current, but the "commutator" with two or more brushes direct the flow in one direction, thus establishing a positive (+) and negative (−) terminal at the brushes, whereas the current taken from a "collector ring" on a shuttle type armature alternates from positive to negative and vice versa.

All generators, generate alternating current, which is converted into direct current at the commutator.

The commutator has as many copper segments as there are coils on the armature. On many generators there are two coils wound in each armature core slot. There are thus twice as many commutator segments as slots.

Parts of an Electric Generator

A sectional view of a typical direct current generator is shown in Fig. 11.

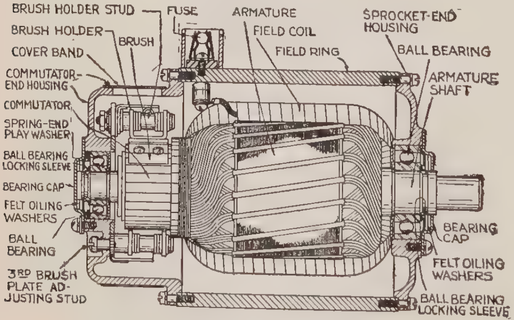

Fig. 11. Parts of the N. E. generator.

The parts are given in the illustration. A "drum" type of armature with a commutator is used.

Single-Unit, Two-Unit, and Three-Unit Electric Systems

A single-unit system (one type of the Delco system, as an example) combines a starting motor, generator (direct current), and ignition all in one machine. See Fig. 12.

The one armature and one set of field magnets serve for both the motor and generator. Thus it is termed a "motor-generator." There are two separate windings and two commutators, however.

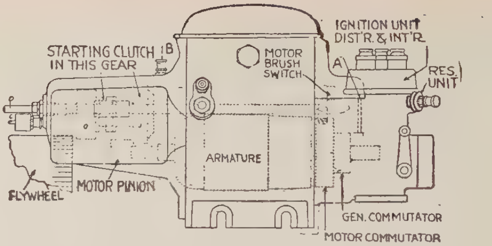

Fig. 12. Parts of the Delco motor-generator; a "single-unit" system.

Ignition timer and distributor are mounted with this unit, but the distributor-drive spiral gear is not attached to the armature shaft, as would naturally be inferred, but is connected to the pump shaft, or shaft driving the generator. In other words, if connected to the armature shaft the action of the clutch used in connection with the generator drive (not shown above) would affect the timing operation.

A two-unit system is where there are two units composing the electric system of starting motor, generator, and ignition, arranged as described below.

Where the starting motor and generator are combined in one unit and the magneto (or coil and distributor) for ignition in another, it is called a "two-unit" system; so also, when the starting motor is in one unit, and the generator and ignition in another, this is also a "two-unit" system.

The three-unit system is where the starting motor, generator, and ignition unit are separate from each other.

Methods of Driving the Starting Motor, Generator, and Ignition Unit

The generator must run when the engine runs, because it is necessary to recharge the battery and supply current for lights and ignition. Current for starting the motor, and also for the ignition to start the engine is provided by the battery.

The amount of current the generator supplies to the battery depends upon the number of lamps burning, and the speed of the engine.

Drive methods: The electric generator can be operated by belt, chain, shaft, or gear drive from the engine, and supplies electric current to charge the storage battery, as well as for lights, ignition, etc.

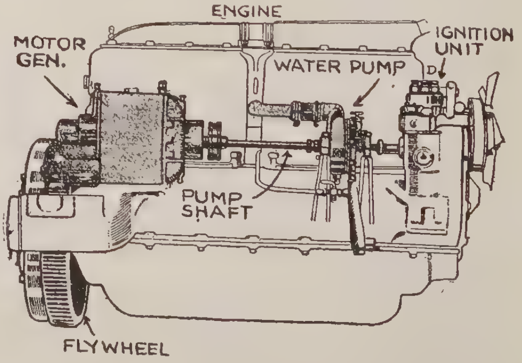

Fig. 13. Generator and motor combined. One armature serves for both. Generator driven from pump shaft, also distributor and timer. Starting motor drives through the flywheel. Delco system used on Hudson and others. This system would be termed a "two-unit" system, because the ignition unit is separated from the motor and generator.

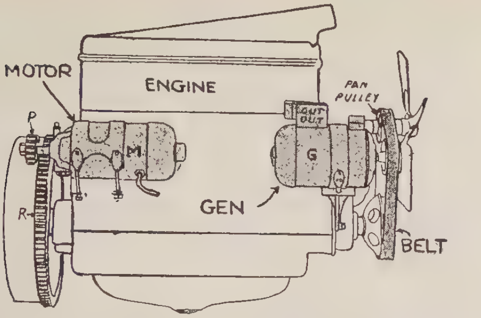

Fig. 14. **Generator driven by belt** which drives the fan. Starting motor is the "automatic Bendix drive," which drives through pinion (**P**) to flywheel gear (**R**). This system would be termed a "three-unit" system. The ignition is driven from cam shaft separately.

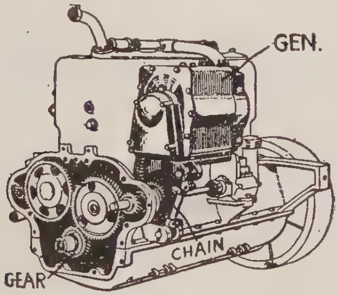

Fig. 15. **Generator, driven by gears and silent chain from crank shaft.** Ignition and starting motor (not shown) are separate units. This would be termed a "**three-unit**" system.

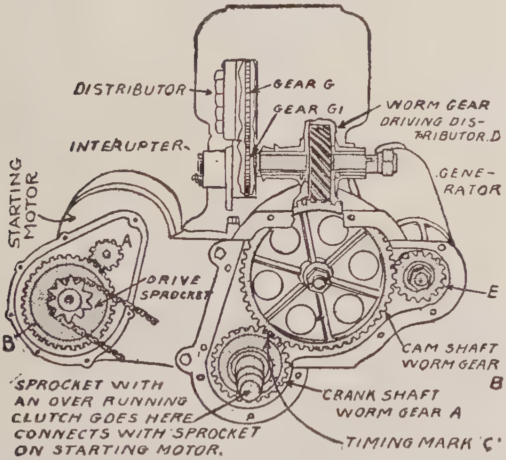

Fig. 16. Driving the generator from cam shaft, also distributor and "interrupter," but independent of each other. The starting motor drives "through the crank shaft" by a silent chain and an over-running clutch. This system is a "**three-unit**" system formerly employed by "Studebaker Six."

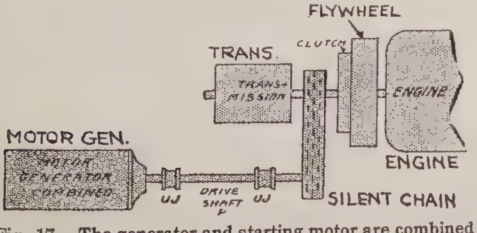

Fig. 17. **The generator and starting motor are combined in one.** Drive is through transmission shaft by means of a silent chain. The ignition is independent. This is a "**two-unit**" system, formerly used on the Chalmers.

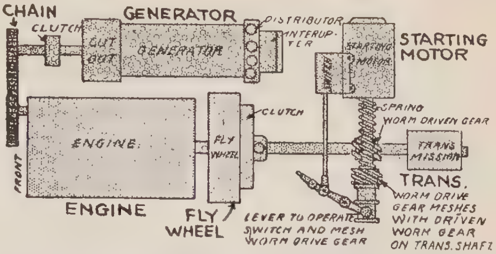

Fig. 18. **Generator driven by gear from crank shaft.** The starting motor drives through the transmission shaft. Ignition is the "interrupter" type mounted on the generator system formerly used on the Reo. A "**two-unit**" **system.**

Fig. 23, page 324, shows an early model Gray & Davis separate motor and generator, as used on the early model Overland cars. Note that the starting motor is mounted above the generator.

The generator is driven by a silent chain from the double sprocket on the starting motor shaft. This double sprocket with a "roller" type of clutch was a feature of this early system and is explained on page 324.

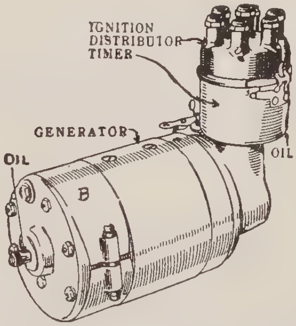

Fig. 19. **A popular method of mounting the ignition unit** on the generator. The generator drive end (end next to ignition unit in this illustration) faces the front of the car and is connected by means of a silent chain and sprocket to the crank shaft (Fig. 19A).

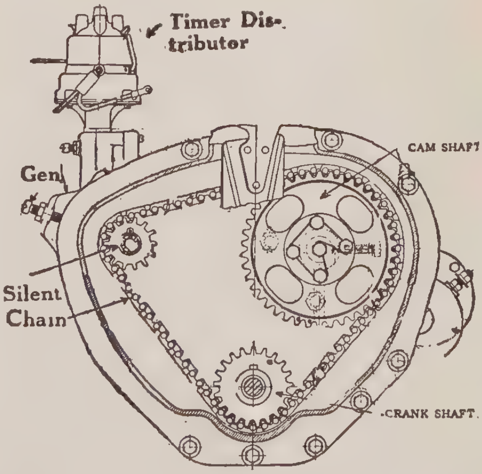

Fig. 19A. **Front end drive** of Studebaker engine. In this example the generator armature shaft is driven by a silent chain at 1½ times the engine speed and a vertical shaft (not shown) is driven by a worm gear from the armature shaft is so geared that the distributor and timer shaft turn at one-half the speed of the engine crank shaft. This would be termed a "two-unit" system, as the starting motor is a separate unit.

RELATION OF A GENERATOR TO AN ELECTRIC MOTOR

The electric generator is similar in many respects to an electric motor, the principal difference being in the winding. The motor field is usually "series"-wound, and the copper wire is heavy or coarse; in fact, it is in the form of copper strips on some motors. The generator field winding is usually a "shunt" winding and of smaller wire.

With a few minor changes the electric **generator can be run as a motor,** using the same winding. A motor-generator is an example of how one armature can serve both a motor or a generator, but there are usually two field windings, as explained farther on.

The series motor possesses great starting power, but under a light load may attain a dangerously high speed. **A series dynamo or generator,**[1] **to be used as a motor,** and run in the same direction as it does as a dynamo, must have the leads from the brushes interchanged.

A "series"-wound generator will rotate in an opposite direction to that in which it rotates when run as a motor.

A "shunt"-wound generator, when used as a motor, will turn in the same direction as when used as a generator.

The shunt-wound motor (seldom used for automobile work) has not such great starting power as a series-wound machine, but runs much more uniformly in speed under a varying load. Brush leads remain as in the dynamo for the same direction of rotation.

A "compound-wound" generator, when used as a motor, will turn in an opposite direction—providing that the "series" winding is more powerful than the "shunt" winding, and in the same direction. If the "shunt" is more powerful than the "series," this is called a differential winding, and will be explained later on, under "Motor-generators," where the same machine used for a motor or generator is described.

The compound-wound motor (used only in motor-generators) is about equal to the shunt motor in starting power, and runs at an almost constant speed under all loads. Brush leads for the motor remain as in the dynamo. To reverse the direction of rotation of the motor, the brush leads must be changed.

The generator is usually separate and distinct from the starting motor. The Delco, however (in some of their systems), employ two field windings (compound) and one armature with two windings and two commutators on the armature, one operating when used as a generator and the other when used as a motor.

The North East system, as used on the Dodge, is another example, but one armature with one winding and two field windings is used for both a generator and a starting motor (explained farther on).

GENERATOR PRINCIPLE

On page 181 we learned that if current is passed through a wire, magnetic lines-of-force in the form of magnetic whirls will be set up around the wire in a clockwise direction, if the current is going into the wire, and in a counter-clockwise direction if the current is coming out (see Figs. 6B, 6C, page 181).

We also learned that if magnetic lines-of-force cut a wire, generated electromotive force, abbreviated e.m.f. (volts or pressure), would be set up in the wire which would tend to move the electricity in the wire. How the electricity comes to be there we don't know. Electricity is in almost everything, but not in motion (see page 175). Therefore, in order to get work out of it, a force called "electromotive force" is generated in the wire by "electromagnetic induction." This force causes a current of electricity to be put in motion, or to flow, and when electricity is flowing or in motion, it is spoken of as a "current of electricity," or merely "current."

With a generator, the wires on the armature cut the "lines-of-force" as they revolve and thus e.m.f. is generated in the wires, which tend to move or conduct the current therein.

Therefore, in order to produce an e.m.f. in the armature wires which will cause the electric current in the wires to flow (if there is a closed circuit), the following is necessary:

1. **Moving wires,** forming a closed loop or circuit.
2. **Magnetic field** for the wires to move in and cut.

The strength of the current thus produced in the wires is dependent upon:

1. **Strength of the magnetic field.**
2. **Speed or rate at which the wires cut the lines-of-force.**

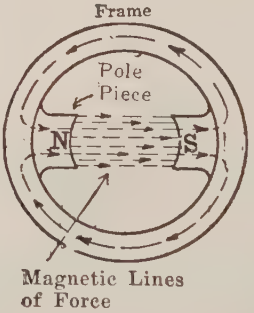

Fig. 8. Magnetic circuit in generator frame.

In Fig. 8 we have **a generator frame,** round pattern, with two pole pieces. Note that the lines-of-force flow from N to S outside of the frame, and from S to N through, or inside of the frame, thus completing a magnetic circuit.

For example: If we take two-bar magnets as shown in Fig. 8A, and bend them as shown by dotted lines, the magnetic circuit would be as shown, with lines-of-force flowing N to S outside of the magnet and S to N inside.

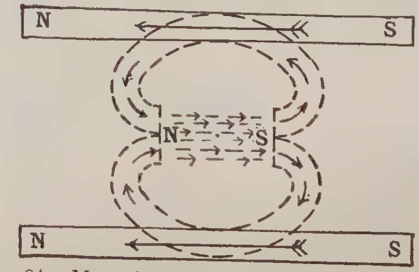

Fig. 8A. Magnetic circuit of a two-pole (bi-polar) generator with a round type of frame.

---

[1] The words dynamo and generator are referred to as meaning the same thing.

In order to produce the magnetic field of lines-of-force, there must be wire wrapped around the field poles and electric current flowing through the wires, thus making "electro-magnets" of the field poles. See page 180 for an explanation of an "electro-magnet."

The direction in which the wire is wrapped around the field poles, and the direction in which the electric current flows in the field windings around the field poles, **will determine the polarity** of the field poles, just the same as in the electro-magnets described on page 183.

The next question is, if the field poles must first have current flowing through the windings around them, in order to produce magnetic lines-of-force for the wires to cut, and if this action generates e.m.f. in the wires, where are the original magnetic lines-of-force obtained?

The field poles are not permanent magnets, but are usually soft iron similar to the **electro-magnet** described on page 182. They lose their magnetism when the current stops flowing through the winding. On page 182, the lines-of-force were shown to be produced around the electro-magnet by current from the battery flowing through the windings, but in the field poles of the generator we cannot pass the current through the windings from a battery. Therefore we obtain our initial lines-of-force from "residual" magnetism, which may be explained as follows:

A slight amount of magnetism is left or remains in the iron field poles, even though it is supposed to lose its magnetism when the generator stops. This magnetism is termed **"residual" magnetism,** and even though it is very slight, there is sufficient magnetic lines-of-force in the iron which flows from N to S across from one pole-piece to the other for the wires to cut the moment the armature starts to revolve. Thus we obtain our initial lines-of-force to start with.

How Direct Current Is Produced from a Generator

Let us glance at Fig. 9, and assume that we have a N and S pole with lines-of-force passing from N to S. We will further assume that the two wires represent one coil of an armature wire, and are closed loops, and revolve in the direction shown by the arrow point above them.

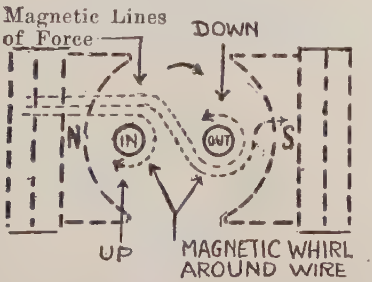

Fig. 9. Showing how the lines-of-force whirl around a wire when it is moved up or down in a magnetic field.

When the wire on the left moves up, it will **cut the lines-of-force up,** and the magnetic whirls will be clockwise around the wire, thus inducing in the wire an e.m.f. causing **current to flow into the wire,** or in the direction away from the reader.

The wire on the right, moving down, would **cut the lines down,** the magnetic whirls would be counter-clockwise, thus inducing in the wire an e.m.f. causing **current to flow out of the wire,** or in the direction of the reader.

If the direction of the lines-of-force is changed, or if the direction of the motion of the wires is reversed, the direction of the flow of current would likewise be reversed.

The strength or intensity of the e.m.f. generated under the conditions described would depend upon: (1) the strength of the magnetic field or the number of lines-of-force; (2) the rate of speed at which the wires cut the lines-of-force; (3) the number of wires cutting the lines-of-force.

The flow of current of any generator is an alternating flow inside the generator, that is, in one direction during one half-revolution, and in another direction during the next half-revolution.

For instance, let us refer to Fig. 10. If a wire loop is revolved between the poles of a magnet from which magnetic lines-of-force flow from N to S pole, and the wire is revolved in the direction shown by the curved arrow, magnetic whirls would be set up around the wire on the left, in a clockwise direction, due to the wire cutting the lines up, and thus causing an e.m.f. to be induced in this side of the loop which would cause current to flow from 1–2, into the wire. If a "collector-ring" was connected with the end of this wire to brush (**B**−), it would be negative (−).

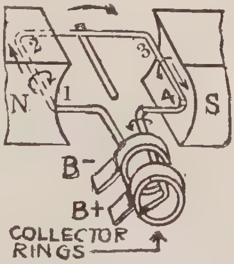

Fig. 10

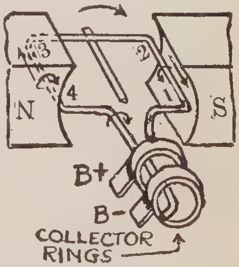

Fig. 11

Fig. 10. The outer brush is (+) and the inner brush (−).
Fig. 11. The outer brush is now (−) and the inner brush (+).

The wire on the right (Fig. 10) would cut the lines-of-force down, therefore the magnetic whirls around the wire would be in a counter-clockwise direction, and current would flow out from 3–4. The brush (**B**+) at the end of this wire would be positive (+).

Fig. 11 shows a half-revolution of the wire loop from the position at which it was in Fig. 10. Note that wire 2–1 is now cutting the lines-of-force down; therefore the brush which was (B−) in Fig. 10 and which is still connected with it, would be (+) instead of (−) as current is now coming out instead of going in.

Wire 4–3 is now cutting up, and current would flow in. Thus the brush which was (**B**+) in Fig. 10 and which is still connected with it, would now be (−) instead of (+).

Thus during a half-revolution the current would flow out of the same brush as (−) and during the next half-revolution current would flow into the brush as (+). This would produce an "alternating" flow of current which is used on magnetos but is not suitable for a generator which charges a storage battery which has a positive (+) and negative (−) set of plates and terminals.

Only a "direct" flow of current will charge a storage battery. Therefore some means must be employed to convert or commutate the "alternating" flow of current to a "direct" flow of current as follows:

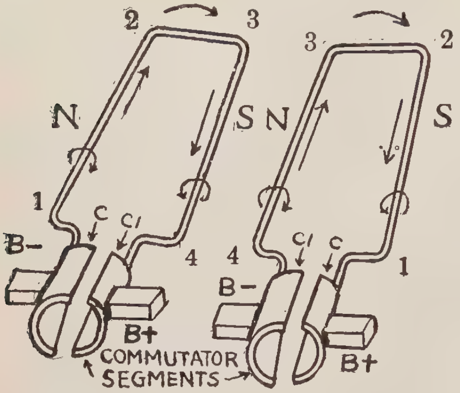

Fig. 12 Fig. 13

Fig. 12. The left brush is (−) and the right brush is (+).

Fig. 13. The left brush is (−) and the right brush is (+), the same as in Fig. 12.

A method of obtaining a direct flow of current at the brushes is shown in Figs. 12 and 13. Instead of having a round or endless collector-ring at the ends of the wires as in Figs. 10 and 11, we have substituted two half-sections of one ring, separated from each other, which we will term **the segments of a commutator.**

Now, when wire 1–2 on the left (Fig. 12), is cutting the lines up, current will flow in, and the brush on the left will be (−). The wire on the right (Fig. 12) will cut the lines down, and current will flow out, and the brush will be (+).

Fig. 13 shows a half-revolution of the wire loop from the position shown in Fig. 12. Wire 4–3 is now cutting up, and current would flow in, and the brush would be (−), just as it is in Fig. 12. Wire 2–1 would cut down, and current would flow out, and the brush would be (+), just as it is in Fig. 12.

Therefore, instead of the brushes being connected with the same end of the wires all the time, as in Figs. 10 and 11, the brushes connect with one wire, for a half-revolution, and with the other wire during the other half-revolution, and the flow of current from the brushes is always in one direct direction. This action is accomplished by the two-part commutator.

The current generated in all generators is an alternating flow of current and it is "commutated" **or changed to a direct flow of current at the brushes by means of a "commutator."**

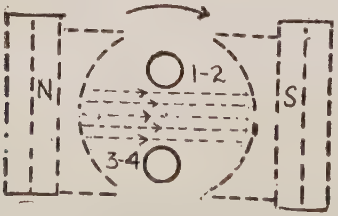

Fig. 14. Wires in a vertical position.

The strength of the current, as previously stated, is dependent upon the e.m.f. induced in the wires, and this in turn is dependent upon the number of magnetic lines-of-force cut by the coils of wire.

When the wires are cutting up or down across the magnetic field, the induced e.m.f. is greatest. When the coils reach a vertical position, as shown in Fig. 14, the e.m.f. induced in this position would be zero, as the magnetic lines are not cut (except perhaps a few stray lines), but flow freely through the coil from N to S pole-pieces.

Thus we have, at every half-revolution, when in position shown in Fig. 14, no current at all, or zero. But as the coils or wires are rotated, the number of magnetic lines cut will increase until it reaches a horizontal or 90° position (Fig. 9), where it reaches maximum. From this position (Fig. 9), traveling in the same direction, the number of lines become less until the vertical or 180° position is reached (Fig. 14), where the e.m.f. again becomes zero.

The e.m.f. induced in this simple dynamo would be called **a pulsating e.m.f.,** because it pulsates or changes from zero to maximum and back to zero at regular intervals or every half-revolution.

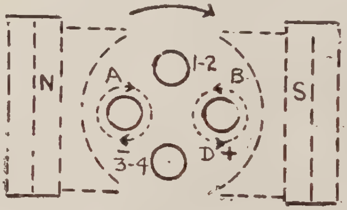

Fig. 15

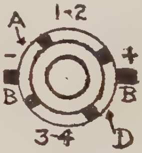

Fig. 15A

If we place two closed loops, or coils, at right angles to each other (Fig. 15) and use four commutator segments, as shown in Fig. 15A, the induced e.m.f. in one coil (**A** and **D**) will be maximum, when zero in the other (1–2, 3–4), if rotated. With the terminals of each coil connected to opposite commutator segments, the e.m.f. between brushes will never drop to zero.

By the use of more coils on the armature and more segments on the commutator, we should have more wires cutting the lines. Thus the e.m.f. would be made more steady with less pulsations.

This type of winding would be termed an "open-circuit" winding, and the coil or loop is connected to the external circuit only while the segments of the commutator to which the terminals of the loop are connected, are in contact with the brushes.

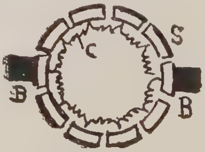

Fig. 15B

A closed-circuit winding (Fig. 15B) would be better, because the loops are connected together in "series-parallel," and thus all of the loops all the time are made use of except when the two commutator segments to which a loop is connected are in contact with a brush or with brushes of the same polarity.

GENERATOR ARMATURES

On a generator of the automobile type, the armature (which rotates and is driven by the engine) is made up of many coils and commutator segments, and various methods of winding and connecting to segments are employed. The principle, however, is very much the same in all cases, the idea being to have as many wires on each side cutting the magnetic lines-of-force as is possible. By adding more wires, the e.m.f. is increased.

A simplified "shunt-wound" generator[1] and its circuit are shown in Fig. 16. Note that the field windings are "shunted" to the brushes. Thus we have a "shunt field circuit" and a "main circuit," the latter being from the brushes to the battery, lamps, ignition, etc.

The armature, which is a "drum type," consists of a laminated iron core (Fig. 16A) with slots in the core for the winding of insulated copper wire.

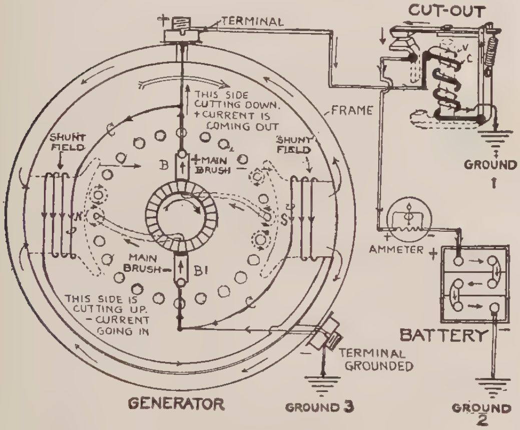

Fig. 16. Circuit of a shunt-wound generator.

The laminated iron core increases the total number of lines-of-force by collecting many stray lines from the surrounding air, and thus concentrating them.

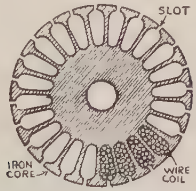

Fig. 16A. Laminated iron core of a drum-type armature.

The wire is wound around the core and in the slots and the ends are connected by soldering to the commutator segments.

An armature shaft passes through the core, which is supported by bearings. The shaft is driven from the engine, and the armature revolves between the pole pieces.

The commutator is made up of copper segments insulated from each other and from the shaft by mica insulation.

Brushes are usually made of carbon and rest on the commutator, and conduct the current from the armature. One brush will take current from wires which revolve on the side cutting the lines down, and the other brush will take current from the wires on the side of the armature which are cutting up; thus one side is (+) and the other (−). This is likewise true of the brushes. (This is true for open-coil armatures, but not for closed-coil armatures.)

The field circuit in Fig. 16 consists of two field poles (usually made of laminated steel and detachable by means of screws), with insulated wire wrapped around them in such a direction that when the armature is revolved in the direction shown by the arrow, the left pole is N, and the right pole is S, or vice-versa.

When the armature revolves the wires on the left cut the lines up, and therefore current flows in. The wires on the right cut down, and current flows out. The (+) side is connected with the (+) brush and the (−) side with the (−) brush. Current flows out to its external circuit from the (+) brush and comes back to the (+) brush, thus completing the circuit.

The shunt field circuit is supplied with part of this current thus produced (usually about 1½ to 2 amperes), and flows from the positive (+) main brush through the field coil on the left, giving this pole a N pole polarity (at the end of the pole next to the armature).

The flow of current is then continued to the other field pole which gives this pole a S pole polarity at the inner end of the pole. The field circuit is completed at the negative (−) main brush. The current flowing through the field windings makes electro-magnets of the field poles, and from them lines-of-force flow from N to S poles directly through the armature core.

As the speed of the armature increases, the rate at which the lines-of-force are cut by the coils on the armature increases. Thus a greater e.m.f. is induced in the armature wires, which causes a greater rate of flow of current through the field windings, thus in turn producing more lines-of-force.

The cut-out voltage circuit is from the (+) brush, to the fine wire voltage winding (V), around the cut-out core, to ground (1), to grounded (−) main brush (ground 3).

The battery-charging circuit from the generator: When the armature speed is such that the e.m.f. or voltage generated is slightly above the battery voltage, the fine wire winding (V) magnetizes the core of the cut-out and draws the cut-out armature to it. The effect of this is to close the points through which the current passes to battery, through the coarse wire or series winding (C) on the cut-out core, through the ammeter, to the (+) terminal of the battery, through the battery to (−) ground (2), to (−) grounded brush of the generator (ground 3). Note that current passes through (V) and (C) winding from the generator in the same direction around the cut-out core.

The action when the generator slows down and the cut-out points open is explained on page 333 (Fig. 5). Note that current flows in a reverse direction through winding (C) when the battery discharges back through it, as in (S) (Fig. 5).

The plain shunt-wound generator, as described, would not be satisfactory, because, as the speed of the armature increases, the e.m.f. increases, and at high speeds of the armature, the lines-of-force and also the rate at which they are cut would increase, and thus the output would be too great.

---

[1] The "shunt field winding" connections of a generator are on the principle used on most generators. But owing to the fact that a shunt-wound generator builds up with speed, a "regulation of the field circuit" must be used in order to cut down the out-put at high speeds. This subject is treated under "Regulation methods," farther on.

In order to obtain a "constant voltage" or a "constant current" output, some form of "regulation," to cut down the lines-of-force in the field circuit is required. The subject of "Regulation of generators" will be treated farther on.

Direction of Motion of Armature Coils and Direction of Main Magnetic Field Governs the Polarity at Brushes

The direction in which the coils on the armature rotate and the direction in which the main magnetic lines-of-force flow govern the direction of the flow of current out of the armature wires into the brushes.

Simplified illustrations in Fig. 16 B show different directions of "motion" of the armature coils, and also different directions of the "main magnetic circuit" (lines-of-force). The field-poles are not shown wrapped with wire, but it is assumed that they are, and that they are so wrapped, that the main magnetic circuit (lines-of-force), passes from N to S pole. Only two wires are shown, as a matter of simplifying the explanation, although there are several coils of wire on the armature.

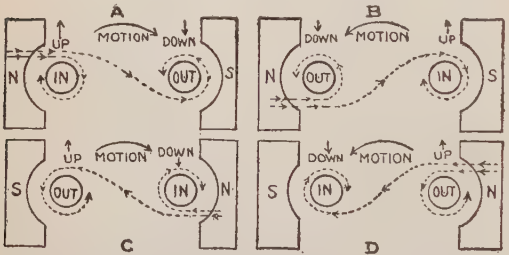

Fig. 16B. Explaining how the direction of motion of the wires on the armature governs the polarity at the brushes.

At **A,** the direction of motion of the armature is as shown by the arrow point. Main magnetic lines-of-force flow from N to S poles; therefore the wire coil on the left will cut up and the "magnetic whirls" will be clockwise around the wire. Thus an e.m.f. will be generated in the wire, causing current to flow into the wire, or away from the reader, and this current will be (−). The wire on the right (**A**), will cut down; therefore the "magnetic whirls" around the wire will be counter-clockwise, or out of the wire (+).

At **B,** note that the direction of "motion" of the armature coils is in the opposite direction to that shown at (**A**). Therefore the magnetic whirls around the wires on each side are reversed, and consequently the direction of the flow of current in the wires is reversed.

At **C,** note that the direction of the "main magnetic circuit" is changed. Instead of passing from N to S pole, from left to right, as at (**A**) and (**B**), they now pass from N to S pole, from right to left. We will assume this change was made by changing the direction of the winding on the field poles. Therefore, while the direction of the motion of the armature coils is the same as at (**A**), the main magnetic field is just the reverse. Thus the direction of the motion of the armature wires is such that the left wire (**C**), on going up, cuts the main magnetic field in such a manner that the magnetic whirls circle around the wire counter-clockwise, producing a generated e.m.f. in the wire, causing current to flow out (+), and on the other side, the wire cuts down, causing current to flow into the wire (−).

At (**D**), note that the direction of "motion" of the armature coils or wires has been reversed from that of (**C**). The main magnetic field (also called lines-of-force and main magnetic circuit) is the same as at (**C**). Therefore the change of direction of the motion of the wires produces a reverse effect to that at (**C**).

The purpose of these illustrations is to point out how the generated current flows **into** a wire when the magnetic whirls are clockwise around a wire, and how the generated current flows **out** of a wire when the magnetic whirls are counter-clockwise around a wire; and also that the direction of motion and the direction in which the main magnetic field or circuit passes from N to S pole, governs the direction of the magnetic whirls around the wire. A study of the illustrations will make these principles clear.

ARMATURE WINDINGS

There are a number of methods of winding an armature; so many, in fact, that armature winding is a trade in itself.

The repairman should not attempt to wind an armature because it requires a special equipment, and furthermore it is cheaper to turn in the old armature for a new one.[1]

The work on an armature that the repairman is usually called upon to do is to test it out, or to make such repairs as re-soldering the wires to the commutator segments, undercutting the mica, turning down or cleaning the commutator, fitting new brushes, etc., which is explained farther on. We shall not go further into this subject here, except to give an idea as to the construction of the armature.

Lap or Parallel Wound Armature

An armature in general use on two-pole generators and motors is shown in Fig. 17. It is termed a "lap" or "parallel" wound "drum" type of armature of the "closed-circuit" type.

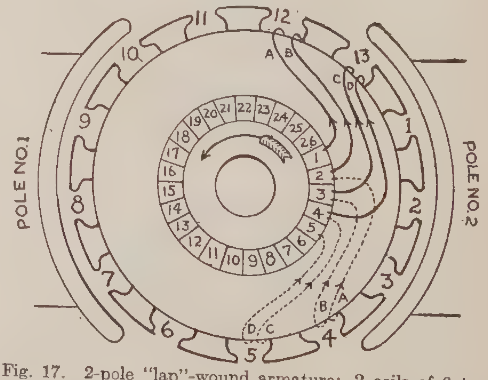

Fig. 17. 2-pole "lap"-wound armature; 2 coils of 6 turns per slot; 13 slots, 26 commutator segments.

In this example of a two-pole Delco generator armature, there are 13 slots in the core and 26 commutator segments. There are 2 coils per slot and 6 turns of double cotton-enameled wire per coil.

---

[1] A. L. Dyke, Elect. Dept., St. Louis, Mo., can furnish armatures and parts of any make of generator or motor. From him can also be obtained a book on **Armature Winding,** price $5 prepaid.

The coils do not go directly from No. 1 commutator segment to No. 1 slot, but a "lead" of five segments, or bars, is given, to the right, from the slot where it enters.

The end of the first coil (A) would begin or "lead" from No. 1 commutator segment to slot No. 12, to slot No. 4 (spanning six slots), and end at commutator segment No. 2.

The end of the second coil (B) for the same slot, would begin or "lead" from No. 2 commutator segment, to slot No. 12, to slot No. 4, and end at commutator segment No. 3.

The end of the coil (C), for the next slot, would begin with commutator segment No. 3, to slot No. 13, to slot No. 5, and end at segment No. 4.

The end of the second coil (D), for the same slot, would begin at commutator segment No. 4, to slot No. 13, to slot No. 5, to commutator segment No. 5.

Thus the same procedure would continue around the core, with two coils of wire in each slot.

The main brushes on two-pole machines are placed 180° apart, or exactly opposite. Thus one brush would be on a near commutator segment No. 15, and the other on No. 2 segment.

Where a third brush is used for regulating purposes, the position would be on No. 5 or 6 segment, when the direction of the armature is as indicated. If the direction is reversed, the third brush would be on the opposite side. (The third-brush regulation is treated farther on.)

Many of the starting-motor armatures have the same number of slots in the cores as there are commutator segments, since there is usually, but one coil per slot.

Wave or Series-Wound Armature

An armature in general use on Delco four-pole generators and motors is shown in Fig. 18. It is termed a "wave" or "series"-wound "drum" type of armature of the "closed-circuit" type.

In this example there are 21 slots in the core, 43 commutator bars or segments, and 2 coils per slot with 5 turns of No. 15 double cotton-covered enameled wire per coil.

The coils do not go directly from No. 1 segment or commutator bar to slot 1, but a "lead" of 6 bars to the left of slot No. 1 is given to the first coil (A), and a "lead" of 7 bars to the left is given to the second coil (B).

Four-pole generators are divided into quarters. The "pitch" or span is from slot 1 to slot 6.

The first coil (A) for slot No. 1, would start with commutator segment or bar No. 6, to slot 1, to slot 6, to bar 28.

The second coil (B) for slot No. 1, would start with commutator bar No. 7, to slot 1, to slot 6, to bar 29.

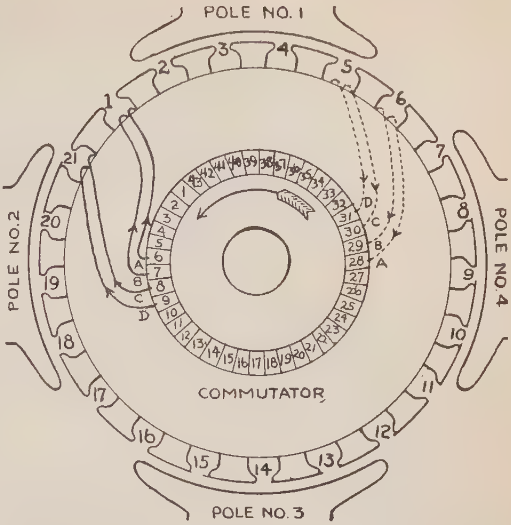

Fig. 18. 4 pole "wave"-wound armature 2 coils of 5 turns per slot, 21 slots, 43 commutator segments.

In order to fill up the remaining slots in this section, the next coil (C) would begin with bar 8, to slot 21, to slot 5, to bar 30.

The second coil (D) in the same slot would begin with bar 9, to slot 21, to slot 5, to bar 31, and thus proceed until all slots are filled up. Commutator bars 1 and 22 would be connected by a jumper.

On four-pole generators, using two main brushes, the brushes are located 90° apart.

The position of the third brush on a four-pole generator (when the regulation system is with a third brush) is somewhere between 130° to 160° from the main brush of opposite polarity.

A two-pole motor or generator usually employs what is termed a "lap winding," and four-pole "wave winding."

In the generator armature windings, one coil consists of four, five, or six turns of wire, depending upon whether the generator is to be driven at engine speed or at one-and-one-half times engine speed. One or the other ratio is generally used.

Motor and Generator Windings on One Armature

Diagrams of a Delco-Buick armature, where there are two windings on one armature, which is a "lap winding," are shown in Figs. 19 and 20. The generator is of the two-pole type.

The motor winding (Fig. 19) consists of one coil per slot. There are 19 slots in the armature core for both the motor and generator winding. There are 19 commutator segments for the motor winding. There are **two commutators**, one for the motor and one for the generator winding.

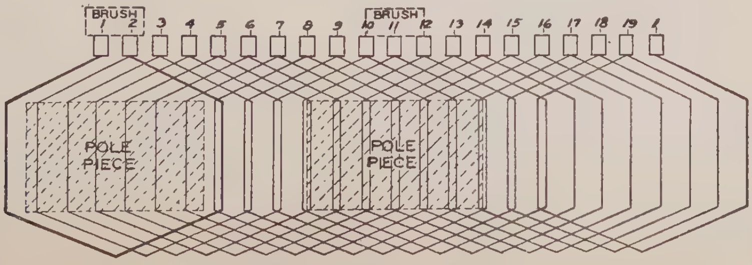

Fig. 19. Motor armature winding 19 slots, 1 coil per slot.

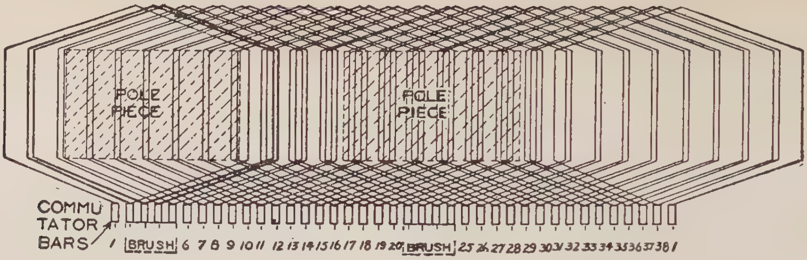

Fig. 20. Generator armature winding, 2 coils per slot.

The generator winding (Fig 20) consists of two coils per slot. There are 19 slots in the armature core (the same number of slots as for the motor). Thus, since there are two coils per slot for the generator winding, there are 38 commutator sgements on the generator commutator.

Meaning of Span and Lead

The "span" of coils on an armature refers to the number of slots, between those in which the two sides of a coil lie, plus the two slots in which they lie.

The "lead" of coils of an armature refers to the number of commutator bars to the right or left of the slot where the coil enters and where it comes out.

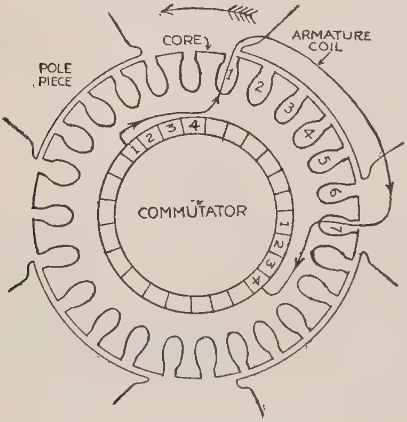

Fig. 21

For example, refer to Fig. 21. There are 25 commutator bars and 25 slots, and 1 coil per slot. The "span" is 1 to 7, and the "lead" is 4 left, 4 right, usually stated as 4 left, the beginning of the coil. Note that the armature coil leads from bar 1, which is the fourth bar to the left of slot 1, where it enters. The coil then "spans" from slot 1 to slot 7, and "leads" to bar 4, which is the fourth bar to the right of slot 7, where it comes out.

Refer now to Fig. 18, page 343. The "span" here is 1 to 6, and the "lead" is 6 to 7 bars left. Note that there are two coils per slot.

Therefore the "lead" of the first coil (A) is from bar 6, which is the sixth bar to the left of slot 1 where it enters. It then "spans" six slots, from slot 1 to 6, and ends at the sixth bar from under slot 6.

The "lead" of the second coil (B) is from bar 7, which is the seventh bar to the left of slot 1, where it enters. It then "spans" six slots, from slot 1 to 6, and ends at the fifth bar from under slot 6. As the winding progresses, the coils in this section are working to the left.

Refer next to Fig. 17, page 342. The "span" is 1 to 6, the "lead" is 5 to 6 to 7 bars right. Note that there are two coils per slot.

The "lead" of the first coil (A) begins with bar 1, which is the fifth bar to the right of the slot 12, where it enters. It then "spans" six slots (from 12 to 4), and ends at the sixth bar (2), to the right from under slot 12 where it entered.

The "lead" of the second coil (B) begins with bar 2, which is the sixth bar to the right of the slot 12, where it enters. It then "spans" 6 slots (from 12 to 4), and ends at the seventh bar (3) to the right from under slot 12 where it entered.

When the bars are connected to the bars opposite the center slots in the span, the lead is said to be "straight down" as in Fig. 17, just referred to.

INSTRUCTION NO. 33

GENERATOR FIELD-WINDINGS AND REGULATION METHODS

GENERATOR FIELD WINDINGS

Shunt winding: On all generators used for automobile work the magnetic field is produced by what is termed a "shunt" connection of the field winding, which is directly across the brushes, as shown in Fig. 1. Thus it is called a "shunt-wound" generator. Where there is a regulation system to the field winding of a generator, the regulation (such as an electric-magnetic principle or third brush) is placed in between the field winding and brush as explained farther on.

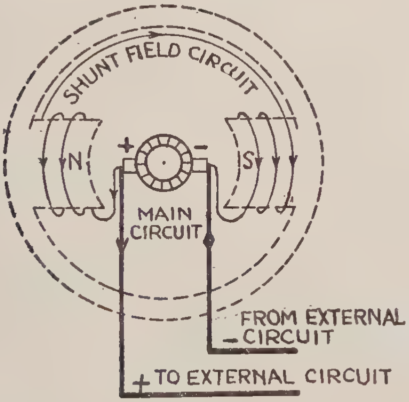

Fig. 1. Shunt field winding.

With a shunt-wound generator about 10 per cent of the total current generated by the armature passes to the shunt field windings. Therefore the strength of the main magnetic field depends upon the current passing through it, and the strength of the current depends upon the speed of the generator armature.

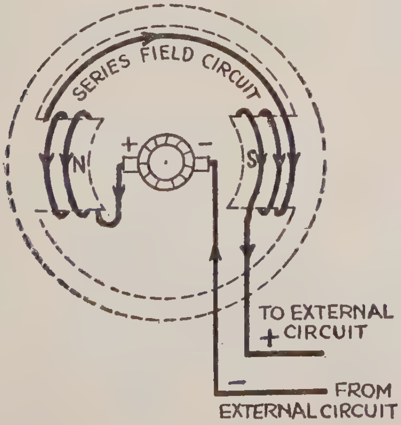

Fig. 2. Series field winding.

Series winding: This winding (Fig. 2) is used principally for starting motor field windings. In many instances the starting motor fields are connected "series-parallel," instead of in straight series. That is, where there is a four-pole starting motor, the field windings are often connected, two in series and parallel with the circuit, as, for instance, in Fig. 4, page 326.

It will be observed that all of the current would pass through the armature and field in series. This winding is not suitable for generator windings, if used alone.

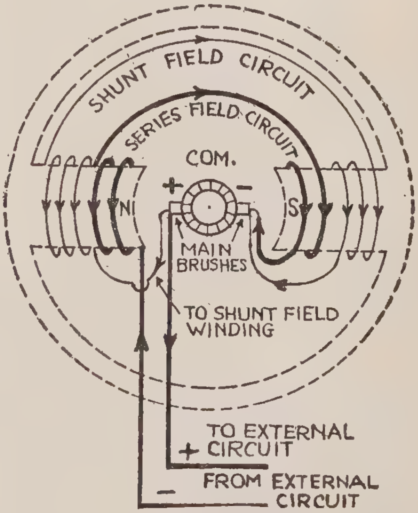

Fig. 3. Compound winding; shunt and series.

Compound windings: On some generators two field windings are used (Fig. 3). One winding is a "shunt" winding and the other a "series" winding.

If the two windings are wound in the same direction (as in Fig. 3), they assist each other in producing magnetic lines-of-force at the field poles, thus producing an **"accumulative" effect** or action.

If the two windings are wound in opposite directions, they oppose each other, thus producing a **"differential" effect** in action.

The shunt winding coils, in this instance, consist of a much greater number of turns of fine wire than the series coils, which are of coarse wire. The shunt winding determines the polarity of the field poles.

Motor-generators use a compound-winding, consisting of a "series" field winding and a "shunt" winding, which are wound in opposite directions on the field poles.

When used as a motor, the two windings have the "cumulative" effect of magnetizing the field poles, and when used as a generator, they have a "differential" effect (treated and discussed farther on).

Thus, in summing up the different windings of generators, motors, and motor-generators, we deal with two windings, a "series" winding and a "shunt" winding, either separately or combined.

If the two windings are combined, they can be wound in the same direction or in opposite directions, thus producing a "cumulative" or "differential" effect.

The two windings can also be connected in two different ways: as a "short shunt" connection, and as a "long shunt" connection.

GENERATOR REGULATION PRINCIPLES

Why Output of a Generator Must Be Regulated

The shunt-wound generator is used most. As stated, about 10 per cent of the current from the armature flows through the shunt field windings. This flow of current through the field windings "builds up" the magnetic lines-of-force in the field poles.

The lines-of-force then flow from N to S pole of the generator, and as the armature coils revolve between these poles, there is set up in the armature coils an induced e.m.f. (electric-motive-force, voltage, or pressure) which causes electric current to flow, as previously explained.

The e.m.f. voltage thus produced by a generator depends upon:

1. **The number of lines-of-force** cut by the armature wires.
2. **The number of the cutting wires** in armature coils.
3. **The speed at which the armature revolves,** or the rate of speed at which the wires cut the lines-of-force.

Thus it is clear that if the speed of the generator armature is increased, the lines-of-force will increase; consequently as the lines-of-force increase, the e.m.f. increases, owing to the greater speed at which the lines are cut by the armature coils.

For this reason, a plain shunt-wound generator will build-up its lines-of-force at high engine speeds (the engine drives the generator armature), and consequently the e.m.f. or voltage would increase to such an extent that the lamps would be burned out and too high a charging rate would pass to the battery.

Constant Current and Constant Voltage

To prevent the generator from increasing above its normal output at high speeds, methods for regulating the output are provided and can be classed as follows:

1. **Regulation of the voltage,** by maintaining a "constant voltage," with the current varying.
2. **Regulation of the current,** by maintaining a "constant current" (amperage), with the voltage varying.
3. **Regulation of both** voltage and current.

As a matter of fact, the number of magnetic lines-of-force and the rate at which they are cut by the armature coils, govern both the voltage and current. Conditions which affect one would affect the other. Some manufacturers, however, provide means for decreasing the lines-of-force through the voltage produced by the generator, and others through the current produced, or both.

Meaning of Constant Current and Constant Voltage

The generator output in watts is equal to the product of the current (amperes) multiplied by the volts (pressure). If there is no other pressure (voltage) in a generator circuit than that delivered by the generator, the current delivered by the generator is equal to the voltage divided by the total resistance of the circuit.

If the pressure (voltage) **generated in the armature remains fixed or constant,** the current supplied by the generator will vary according to the amount of resistance in the circuit, as, for example, a charged or discharged battery, lamps, etc. If, by way of illustration, the resistance is increased in the circuit (perhaps by the battery being fully charged), the current in the circuit will decrease, and if the resistance in the circuit is decreased, through a discharged battery in the circuit, for instance, the current will increase.

If the generated pressure or voltage in the winding of the armature is changed or varies, and the resistance of external circuit does not change, there will be an equal change in the output of current. For instance, if the pressure (voltage) increases, the amperage will increase, and if the pressure decreases, the amperage will decrease.

If the pressure of the generator and the resistance of the circuit both change, then the amperage is equal to the pressure at the time, divided by the resistance at the time.

When the generator output is being delivered as a constant current and the pressure or voltage is varying, the generator is termed a **constant current** generator.

When the output is being delivered at a constant voltage or pressure and the current is varying, the generator is termed a **constant voltage** generator.

With the "constant voltage" regulation system, the amount of current generated, as previously stated, depends upon the state of the battery charge and the amount of lamp load in use. With a discharged battery, the voltage delivered to the battery is a minimum, but as the charge of battery proceeds the voltage of the battery will increase, so that the difference in pressure between generator and battery is continually diminishing. For instance, if the battery is fully charged, and is, say, 6 volts, and if the generator voltage is 7 volts, then there is one volt pressure to send current through the battery, and the generator charging current will be small.

Therefore the charging current is variable even at the same speed of rotation, and tapers from maximum (about 12 to 20 amperes) with a discharged battery, to minimum (4 to 6 amperes) with a fully charged battery.

After the generator reaches a speed at which it develops its normal voltage, the voltage does not increase with speed, but remains constant—if a regulation method is used to decrease the strength of the magnetic field.

Voltage regulation permits of a battery being charged at a high-current rate when the battery voltage is low, and at a much lower rate when the battery voltage is high.

With the constant current regulation, the generated current is independent of the voltage of the battery or the amount of lamp load connected, but depends upon the speed at which the machine is driven and on the regulation system.[1]

GENERATOR REGULATION METHODS

To maintain either a "constant voltage" or a "constant current" (amperage) or both, the following methods are available:

1. **Mechanically, by hand:** Where the resistance is cut into the shunt-field circuit, thus decreasing the strength of the magnetic field (not practical).
2. **Electromagnetic method:** Where the resistance is cut into the shunt-field circuit automatically by an electromagnetic device placed externally to the generator. This was formerly extensively used.
3. **Mechanically, by an automatic governor:** Where a mechanical governor is used to regulate the speed of the generator (obsolete).
4. **Inherent method:** Where there are "two windings" (compound windings) on the field poles, or where a "third-brush regulation" is used. Thus with both of these methods the regulation is "inherent," or within the generator and without the use of external devices. The third-brush method is used most.

The Delco and North East are examples of compound-wound generators which also use a third-brush regulation.

The object of all the regulation methods mentioned above is to decrease the current flowing through the shunt-field winding at very high speeds of the generator, in order to reduce the strength of the magnetic field and to maintain a "constant voltage," or "constant current," or both.

Mechanical Hand Method

The hand method (Fig. 4) of cutting resistance into the shunt-field circuit of a straight shunt-wound generator is impractical, because it would necessitate someone moving the lever (H) constantly back and forth. For instance, if the generator speed is high, the resistance (M) should be cut into the field circuit by moving the lever (H) to 2. As the speed decreases, the lever (H) would be moved back to 1, cutting out the resistance.

Fig. 4. Mechanical hand method of regulation (not used as a general practice).

Therefore some means whereby this action can be made to be "automatic" is the method which we shall discuss.

Electromagnetic Regulation Methods

Electromagnetic methods consist of an electromagnetic device (Figs. 5, 6, and 7) similar to a cut-out in appearance. Its purpose is to cut-in resistance into the field circuit at high speeds magnetically thus decreasing the strength of the magnetic field.

Note. Do not confuse the electromagnetic cut-out with the electromagnetic regulator.

The purpose of the cut-out is to open and close the circuit between the generator and the battery and this is explained on page 332. It is placed in the external circuit with practically all generators, regardless of the type of regulation, and is shown in the various illustrations, but is not referred to.

There are three electromagnetic methods. These are:

(1) To regulate the current (amperage) so as to obtain **constant current** or amperage.

(2) To regulate the voltage so as to obtain **constant voltage,** or pressure.

(3) To regulate both voltage and current so as to obtain **constant current and voltage.**

Electromagnetic Voltage Regulation

Voltage regulation of the generator by the electromagnetic method is shown in Fig. 5. The principle of construction is similar to that of an electromagnet with a fine wire voltage winding **(F)** around an iron core (G). This winding is connected **across** the generator charging circuit, and not in series with the generator charging circuit as in Fig. 6; therefore the magnetic force of the core (G) will depend upon the voltage in the fine wire winding (F).

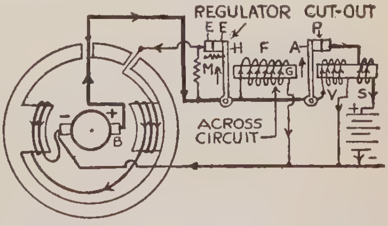

Fig. 5. Electromagnetic voltage-regulation method.

This generator (Fig. 5; also Figs. 6 and 7) is a plain shunt-wound generator. Instead of connecting the ends of both field poles directly to the brushes inside of the generator, the shunt-field circuit is from (+) of the main brush, to the regulator arm **(H)**, to points **(EE)**, through the field windings, to (−) of the main brush. This extension is made in order to be able to insert resistance **(M)** into this shunt field circuit when the generator is running at high speeds, and thus weaken the current flowing in the shunt field circuit and preventing too high an output of the generator. The resistance (M) on the regulator is connected into the field circuit only when points (EE) are open, which is at high speeds of the generator. These points are normally closed, so that the generator field can "build-up," magnetic lines-of-force at low speeds.

---

[1] For instance, on the Bijur "third-brush regulated," "constant-current" generator, the cut-out closes at a generator voltage of 6.5, or a generator speed of 500 or 600 r.p.m. With increasing speed, the current increases to maximum value, at speeds of about 1,000 to 1,600 r.p.m; at higher speeds the current gradually decreases owing to the third-brush regulation (explained farther on).

It is not feasible to supply current for lights from a "constant-current" generator without a battery being connected in circuit. For instance, if lamps require 7 amperes and the generator, at speed, delivers 15 amperes, the generator voltage would rise until the additional 8 amperes not required by the lamps will be forced through the lamp circuit and burn them out.

The voltage generated by the generator will determine the opening of the points (EE). The fine wire voltage winding (F) of the regulator is so wound, that with a 6-volt battery, the generator voltage will reach about 7.5 to 8 volts maximum, and points (EE) will remain closed; but on higher speeds and where the generator reaches a higher voltage than the maximum, then the core (G) becomes magnetized sufficiently to draw blade (F) to it, thus opening points (EE), and cutting in resistance (M) into the field circuit. This has the result of weakening the magnetic lines-of-force of the fields.

When the generator speed is less than 8 or 10 miles per hour car speed, the generator voltage drops to less than 6.5 volts, and the core (G) loses its magnetism, and points (EE) close again, thus cutting resistance (M) out of the field circuit. This permits the magnetic lines-of-force to build up again in the fields. This action is repeated over and over as the speed of the engine and generator varies; and thus the blade (F) vibrates back and forth.

With the "constant voltage" regulation, the amount of current generated depends upon the battery voltage (if charged or discharged), and also on the load in the circuit, such as lamps, etc.

Note that the charging circuit from the generator to the battery is not through the regulator winding.

The voltage can be increased or decreased, where the regulator cuts in and cuts out, on many regulators of this type, by increasing the spring tension of blade (H) for an increase of voltage and by decreasing, for a lower voltage.

Electromagnetic Current Regulation

Current regulation of the generator by the electromagnetic principle is shown in Fig. 6. Note that this is a plain shunt-wound generator, as in Fig. 1, and the difference between Fig. 5 and Fig. 6 is that the winding (F) on core (G) is a coarser wire and is in series with the charging circuit instead of across it, and the magnetic force of the core (G) will depend upon the current or amperage passing through this winding.

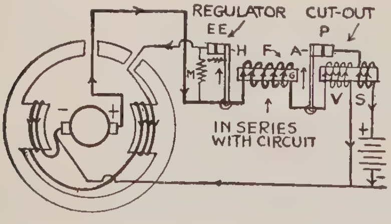

Fig. 6. Electromagnetic current regulation.

The shunt field circuit is from (+) of the main brush of the generator, through regulator blade (H), through points (EE), which are normally closed, to the field winding, through the field windings to (−) main brush.

Note that **the charging from generator to battery** must pass through the regulator winding (F).

When the engine speeds up, the generator builds up voltage (e.m.f.). When the voltage of the generator is sufficient to cause the cut-out points (P) to close, which completes the battery charging circuit, the generator then charges the battery. And as the charging current flows through the regulator winding (F), this will cause core (G) to become magnetized, and when the maximum output of current from the generator (approximately 12 to 15 amperes) is passing through this winding, the blade (H) will be drawn to core (G) against the tension of the spring, thus opening points (EE). This action inserts the resistance (M) in series with the shunt field circuit, thus causing the voltage of the armature to drop and the charging current to decrease, because of the weakening of the shunt field strength, or magnetic lines-of-force.

When this current decrease drops to about 10 amperes, the coil (F) is wound with such a size wire and number of turns that the core (G) loses its magnetizing force and the blade (H) is released and closes the points (EE), thus cutting the resistance (M) out of the field circuit, and permitting the field strength to build up again to its maximum.

The blade (H), in actual practice, vibrates, or opens and closes rapidly, so that the generator will not charge over 12 to 15 amperes (or 15 to 20 on some generators), at high speeds, and thus **the current output is constant,** regardless of the voltage of the battery, whether charged or discharged.

It will be clear, by referring to Fig. 6, that if the battery should be removed, or if the battery terminals are loose, or some other open circuit should exist, there would be no current flowing through the regulator current coil (F), and there would be no regulation of the generator. Thus, at high speeds, it could build up voltage to such an extent that it would damage the generator.

If the battery is removed, open the field circuit by disconnecting the field wire. Usually there is a fuse in the field circuit which can be removed.

To increase the charging rate, the spring tension of blade (H) is increased, and to **decrease the charging rate,** the spring tension is decreased.

Electromagnetic Voltage and Current Regulation

Current and voltage regulation by the electromagnetic principle can be combined as shown in Fig. 7.

This regulator winding (F1) is on the same core as the cut-out winding (F2), with blade (A) on one end of the core as a cut-out blade, and with a regulator blade on the other end of the core.

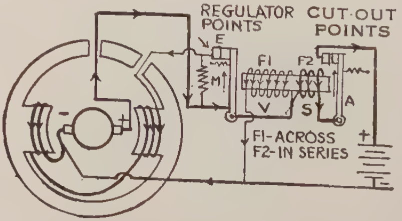

Fig. 7. Electromagnetic voltage and current regulation.

The windings (F1) and (F2) differ, in that (F1) is a fine wire voltage winding and connects across the charging circuit, and the coarse wire current winding (F2) is in series with the charging circuit from the generator to the battery. The charging current does not pass through the voltage winding (F1), but does pass through the current winding (F2). Both windings are in the same direction on the core. The only difference between the regulator and cut-out windings and that of a regular cut-out winding as shown in Fig. 3, page 332, is that in the latter, a regulator blade is provided with points (E) and resistance (M) which can be cut into the field circuit when the points (E) are open.

When the voltage of the generator reaches about 6.5 volts, the current passing through the fine wire winding (F1) is sufficiently magnetized to draw blade (A) of the cut-out against the spring tension, which is so adjusted that the cut-out blade (A) is drawn to the core, and the cut-out points are closed. The charging current then passes through the cut-out winding (F2), through the points, to the (+) terminal of the battery, in the usual manner.

When the voltage or current reaches more than the output should be, the regulator blade (on the left) is drawn to the core against the tension of the spring which is adjusted higher than that of the cut-out blade. This action cuts resistance (M) into the field circuit, as previously explained in connection with Figs. 5 and 6.

It will be noted that **if the cut-out points should not close, or if the battery is disconnected,** current will not flow through the current coil (F2), and the generator will be dependent upon the voltage winding (F1) for regulation. If the voltage winding should become disconnected, then the cut-out points could not close; thus the charging current would not pass to the battery.

If the battery is removed from the circuit, disconnect the shunt-field wire at the regulator, so as to open the field circuit.

An example of a regulation system, similar to the one described is the Ward Leonard "type CC," shown on page 352.

EXAMPLE OF A CONSTANT-VOLTAGE REGULATION (BIJUR CONSTANT-VOLTAGE-REGULATION GENERATOR AS AN EXAMPLE)

The Bijur voltage regulation system is shown in the illustration below (Fig. 8). With this system the amount of current generated depends upon the state of charge of the battery and the amount of lamp load in use. With a discharged battery the voltage is at a minimum, but as the charge of the battery proceeds the voltage of the battery will increase, so that the difference in pressure between generator and battery is continually diminishing. If the battery is fully charged, then the generator charging current will be small. Therefore the charging current is variable even at the same speed of rotation, and tapers from the maximum with a discharged battery to minimum with a fully charged battery.

After the generator reaches a speed at which it develops its normal voltage, the voltage does not materially increase with speed, but remains nearly constant.

Voltage regulation permits of a battery being charged at a high-current rate when the battery voltage is low, and at a much lower rate when the battery voltage is high.

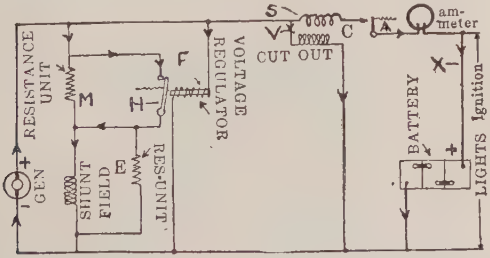

Fig. 8. Bijur electromagnetic voltage regulation system.

Operation of cut-out (C) (Fig. 8): Its purpose is to connect and disconnect the generator to or from the battery when the generator is at rest or at very low speeds. It has a shunt or voltage winding (V), and a series winding (S). The shunt winding (V) is connected across the generator, so as to receive the full voltage of the generator, and when the machine attains a speed at which it develops 6.5 volts, the shunt winding is sufficiently energized to close the cut-out armature (A). The series winding (S) is connected in the main circuit, and current flows through it, and its pull reinforces the pull due to the shunt winding and firmly holds the cut-out armature (A) closed. When the speed of the generator is decreased to a speed where it generates voltage lower than the battery, then a momentary discharge from the battery through the series winding demagnetizes the core of coil (C) and the cut-out is opened.

The voltage-regulating unit (F) (Fig. 8) has a single winding connected across the generator in a manner similar to that of the cut-out voltage winding. It is opened and closed according to the amount of pressure developed by the generator. Below 7.75 volts the resistance (M) is cut out of the field circuit, the path being around it through (H), giving the generator a chance to build up. Above 7.75 volts, the coil (F) pulls (H) to it, which throws resistance (M) into the field circuit, which automatically reduces the generation. While running, this regulator armature vibrates rapidly, cutting the resistance into and out of the field circuit by means of vibrator (H). Thus the pressure never goes above 7.75, or the lamps would burn out.

The other resistance unit (E), which is connected in parallel with the shunt-field winding, is to absorb the field energy when the regulator contacts are open and to reduce sparking at contacts.

Ammeter: In this particular system the meter is connected between the generator and battery, which indicates the generator output only, and does not show a discharge when the generator is at rest. On some cars the meter is connected at branch (X), and with the generator in operation the meter will indicate the output less the current consumed by lights and other devices.

Adjustments: A hole is provided on the regulator box for adjusting the voltage regulator, and another for the cut-out. Turning the adjusting nut to the right on the cut-out raises the cut-in voltage. Turning the adjusting nut on the voltage regulator to the right raises the generator voltage.

Before adjusting cut-out, disconnect one of the battery terminals and place the headlight switch on. Voltmeter leads should be clipped to the generator brushes, and the engine should be run slow, gradually increasing speed. Adjustment should then be made so that the cut-out will close at 6.5 volts. The voltage will then immediately drop on closing, which indicates that it has closed.

In setting the voltage regulator, connect generator to battery, having specific gravity of 1,250 and with light switch off. Voltage should be measured across the brushes as above. Run the engine at such a speed that the generator will turn 1,000 to 1,400 r.p.m. and with the tension of spring regulated until 7.75 to 7.8 volts are generated. Always set adjusting nut tight after adjusting.

The generator can be used without the battery, if lights are on, otherwise the resistance unit is liable to burn out.

Wiring: A single or double wire system can be used with this generator.

Care: (1) every two weeks 2 or 3 drops of thin mineral oil should be put in the oilers; (2) every two weeks **reverse regulator disconnect plug** by pushing it in to unlock, then turn and reverse its connections, which changes the direction of the flow of current through the points of the regulator, thus preventing pitting of points or depolarization, as explained on page 203; (3) inspect brushes every 1,000 miles, to see that they make good contact and move freely up and down.

EXAMPLE OF AN ELECTROMAGNETIC CONSTANT-CURRENT REGULATION SYSTEM (REMY "RELAY-REGULATOR" TYPE)

The Remy generator used with this regulator (Fig. 9) is usually a four-pole generator; however a two-pole type generator is used as an example, which makes no particular difference, because it can be used with either a two or four-pole generator.

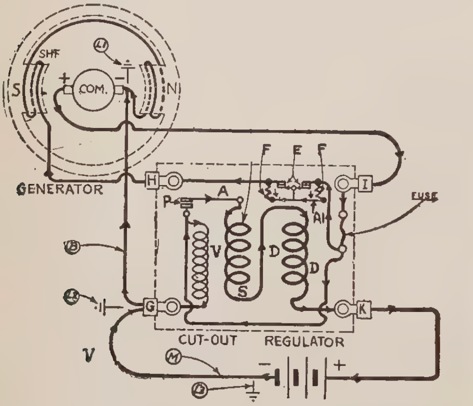

Fig. 9. Remy "relay-regulator"; a current-regulation method. The relay is the same as a cut-out. The cut-out and regulator are mounted on one base, as shown in Fig. 10. See also, Index under "Wiring diagram of Oakland '32'."

The generator is a plain shunt-wound machine and does not have the third-brush regulator, but a "resistance regulation" which is cut into the shunt-field circuit at high speeds by an electro-magnet.

Remy terms a "cut-out" a "relay." Therefore when we speak of a "relay," it is the same device that has been termed a "cut-out" in preceding instructions.

Shunt field circuit: From the (+) main brush of the generator to terminal (I) of the "relay-regulator," through the fuse, through points (E) of regulator, to terminal (H), through the shunt field windings, to the (−) main brush.

Cut-out or voltage circuit: From the (+) brush, to terminal (I), through the fuse, to cut-out voltage winding (V), to terminal (G), to the (−) main brush.

Note. On a grounded or one-wire system, ground connections are made at points (L1), (L2), and (L3) and wires (B) and (M) are not used.

Battery charging circuit: We will assume that the generator has reached a speed where voltage winding (V) has drawn blade (A) to its core, and points (P) are closed. Then the battery charging circuit would be from the (+) main brush, to (I), through the fuse, through points (P), through cut-out blade (A), through cut-out series or current winding (S), through regulator winding (D), to terminal (K), to (+) of battery, to terminal (G), to the main (−) brush.

Note. **If a grounded system,** it would be from (L3) to (L1).

Regulation at high speeds: At high speeds, the current passing through regulator winding (D), which is in series with the charging circuit, would exert a magnetic pull through its core (not shown in the illustration) which would draw the regulator blade, or the armature (A1), to its core, thus opening points (E), which causes resistance (F) to be cut into the shunt-field circuit, thus reducing its lines-of-force, and consequently its current output. The **shunt-field circuit** would then be from the (+) brush, to (I), to the fuse, through resistance (F) because points (E) are open, to (H), to the (−) main brush.

Since the regulator winding (D) is of heavy wire, the amperage or current controls the magnetic strength instead of the voltage, as explained under Fig. 6, page 348. Thus it would be termed "constant-current regulation," by means of an "electro-magnetic" action.

Note. Resistance coils (F) are shunted across each set of regulator points. It is essential that the two sets of regulator points be adjusted so as to be separated by the same current through the regulator coil, and that both sets vibrate together.

Remy Relay-Regulator Adjustments

An internal view of the circuit of the regulator and cut-out (relay), of the Remy system just described, is shown in Fig. 9.

An external view is shown in Fig. 10. Note that the cut-out and regulator are separate windings, but each is mounted on one base, which is usually mounted on the generator.

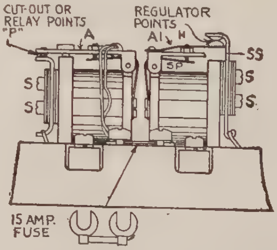

Fig. 10. Cut-out (relay) and regulator used with Remy "relay-regulated" generators.

This cut-out and regulator (Fig. 10) is the combination used with the Remy relay-regulated generator (Fig. 9).

First, however, in order to explain **the adjustment of the cut-out** (relay), we will use an illustration of the Remy cut-out alone (Fig. 11), which represents the same principle as the cut-out shown in Fig. 10 (above).

This cut-out (Fig. 11) is the cut-out used on Remy generators where the regulation is by means of a third-brush (explained farther on), and a regulator of the electromagnetic type (Fig. 10, right) is not used, but, as stated, the cut-out principle of both is similar.

Fig. 11. Remy cut-out as used with Remy "third-brush regulated" generators. Used as an example to explain the principle of adjustment of the cut-out in Fig. 10, which is similar.

The Remy Cut-Out

The cut-out (termed a "relay") is simply an automatic switch for connecting and disconnecting the generator and the storage battery, as explained on page 332. If the battery were left connected to the generator when the latter runs very slowly or stops, a reverse current would flow from the storage battery back through the generator windings and would soon discharge the storage battery. To prevent this a reverse-current cut-out is provided to act like a check valve, permitting the charging current to flow into the battery when the generator is driven rapidly, but opening the circuit whenever the generator slows down or stops.

The cut-out has two windings, a "shunt" or voltage (V, Fig. 9), consisting of many turns of fine wire, and a "series" winding (S), consisting of comparatively few turns of heavy wire. On the model shown (Fig. 11), the windings are placed on separate iron cores, but in some other models both windings are on the same core.

Whenever a current flows in either winding the core becomes a magnet, the strength of which depends on the amount of current flowing. The shunt or voltage coil is connected directly across the generator terminals in the same manner that a voltmeter would be connected. Hence the current in this coil will depend on the voltage at the generator terminals. The series coil is connected (through the contact points) between the generator and storage battery in the same way that an ammeter would be connected. The internal connections of the cut-out and regulator are shown in Fig. 9.

Cut-Out Adjustments

For correct adjustment of the cut-out (Figs. 10 and 11), it will be necessary to have an ammeter connected between the cut-out and the battery, so that the direction and amount of current flowing can be determined.

The ammeter on the car can be used, but it should be checked to make sure that the hand stands at zero when the engine is at rest and that no lights or other electrical equipment is in use. If it does not indicate correct zero, be sure to allow for the error when making adjustments.

The "air-gap" (Fig. 11), or distance between the end of the core and the armature (A) will affect the operation of the cut-out. Consequently this should be the first point to be considered when the cut-out is to be adjusted.

When the contact points are closed, the air-gap distance between the end of the core and the armature should be .012" to .015". This distance can be changed by moving the stationary contact point up or down. A thickness gauge may be used to check this adjustment. When making this adjustment be sure that the contact points meet each other squarely.

Note. A Remy Service Manual sells for $3. It gives all tests, adjustments and diagrams of generators, etc. See also advertisement on Wiring Diagram Book in the back of this book.

When the contact points are separated, the distance between them should be .012" to .015" on the 263 and 264 models, and .017" to .020" on the other models. On the 263 and 264 models this can be adjusted by bending the armature stop up or down (see Fig. 11). On the other models the stop pin which passes through the armature should fix this adjustment. If it does not, it can be raised or lowered slightly.

"Cut-In" Adjustment of Cut-Out

After having completed these adjustments start the engine and let it idle very slowly; then gradually speed it up until the relay contacts close. This is called the "cut-in," and can usually be determined by watching the ammeter. When the contacts close, the hand should move slightly to indicate a charging current of two or three amperes.

If, when the cut-out "cuts in," the current is greater than three amperes, the armature spring tension should be decreased. This is accomplished as follows: on the 263 and 264 models, by bending the brass strip through which the spring passes; on the M, O, 165, 3923, and similar models, by bending the spring under the armature; on the 60, 66, 261, and 262 models, by backing out the adjusting screw in the center of the armature.

If, when the relay "cuts in," the ammeter indicates a discharge current, the spring tension on the armature should be increased by reversing the processes described above.

Note. The relay cut-in can also be adjusted by connecting a voltmeter across the generator terminals and varying the armature spring tension until the cut-in occurs at the voltage given below:

Models O, 60-A-B, 61-A, 62-A, 64-A, 65-A, 165-D, 261-A-B, 3923	6.4 to 6.6 volts
Models 263-A-C-D-F, 264-A-B-C	7.0 to 7.4 volts
Models M, 66-A, 262-A	12.4 to 12.6 volts
Models 263-B-E	13.5 to 14.0 volts

"Cut-Out" Adjustment of the Cut-Out

Having adjusted the relay to "cut in" properly, speed up the engine until the generator delivers its maximum output, and then gradually reduce the engine speed until the cut-out contact points separate or "cut out." The ammeter hand may swing past zero to the discharge side of the scale for a moment before it cuts out. The discharge current should not be greater than two amperes, nor should the ammeter hand remain on the discharge side for more than a few seconds.

If the discharge current from the battery, back through the cut-out winding, series winding, exceeds two amperes, or if the ammeter hand shows a tendency to remain on the "discharge" side of the scale, the cut-out armature (A, Fig. 11) spring tension should be increased.

If the cut-out "cuts out" while the ammeter still indicates "charge," the armature spring tension should be decreased.

Should the cut-out armature (A) vibrate when the points close it is well to stop the engine and close the contacts by hand for an instant, and then make sure that they open again. This will allow the battery current to flow through the generator windings and magnetize the generator poles with the correct polarity. If the generator polarity is incorrect, the cut-out contacts may be burned.

Vibration of the cut-out armature (**A**) may also be due to "cutting in" when the generator voltage is below that of the battery. This can be corrected by increasing the armature (**A**) spring tension as explained above.

After completing the adjustment of the cut-out, check its operation several times to make sure that it cuts-in and cuts-out properly.

Regulator Adjustments

The action of the regulator, as well as the cut-out just described, is given on pages 350, 351.

After reading the explanation of the action of the regulator, given on page 350, it will readily be seen that an increase in the spring tension on the regulator armature (A1, Fig. 10) would increase the charging rate of the generator, as the current through the regulator winding (D) (Fig. 9), page 350, would have to reach a higher value before the magnetic pull on the armature (A1, Fig. 10) would overcome the increased spring tension.

Before starting to adjust the armature spring tension of the regulator, raise or lower the stationary contact supports (SS, Fig. 10) until the armature stands in the position shown in Fig. 10. The end of the armature should be slightly above the end of the core. Now press down lightly with the finger on the center of the armature and watch the contacts, to determine whether both pairs separate at the same instant (there are two sets of points on the regulator as shown in Fig. 9, page 350). If they do not, adjust one of the stationary contact supports up or down until both pairs separate at once. There are two supports (SS); one for each set of points.

Adjust the spring tension by turning the small screw in the center of the armature in or out until the correct charging rate is obtained (see table below). In some cases it may be necessary to bend the armature tension spring slightly before the correct adjustment can be obtained.

The maximum generator output depends on the model of the regulator as shown by the following table:

Models 60-A, 261-A, 261-B	.13.5 Amperes
Model 60-B	.10.0 Amperes
Models 66-A, 262-A (12-volt)	. 6.5 Amperes

Note. Data books on the regulation, speed, air-gap, cut-in and cut-out speeds of generators, other tests, speeds, etc., for all makes of generators, regulators, and cut-outs can be obtained of A. L. Dyke, St. Louis, Mo. Write for circular.

Care of Remy Cut-Out and Regulator

The cover (Fig. 10) should be removed for inspection at least once every two months. If the contact points are rough, pitted, or dirty, a strip of 00 sandpaper (which has been used) should be drawn through between the contact points (Fig. 12) several times, reversing sides each operation, so as to remove any rough surfaces or foreign material which might have accumulated. Be sure and clean the contact points by drawing a sheet of white paper through the points to remove any material such as sand or dirt.

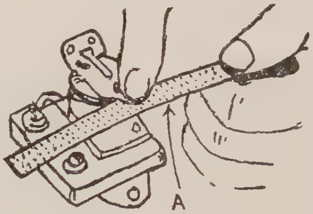

Fig. 12. Strip of sandpaper (A) being drawn between points of cut-out or regulator.

Contact Points

The points should have a smooth, clean surface and make good contact. One of the points is mounted on the end of a screw which can be turned in or out to adjust the air-gap. This gap should be adjusted as previously explained. Three different metals are used for these points: silver, platinum, and tungsten. When silver points are used, a reversing switch (termed a "pole-changing switch"; see Index) should always be used, the reason for this being that the silver passes from one contact to the other with the current, and it is necessary to reverse the direction of current flow occasionally so that the silver will not all build up on one point, leaving none on the other. Tungsten is now used most, and the pole-changing switch is seldom used.

EXAMPLE OF AN ELECTRO-MAGNETIC CONSTANT CURRENT AND VOLTAGE REGULATION SYSTEM (WARD-LEONARD, TYPE "CC")

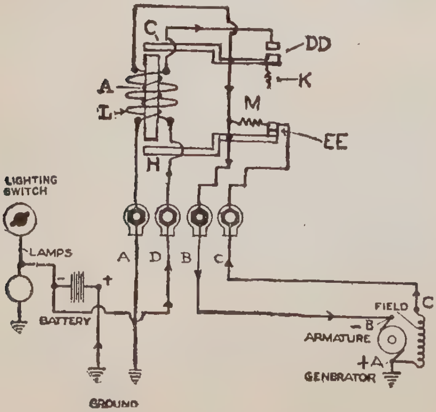

Fig. 13. Internal circuits of the Ward-Leonard type "CC" cut-out and regulator.

An example of a regulator by which **the voltage and current are regulated** is shown in Fig. 13 of the Ward-Leonard, type "CC" cut-out and regulator.

When the generator reaches sufficient speed to generate sufficient voltage to overcome the voltage of the battery, which is usually about 6.5 volts, the current flowing through voltage winding (**A**) magnetizes the core and draws cut-out blade (**C**), thus closing cut-out points (**DD**).

The charging circuit is then from the generator (+) grounded brush, to the (+) grounded terminal of the battery, through the battery, through current winding (**L**), through points (**DD**), to the (−) brush of the generator.

The field circuit is from the (+) brush of the generator, through the field winding, through regulator points (**EE**), through blade or arm (**H**), to the (−) brush of the generator.

This regulation method is similar in principle to that shown in Fig. 7, page 348.

When the charging rate reaches 10 amperes or more (according to tension of spring), the core pull is such that the regulator arm (**H**) is drawn to the core, and thus the points (**EE**) are separated. This action cuts the resistance (**M**) into the field circuit which weakens it, thus the voltage and current are reduced.

When the current decreases slightly below 10 amperes, the core does not have sufficient magnetism to hold the blade (**H**) against its spring tension; it is released, and points (**E**) close, thus cutting out the resistance (**M**).

This blade vibrates as the speed of generator increases and decreases, and thus the output of voltage and current is kept constant.

MECHANICAL REGULATION METHODS; EARLY MODEL AUTOLITE, GRAY & DAVIS AND DELCO

Mechanical Regulation Method (Early Model Autolite)

Mechanical methods for regulating the output on some of the early types of generators were employed. For instance, on an early type of Autolite generator (model "C-60," Fig. 14) permanent magnets were used to produce the lines-of-force for the wires on the drum-type armature to cut.

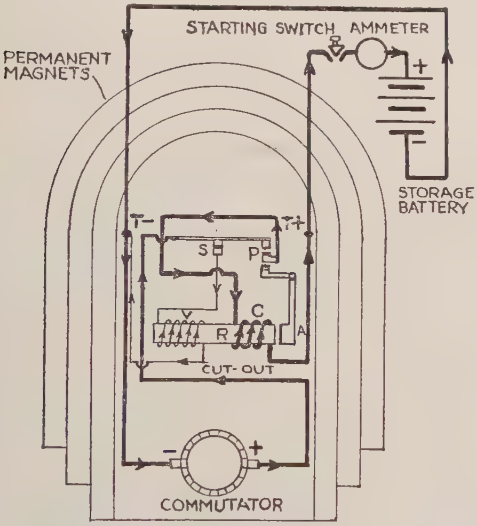

Fig. 14. Early model Autolite mechanical regulation method.

A cut-out, for connecting the generator to the battery when the generator reached about 800 r.p.m. was placed under the magnets above the armature. (Very near all generators have used and now use cut-outs, no matter what regulation method is employed.)[1]

Note that there are two windings, a fine wire voltage winding (**V**) through which current flows when the generator is started, from the (+) brush, to points (**S**), through (**V**) winding, to the (−) generator brush. At 800 r.p.m. of the generator armature, sufficient voltage would be generated for this cut-out voltage winding (**V**) to produce sufficient magnetizing force around core (**R**) to draw arm (**A**) to it, which action closes points (**P**) and opens points (**S**).

The charging circuit is then from the (+) brush, through points (**P**), through the coarse wire current winding (**C**), to the generator (+) terminal, to the switch, to the ammeter, to the battery (+) terminal, through the battery, out battery (−) terminal, to the (−) terminal of generator.

The regulation of output at high speeds could not be controlled by varying the magnetic field, because the strength of the field was permanent. Yet at high speeds the rule is that the greater the rate of speed at which the lines are cut, the greater the e.m.f. generated causing the current to flow. Therefore, in order not to produce too high an output, a **mechanical governor** was employed, which at high speeds disconnected the armature shaft with the drive system. Thus the regulation was a mechanical method of regulating the speed of the generator which reduced the rate of speed of cutting the fixed number of lines-of-force.

This method would be classed as **a mechanically regulated generator** of the "constant-speed constant-current" type.

Mechanical Regulation Method (Early Model Gray & Davis)

One of the first generators designed for automobile work was a Gray & Davis, as shown in Figs. 15 to 15B. This generator used electro-magnetic fields instead of permanent magnets.

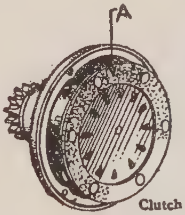

Fig. 15

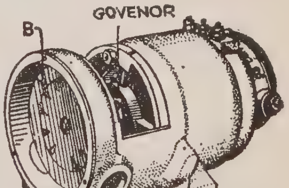

Fig. 15A

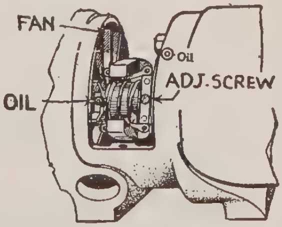

Fig. 15B. Governor of generator.

The mechanical regulation of maximum output was effected by a centrifugal governor, which kept the speed of the machine constant. For that reason this generator may be placed in the class of mechanically regulated machines of "constant-speed constant-current." Variations in speed are taken care of by the automatic "friction" type of clutch.

The friction clutch (**A** and **B**) will slip more or less according to the speed of the engine, and the amount of such slippage is controlled by a governor.

As soon as the speed of the armature increases beyond the rated number of revolutions, the governor will act on the friction clutch. In other words, the two clutch halves (**A** and **B**) will be pulled apart and slip in such a manner that the armature will rotate not faster than the predetermined speed.

---

[1] On some of the Delco generators the cut-out is not used. This is explained under the Delco instruction farther on.

A cut-out for connecting and disconnecting the battery and the generator (not illustrated) was used with this system. This generator was an early model and is now obsolete; but it is shown in order to explain one of the mechanical methods for regulating the output of a generator.

Adjustment for a higher or lower charging rate of the output of the generator was made by altering the pressure of the governor clutch spring.

Mechanical Regulation Method; Early Model Delco

On one type of Delco electric system, used on the Hudson "6-40," a **"variable resistance"** was introduced into the field windings mechanically by action of a governor. This is explained under the Delco instruction, as is also the Delco early model "Mercury type voltage regulator," as well as later models where a "third-brush regulation" is used.

INHERENT REGULATION METHODS

Inherent regulation refers to regulation methods inherent of, or **inside of, the generator.** Inherent methods of regulation in most all instances maintain a "constant current" or amperage, the constant-current method being used most.

Inherent, "constant-current" regulation methods would include:

1. **Compound-wound generators** (two windings on the field poles).
2. **Third-brush regulation.**

Compound-Wound Generators

There is a "shunt" winding and a "series" winding on the field poles of a compound-wound generator. The direction in which they are wound relative to each other will produce different actions, as follows:

1. **Cumulative action:** Where the two windings are **wound in the same direction** on the field core, so that one winding assists the other in the magnetizing action of the field poles, it is termed "cumulative" action, and the generator is termed a "cumulative compound" machine.
2. **Differential action:** Where the two windings are **wound in opposite directions** on the field core so that they oppose, or have a "bucking effect," due to the series winding being wound in a reverse direction to that of the shunt winding, it is termed a "differential" action, and the generator is said to be a "differential compound" machine, often termed a "reverse-series" generator.

Simplified Explanation of Cumulative and Differential Action of Windings

Before taking up this subject, glance at Figs. 10 and 10A, and note the **direction of the current** flowing through the wire wrapped around an iron core. Note that the direction in which the wire is wound,

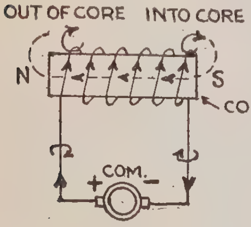

Fig. 10

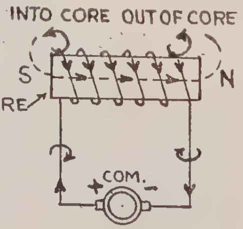

Fig. 10A

Fig. 10. Wound left-hand.
Fig. 10A. Wound right-hand.

and the direction of the current will determine the polarity, or which end of the core will be N and which end S (additional explanations of polarity of electro-magnets are given on page 183). The same principle applies to the iron core, or field poles of a generator, on which is wrapped the field windings.

Suppose, however, that we have two windings on the core, as in Fig. 10B, and that both windings (S and SHF) are wound in such a manner that the current flows through the windings in the same direction around the core. The two windings would then assist each other in establishing a strong polarity of the N pole at one end and of the S pole at the other end. Thus a "cumulative" action is produced.

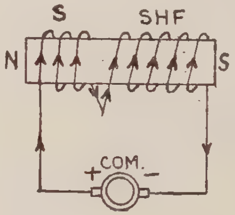

Fig. 10B

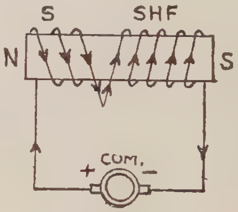

Fig. 10C

Fig. 10B. Cumulative action.
Fig. 10C. Differential action.

Suppose, again, that we have two windings on the core, as in Fig. 10C: one winding (S) with, say, three turns, wrapped in one direction, and another winding (SHF), say, of five turns, wrapped in another direction.

The winding (SHF) (Fig. 10C), having the greatest number of ampere turns, would establish the polarity of the core, making the left end, in this example, the N pole and the right end, the S pole, as in Fig. 10.

The winding (S, Fig. 10C) would **"buck" or oppose the core being thus magnetized,** because the direction in which the current flows through its winding would tend to establish the polarity at opposite ends of the core, as in Fig. 10A. Thus the strength of the magnetic lines-of-force around the core would be weakened, because the current strength which is magnetizing the core is only the difference in the winding (S, Fig. 10C) with three turns, and the winding (SHF) with five turns. Thus this difference holds the polarity of the core, and explains why the principle is termed **"differential action."**

Let us apply this elementary bit of information to the generator of the compound-wound type.

Compound-Wound Generators with "Cumulative" Action

A compound-wound generator with a "shunt" winding and another winding of coarser wire, called a "series" winding is shown in Fig. 11. The shunt winding is connected to the brushes—the usual shunt connected method. The series winding is in series with the generator brushes and the charging circuit. This connection is termed a "short shunt."

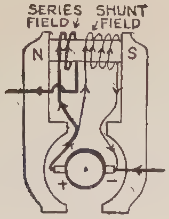

Fig. 11. Compound-wound generator "cumulative" in action; "short shunt" connection.

The series winding, and the shunt-winding both being in the same direction around the field core, the action would be termed "cumulative," as both windings assist each other in building up a strong magnetic field at the N and S poles. The generator would then be termed a "cumulative compound-wound machine" with a "short-shunt" connection. Owing to the fact that both windings assist each other, some sort of regulation at high speeds would be necessary.

The Gray & Davis concern used this principle on an early type of generator, models "C," "C1," "G," and "G1" (see Fig. 11A).

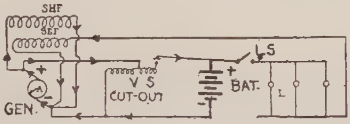

Fig. 11A. **Shunt field circuit:** From (+) brush through shunt field windings (SHF) to (−) brush.

Charging circuit: From (+) brush to cut-out, through cut-out current winding (S) to (+) of battery, to (−) brush of generator.

Lighting circuit: From (+) brush, through cut-out, to lighting switch (LS), through lamps, through series winding (SEF) to (−) brush.

This generator, through its "cumulative" action, would build up just the same as a plain shunt machine. Therefore the mechanical centrifugal governor principle was used to regulate the speed of the generator armature and thus keep the generator at a constant speed, and it was thus termed a **"constant speed"** and **"constant current"** type of generator.

Connections of this system are shown in Fig. 11A. When lamp switch (**LS**) is open, the shunt field winding (**SHF**) is acting alone, and sufficient pressure is generated in the armature winding to overcome the pressure of the battery and produce a charging current.

When the lamp switch (**LS**) is closed, the current to lamps (**L**) passes through the series field (**SEF**) in the same direction as in the shunt field (**SHF**), thus increasing the strength of the magnetic field in which the armature is rotating, and increasing the electromotive force, or pressure generated.

Thus it is possible for the generator to carry the lamp load and to continue to charge the battery at the same rate at which it was charging the battery before the lamps were turned on.

A compound-wound machine with a shunt and series winding is shown in Fig. 12. It is wound so that the current path is in the same direction in both windings, and it would thus be termed **"cumulative compound-wound,"** but it differs from Fig. 11, in that it is "long shunt" connected instead of "short shunt" connected.

Follow the field circuit in Fig. 11, from the (+) brush, and note that the shunt winding connects direct with the brushes and is thus termed a **"short shunt."**

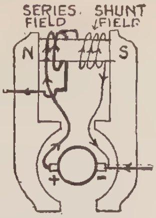

Fig. 12. Compound-wound generator "cumulative" in action; "long shunt" connection. See also Fig. 10B.

Follow the field circuit in Fig. 12 from the (+) brush of the generator and note that the current must first pass through the series winding before it reaches the shunt winding. This is termed a **"long shunt."**

Both are "cumulative" wound and are seldom used, for the reason that the field builds up at high speeds, the same as in a plain shunt generator, and some form of regulation is required.

Compound-Wound Generator with "Differential Action"

A compound-wound machine with a shunt and series winding is shown in Fig. 13. The series winding is wound so that the path of the current through it is in an opposite direction to that in the shunt winding. In other words, the series winding is "reversed"; hence the term often used, **"reversed series"** winding.

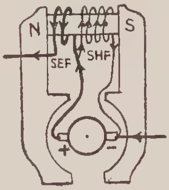

Fig. 13. Compound-wound generator "differential" in action; "short shunt" connection (also termed a "reverse-series" winding).

Connection of the "shunt" and "series" windings with the brushes would be termed a "short shunt," as the shunt winding is connected direct to the brushes.

When the magnetizing action of the current-flow through the series and shunt field windings of a generator is in opposite directions, the action is said to be "differential." Thus we have in Fig. 13 a **"differential compound-wound" generator,** with "short shunt" connection, also termed a **"reverse series"** field winding regulation. This principle is a typical example of "inherent" regulation.

The **shunt winding** (**SHF**), (Fig. 13) is connected with the brushes and establishes the N and S polarity of field pole. Only the field current passes through it. As the generator armature speed increases, the magnetic strength of the field pole increases and would continue to do so if the reversed series winding (**SEF**) did not come into action.

All of the current from generator to battery, lights, etc., must pass through the **reversed series winding** (**SEF**). Note that in Fig. 13 it is wound in an opposite direction to the (**SHF**) winding; therefore as the increasing current passes through the (**SEF**) winding, it tends to **buck or oppose** the (SHF) winding, or, in other words, the effect is to endeavor to reverse the polarity, thus weakening the magnetic field strength, and consequently weakening the output.

COMPOUND-WOUND GENERATORS WITH "DIFFERENTIAL" ACTION—AN EXAMPLE

An example of **a differential-compound wound generator with a "reversed-series"** regulation is shown in Fig. 14. This shows the models "G," "GA," and "GF" Autolite, used on the Overland 82, 86-6, and other cars from 1915 to 1918.

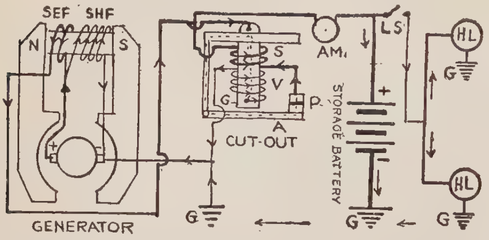

Fig. 14. A compound-wound generator "differential" in action (also termed "reverse-series"); "short shunt" connection.

The generator is a two-pole machine with the two windings on a field core at the top arch of the generator.

The shunt-field circuit is from the (+) main brush through shunt winding (SHF) to the (−) main brush. This establishes the polarity of field poles as N and S.

Cut-out voltage winding circuit: At slow speeds the starting generator current builds up voltage in the cut-out fine winding (V). This circuit is from the (+) brush through series field windings (SEF), to ground (G) on the cut-out frame, through winding (V) to ground (G), to grounded (−) generator brush (G). When the voltage reaches about 6.5 volts the winding (V) magnetizes the core, and armature (A) is drawn to it, thus closing points (P).

Note. The ground (G) on the cut-out frame is insulated from the ground of the car; that is, the cut-out frame is used as an insulated conductor.

The charging circuit is then from the generator main (+) brush, through series field (SEF), to ground on the frame of the cut-out, through points (P), through cut-out series winding (S), through the ammeter, to the (+) terminal of the battery, through the battery to the grounded (−) terminal of battery, to the grounded (−) brush of generator (G).

Regulation of output: At 1,150 r.p.m. the generator gives approximately 12 amperes, and its maximum, 16 amperes, is at 2,000 r.p.m. Above 2,000 revolutions, or at 2,200 r.p.m., it drops to 15 amperes, owing to the effect of the reversed series field winding (SEF).

Refer to the illustration and note that the charging current flows through the series winding (SEF) in a reverse direction to the flow of current through the shunt-field winding (SHF); note also that the series winding (SEF) is in "series" with the battery and generator.

As the current flow increases with the speed of the generator, the current through the series winding (SEF) becomes stronger and stronger until it opposes the shunt-field winding to such an extent that it has the effect of demagnetizing the field core, thus reducing the number of lines-of-force and the output.

This is a form of regulation termed a **"reverse-series" winding regulation,** and is a typical type of an "inherent" system without the use of external devices.

It is clear that since the current for battery and lights is carried through the series winding (which winding serves as a "regulator"), if an open circuit should exist, at high speeds, say, at cut-out points or at the battery, the series field which regulates the output would be open and the generator voltage would build up through the shunt winding (SHF) as on a plain shunt generator and burn out the lights, and in most instances burn out the voltage winding of the cut-out.[1]

Thus, if the battery is disconnected, either a heavy wire should be placed across the brushes or the brushes of the generator should be disconnected altogether.

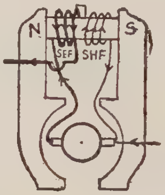

Fig. 15. Compound-wound generator "differential" in action; "long shunt" connection. See also Fig. 10C.

The connections of the compound winding, connected as a "long-shunt" connection are shown in Fig. 15, whereas the short-shunt connection is shown in Fig. 14. It is "differential" in action, as the current flows in opposite directions around the field poles, and thus differs in action from that shown in Fig. 12, which was "cumulative" in action. In other words, current flows in the same direction in both windings.

The principle of the "short" and "long" shunt is similar, except that in the long-shunt connection, the current to the shunt-field must flow first through the series-winding before completing its circuit.

Charging rate adjustments of compound-wound generators with reversed-series winding and shunt winding, differential in action to each other (that is, wound in opposite directions, so as to oppose each other, as in Figs. 13, 14, and 15), are not provided with means for adjustment.

The output can be increased by connecting a resistance wire of low resistance in parallel with the series field. The amount of resistance can be determined only by experiment.

Another method would be to cut out a few turns of the reversed series field coil.

To decrease the output, a few turns could be added to the reversed series coil (SEF).

Compound Winding—"Bucking-Series"

A compound-wound generator with a shunt winding and a "reversed-series-field" winding with a "thermal unit" for cutting into the series-field at high speeds is shown in Fig. 16.[2] This system would be termed an "inherent, constant current" system with a "differential" or "bucking-series" action.

The difference between this system (Fig. 16), and the "differential" system shown in Figs. 13, 14, and 15 is that the series field winding (SEF), also called "regulating winding," does not take all or even a part of the current delivered by the generator until the generator speed reaches a point above a car speed of 15 miles per hour. The current up to this point passes through an iron wire resistance (B), called a "ballast coil," and when cold offers no resistance. Thus the current does not pass through the series winding, because there is less resistance through the resistance coil (B), when cold.

---

[1] The voltage winding is also often burned out when the cut-out points stick and the battery discharges for a long period back through the generator.

[2] Formerly the Rushmore (now known as the Bosch) "thermal principle of regulation."

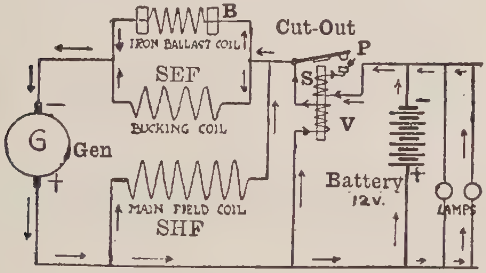

Fig. 16. **Shunt-field circuit:** From (+) brush, through shunt-field winding (SHF), through ballast coil (when cold), to (−) brush of generator (G). When (B) becomes hot, resistance is offered and the path is then through (SEF).

Cut-out voltage winding: From (+) brush, through winding (V), through ballast coil, to (−) brush of generator.

Charging circuit: From (+) brush, through battery (+), to cut-out series winding (S), through points (P), through series bucking coil (or ballast coil, if less than 15 m.p.h.), to (−) brush of generator.

The generator, therefore, acts as a plain uncontrolled shunt-wound machine, and builds up voltage rapidly.

As the speed of the generator increases, the charging current passing through the ballast coil (iron wire B) increases, and thus its temperature is raised. At 15 m.p.h. car speed, the charging current reaches a higher value, and the ballast coil is heated to such an extent that it offers more resistance than does the series winding (SEF). Therefore the current takes the easier path through the series winding, which causes the "differential" effect of opposing the shunt-field winding (SHF), which in turn demagnetizes the field core and reduces the output, as explained under Fig. 14.

This action of **the series field opposing the shunt field is often termed "bucking,"** and the series field (SEF) is often termed a "bucking coil," as it bucks against the shunt-field (SHF) magnetizing effect of the field core.

THIRD-BRUSH REGULATION

The generator using a third brush to regulate the output at high speeds is a shunt-wound generator, and not a compound-wound (unless it is a motor-generator combined, which is explained farther on). The third brush regulates the current out-put of the generator, and is termed a **"constant current"** regulation method.

The third-brush regulation of the out-put of a generator is a typical example of an "inherent" method of regulation. The regulation is accomplished without the use of resistance, or electro-magnets, or any external devices whatsoever, and is the system now in general use.

Fig. 17. Third-brush regulated generator.

A diagram of the internal connections of a third-brush regulated generator is shown in Fig. 17.

Note that instead of both terminals of the shunt-field windings being connected direct to the main brushes, one end of the shunt-field winding is connected to the third brush, and the other end is connected to the (−) main brush. This **third brush** regulates or controls the amount of current passing to the shunt-field windings, and thus tends to keep the current out-put of the generator constant.

The third brush is always connected with one end of the shunt-field windings, either the (+) or the (−), depending upon the direction of rotation of the armature and the side of commutator on which it is placed. In the example given above it is connected with the (+) side; thus the current leads from it into the field windings.

The shunt-field circuit, in Fig. 17, is from the third brush (which is on the (+) side of the armature), through the field windings, to the (−) main brush.

As stated above, the amount of current passing to the field windings is dependent upon the third brush. In a plain shunt-wound generator the field windings are connected direct to the main brushes, but by connecting one end of the field winding to the third brush, we cut out part of the armature coils.

Magnetic Circuit of Generators

Before the principle of the third brush can be understood, it will be necessary to take up the subjects of "magnetic circuits of generators," "brushes," and "armature reaction," which will lead us to the explanation of the third-brush principle.

The same principle applies to the magnetic circuit of a motor.

The main magnetic circuit of a two-pole round-frame generator, with poles 180° apart, is shown in Fig. 18 (page 358). The polarity of the pole is determined by the direction in which the wire is wrapped around it, and the direction in which current flows in the wire, just the same as the polarity of the electro-magnets shown on page 183. The word "polarity" refers to the N or S pole.

The main magnetic circuit, also called the "main magnetic field," or the path of the magnetic lines-of-force is very much the same as on an electro-magnet. In fact, we could term the two field poles "electro-magnets."

Let us assume that wire is wrapped around the field poles and that current is flowing in such a direc-

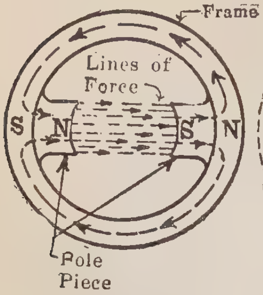

Fig. 18

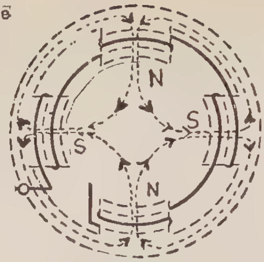

Fig. 19

tion as to give the pole on the left (Fig. 18) a N-pole polarity, and the pole on the right a S-pole polarity.

Therefore the lines-of-force would pass out from the N-pole end of the left electro-magnet (field pole), across the air gap (where the armature revolves), to the S-pole end of the electro-magnet on the right, then out the N-pole end of this magnet on the right, through the frame to the S-pole end of the magnet on the left, back to its N-pole end. Thus the magnetic circuit is completed, above and below and all around.

The magnetic circuit of a four-pole round-frame generator, with field poles 90° apart from the center of each pole, is shown in Fig. 19. Poles opposite each other are of the same polarity, or, in other words, the polarity alternates. This is necessary in order that there be a magnetic circuit.

If the poles opposite each other were of opposite polarity, the lines-of-force could flow only in two directions, as shown in Fig. 21.

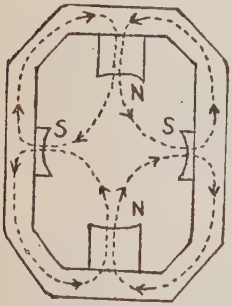

Fig. 20

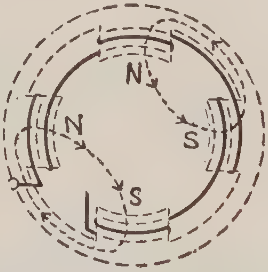

Fig. 21 (wrong).

The main magnetic lines-of-force will not flow across the air-gap from one pole to another, where there are a multiple of poles, because they take the easier path, from one pole to the adjacent pole. They could not flow across air-gap, from one pole to another, because they would have to cross each other and lines-of-force cannot cross or merge into each other.[1] Therefore the plan shown in Figs. 19 and 20 is the usual polarity for "multi-polar" generators.

A four-pole rectangular generator frame with two field poles on which wire is wrapped (the upper and lower poles), and two field poles without wire, is shown in Fig. 20. The field poles on which there is no wire are called "consequent" poles. The magnetic circuit is similar to the four-pole generator (Fig. 19). The magnetic circuit takes the shortest path, as shown.

If the top pole was N and the bottom pole S, then the lines-of-force would only be made to pass from the top to the bottom pole by having the space between poles less than from the pole to the sides of the frame. In other words, the lines take the shortest path.

A two-pole generator has more wire on the field poles than a four-pole generator, the capacity being the same.

It will be noticed that on two-pole generators the magnetic lines-of-force flow straight across and through the armature, and that on four and six-pole generators the lines pass through only a portion of the armature. For this reason, the armature wires are wound accordingly. The two-pole armature is divided into halves, and the four-pole into quarters called "spans." Hence the reason for placing brushes in different positions, as will be explained farther on.

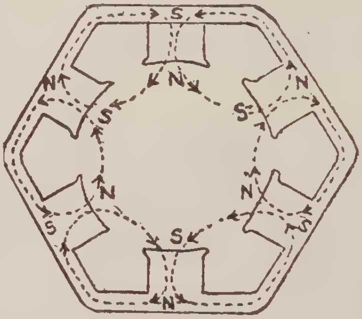

Fig. 22

A six-pole, multi-polar generator frame is shown in Fig. 22. Note that the polarity of the poles alternates, as was the case in Fig. 19.

Note, too, that there are six field poles. If wire was wrapped on these field poles and current passed through the winding, each field pole would be an electro-magnet; one end of the field pole would be N and the other S.

Therefore, if the field pole, say, in the center, at top, was wrapped with wire in such a direction that its inner end, facing the center of the generator was the N pole, its other, or upper end, would be the S pole, just the same as in the case of an electro-magnet.

The next pole would have the wire wrapped around it in such a direction that its inner end would be the S and the upper end of it would be the N pole, and so on, around the entire lot of field poles.

The main magnetic circuit would then be just the same as explained in Fig. 19, page 358, which is: out of the N-pole end, into the adjacent poles at the S-pole end, out of the N pole, or the upper end of the S pole, into the frame, into the S-pole end of the N pole, thus completing the magnetic circuit.

Note. Diagrams showing the N and S pole polarity of generators are rarely marked at the upper end, next to the frame. Where they are marked, which is usually at the inner end, or it may be at the upper end, as a matter of convenience, such marking always refers to the polarity at the inner end of the field pole next to the armature.

---

[1] Lines-of-force do not cross or merge into each other. Although there are millions of them, each line is independent of the other.

Brushes

It is also necessary to explain the location of brushes on a generator commutator, in order to lead up to the principle of the third brush, because the position of the third brush and the distortion of the main magnetic field are two factors governing the operation of the third brush,

Main brushes on a two-pole (bi-polar) generator are placed 180° apart (Fig. 26). One is positive (+), the other negative (−).

Main brushes on a four-pole (multi-polar) generator can use either two or four main brushes.

If two brushes, they would be placed 90° apart (Fig. 26A), and one would be negative and the other positive.

If four brushes (Fig. 26B), two would be positive (+) and two negative (−), the brushes opposite each other being of the same polarity.

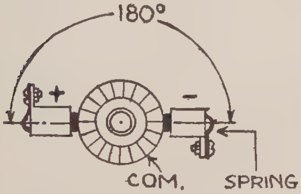

Fig. 26

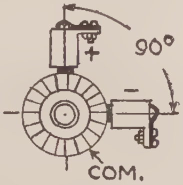

Fig. 26A

Only two brushes on a four-pole generator are necessary, if they are large enough to carry the current, as they are more accessible.

On many of the Remy four-pole generators of the straight shunt-wound type, using an external regulation system (Fig. 17, page 422), there are **three brushes** (Fig. 26E). Two of these are "main brushes" and the third is a "field brush." **This is not a "third brush,"** and it is not absolutely necessary, but is used as a common ground for the armature and field.

The third brush is usually smaller than the main brushes and is usually black, whereas the main brushes are often copper plated.

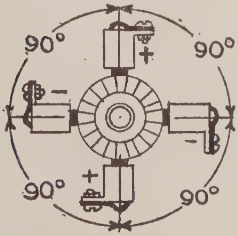

Fig. 26B

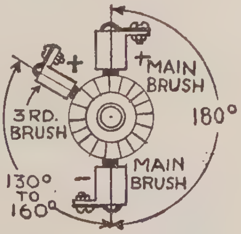

Fig. 26C

On a two-pole, or bi-polar generator, the third brush is placed slightly nearer to either the (+) or (−) main brush, as in Fig. 26C. Thus it will usually be (−) if nearer the (−) brush, or (+) if nearer the (+) brush. The location varies according to the direction of motion of the armature and the direction of current through the field windings.

On a four-pole, or multi-polar generator where there is a third brush, the two main brushes are usually located 90° apart. The position of the third brush will be between 130° and 160° from the main brush of opposite polarity, as shown in Fig. 26D.

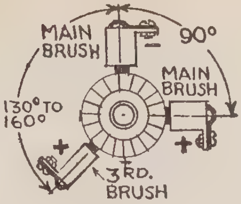

Fig. 26D

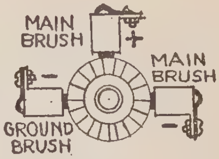

Fig. 26E

Brush construction: The brushes used on generators are usually carbon brushes. The reason carbon is used is because they have the advantage of giving better commutation than copper brushes, as they offer a higher resistance in the path of the short-circuited coil (C, Fig. 26H) than copper brushes do, and thus keep down sparking to a certain extent. They are quite often copper plated, so that the current will be conducted to the main circuit without this resistance effect, but the part resting on the commutator segments is plain carbon, and thus offers resistance to the coil (C) of the armature, which it short-circuits across when over two segments.

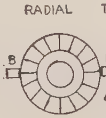

Fig. 26F.

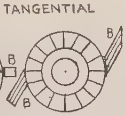

Fig. 26G.

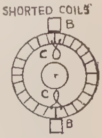

Fig. 26H.

Brushes on motors were formerly made of gauze, but are now made of composition, something like graphite and carbon.

A radial brush is where the brushes butt directly against the commutator, as in Fig. 26F. They are usually of carbon and this is the principle of construction for brushes used on automobile generators and motors.

Tangential brushes are usually made of copper, and are placed as shown in Fig. 26G. They are seldom used. Starting motor brushes are now made of a composition similar to carbon, but softer, and are placed in a radial position (Fig. 26F).

Brushes must be seated (rounded out) to fit the curvature of the commutator. See Index under "Seating brushes."

Setting Brushes

An armature with wires around the core is shown in Fig. 27. The commutator is not shown, but the brushes are shown as if connected with the wires.

The lines-of-force are flowing from N to S, as indicated by the straight arrows. We will term this the "main magnetic field." Therefore, the armature revolving as it does, it would cut the lines up on the left, and current would flow in, and as the wires cut down on the right, current flows out.

If these lines-of-force always passed in a straight line as shown, a "neutral" line could be drawn directly down through two commutator bars at a position where the current in the wires on the two sides are opposed to each other. In other words, one side is (+) and the other (−). The "neutral line" therefore would be as shown.

Armature Reaction

Owing, however, to what is termed "armature reaction," this line is always farther advanced in the direction of rotation, for the reason mentioned on the next page.

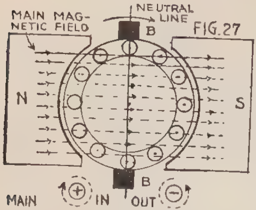

FIG. 27

MAGNECTIC LINES FLOWING STRAIGHT ACROSS

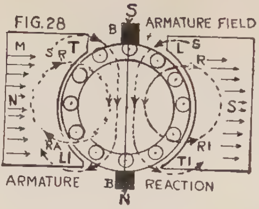

FIG. 28

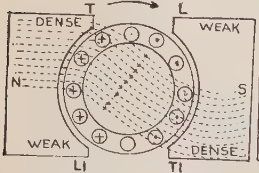
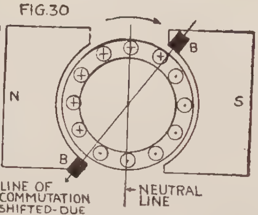
FIG. 29



DUE TO ARMATURE REACTION THE MAIN MAGNECTIC LINES ARE THROWN OUT OF LINE

FIG. 30



LINE OF COMMUTATION SHIFTED-DUE TO ARMATURE REACTION

When the armature revolves, current flows through its winding, and it immediately does what an electro-magnet would do; its core would become magnetized. That is, it would produce an electro-magnetic effect of its own, independent of the "main magnetic circuit," with a N and S pole polarity, as shown in Fig. 28, resulting from the lines-of-force produced around the wires by the current flowing in the wires. As will be noted in Fig. 28, these lines are directly across the main magnetic field, as shown in Fig. 27.

It will be noted, by referring to Fig. 28, that the "main magnetic field" (straight arrows), in passing from the N to the S pole, would flow in the same direction at the "trailing pole tip" (T), as the lines-of-force produced around the armature (curved lines), and thus would offer no opposition, and the main magnetic lines-of-force would be dense, as at (T) (Fig. 29).

On the other side, however, at the top (Fig. 28), at the "leading pole tip" (L), the lines-of-force around the armature wires are flowing in the opposite direction to the "main magnetic field" and would oppose it. Therefore the lines would drop, and at this pole tip (L), the magnetic field is weak (Fig. 29).

At the bottom (L1) (Fig. 28), opposition is offered, and thus this "leading pole tip" would be weak (see Fig. 29), whereas at the "trailing pole tip" (T1), the "main magnetic field" and "armature field" would be in the same direction, and thus (T1) would be dense, as in Fig. 29.

Refer now to Fig. 29, and note that **the magnetic lines have been distorted out of a regular straight line,** so as to weaken the "leading pole tips" (L) and (L1) and to strengthen the "trailing pole tips" (T) and (T1) because of the "armature reaction," or lines-of-force set up in the armature, as in Fig. 28.

The position of neutral plane will not therefore now be as in Fig. 27, but would be somewhere in the position shown in Fig. 30, in the direction of rotation of the armature. And the angle would increase as the current from the armature increased.

Therefore the necessity of **shifting brushes forward or backward** to locate the **"line of commutation"** in order to reduce sparking at the brushes will be evident. This **"neutral line"** must be found when setting brushes, otherwise the voltage may not come up to normal.

On some of the Westinghouse generators the brushes are set on this neutral line (Fig. 30). The brush rigging holding the main brushes is permanent, but they can be shifted, if necessary, by loosening and moving the commutator end housing.

The Remy generator brushes are moved one-half or two-thirds the width of the segment in the direction of rotation from the neutral line. The Delco and Bijur main brushes are set permanently.

To Find Neutral Position

To find the neutral position on the commutator it is necessary to "motor" the generator, that is, to connect a battery of the same voltage as the generator to the main brushes, and then shift the brushes one way or the other until the armature will not turn in either direction. This is "neutral point," or where the wires on one side are positive and the other side negative, and the neutral line is between.

This position can also be found by connecting a voltmeter between the brushes and moving the rocker-ring until the point of highest voltage is reached. The voltage will decrease as the brushes are moved away from the neutral plane.

Note. The current on this test is sent through the armature. Therefore always disconnect one side of the field from the circuit. If in a third-brush generator, this can be done by raising the third brush, as the third brush connects with one end of the field. As an example relative to finding "neutral" position, the Ford generator will be used.

To locate neutral position of brushes on a Ford generator: When brushes seat properly, the main brushes should be set on the neutral point. Raise the third brush and disconnect the field circuit. Connect the battery wire to the generator terminal. If the armature revolves, the brushes are not set on the neutral point. Turn the ring against the direction of rotation until the armature ceases to turn or until it revolves in the opposite direction. If it turns in the opposite direction, bring the ring back until the armature will not revolve in either direction, even when started by turning the shaft by hand. The brushes are now set on neutral point. Tighten the screws which hold the ring to head; lower the third brush and try it for running. If it turns over properly, drawing less than six—preferably less than four—amperes, the generator should be assembled to the engine, and proper connections should be made through the cut-out to the battery.

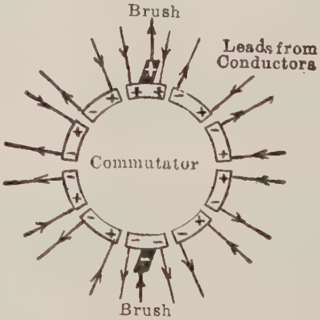


Fig. 30A. Showing the reason for placing the brushes in a neutral position.

Why a brush must be set on or near to neutral: Without going into the subject of armature winding, which would require considerable explanation, of value only to an armature winder, a simplified explanation is given as follows:

In the case of either a lap or wave-wound armature, by referring to Fig. 30A, it will be noted that two conductors are connected to each commutator bar. On most of these commutator bars, the current is flowing into the bar from one of the conductors, and out of this same bar to the other conductors.

Note that there is only one commutator bar to which current is flowing from both conductors;

consequently the (+) brush should be in contact with this commutator bar. In the same way there is only one commutator bar from which current is flowing to both conductors; consequently the (−) brush should be in contact with this commutator bar.

Brushes on motors are shifted in the opposite direction to that of generators owing to the fact that the armature reaction is in the opposite direction.

Figs. 31 and 32 illustrate methods of keeping the **brushes pressed firmly to the commutator** by spring tension. Note the spring.

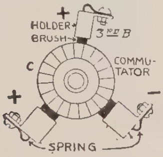

Fig. 31.

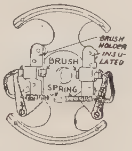

Fig. 32.

Fig. 31 represents **two main brushes and a third brush** as on the Ford "FA," 4-pole generator.

Fig. 32 shows the **brush holder, the brushes, and the end plate** of a two-pole generator, as shown in Fig. 33.

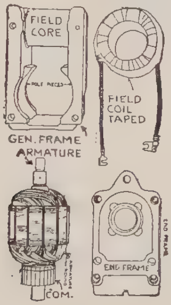

Fig. 33.

Fig. 33 illustrates the parts of a two-pole generator with a single-field winding. The field coil is shown to the right at top, and the armature and end plate are at the bottom of the illustration. The **round frame** with two and four poles is **used most.**

The Principle of Operation of the Third Brush

Now that we have learned how the magnetic circuit is distorted and how the pole-tips are weakened, the principle of the third brush will be easier to understand.

Refer to Fig. 34. Suppose the voltage from the main brush (C) to the main brush (D) is 6½ volts, the voltage would be about 5 volts from the main brush (C) to the third brush (E). Thus 5 volts would be applied to the shunt-field winding, which is sufficient pressure to cause approximately 1¼ amperes to flow to the shunt-field windings. At low speeds, where the generator armature sends little or no current into the battery, the "main magnetic field" is almost straight across from N to S poles, as in Fig. 27, page 360.

As the generator speed rises, the current going to the battery increases. This current of course flows through the armature, from the main (+) brush (D), to the battery, to the main (−) brush (C).

This current flowing through the armature winding sets up what is termed "armature reaction," as explained on page 360 (Fig. 28), with the result that the "main magnetic field," which at low speeds moved straight across from N to S pole (as in Fig. 27, page 360), is now distorted or twisted out of its original position, very much like two streams of water coming together, and as shown in Fig. 34. Thus, as explained on page 360, at the trailing pole tips (T) and (T1), the lines-of-force are dense and strong, and at the leading pole tips (L) and (L1), they are weak.

Fig. 34. Explaining the principle, or action of the third brush.

Therefore the armature coils, in passing from brush (E) to (D), is passing through the weakest magnetic field, and consequently a very low voltage is generated.

The greater part of the voltage is generated when passing from brushes (C) to (E), as this part of the magnetic field is strongest.

Thus, as the speed increases the distortion is greater, weakening the leading pole tips where the third brush takes its current for the field windings. As the magnetic lines-of-force are weakened, the current to the field weakens, and the voltage of the machine becomes less than would be the case with the full-field strength, thus holding the generated current down to the maximum for which the brush is set. Clearly, then, the shunt-field current decreases as the speed increases.

Adjusting Output of Third-Brush Regulated Generators

The maximum output of a third-brush regulated generator can be increased by moving the third brush on the commutator away from the main brush, which is connected to the field-windings. **To decrease,** move it in the opposite direction.

Since the field is connected between these two brushes, it can readily be seen that increasing the distance between them will insert a greater number of armature conductors between them, thus increasing the voltage applied to the field windings, which in turn will increase the field strength, consequently increasing the generator output.

Most third-brush generators have **an adjustable brush arm** which can be adjusted in either direction.

It is important that all brushes be fully seated, especially the third brush.

The third-brush regulated generator is now used more than any other method of regulation.

The third-brush regulated generator is a "constant-current" regulated type of generator, because of the fact that the charging current flowing through the armature winding produces the field distortion necessary for regulation. Therefore, **the charging circuit must not be opened** by removal of the battery or open circuits, otherwise the generator would build up voltage to a high value.

When disconnecting the battery, the main generator terminal should be grounded or the shunt-field fuse removed.

Most third-brush regulated generators have **field fuses** connected with the shunt-field winding.

If lamps are operated from a constant-current generator, the lamps will be burned out when the battery is disconnected unless the lamps are so connected that they consume the entire output of the generator.

EXAMPLE OF A THIRD-BRUSH REGULATED GENERATOR (REMY)

A Remy four-pole, third-brush regulated generator is shown in Fig. 35.

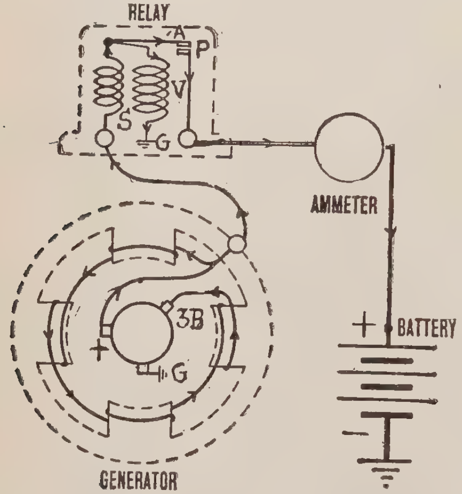

Fig. 35. A Remy four-pole, third-brush regulated generator.

Shunt-field circuit: From the (+) main brush, through the field windings, to the third brush, which in this instance is connected on the (−) side. This completes the field circuit. The regulation of this field circuit at high speeds is by means of the third brush, as explained on page 361.

The cut-out voltage winding circuit is the next circuit to trace. This circuit starts at the (+) main brush, to cut-out[1] series coil (S), to voltage winding (V), to ground, to the grounded (−) main brush of the generator. Thus the cut-out voltage winding is completed.

Battery-charging circuit: When the speed of the generator reaches a voltage higher than that of the battery, the voltage is such that the voltage winding (V) exerts sufficient magnetizing effect to draw the cut-out armature blade (A) to the core, thus closing points (P). The charging circuit is then from the (+) brush, through series coil (S), through blade (A), through points (P), to the ammeter, to (+) of the battery, through the battery, to (−) ground of the battery, to the (−) grounded main brush.

The battery discharge circuit is about 2 amperes back through the cut-out series coil (S) to cause the points (P) to open when the generator speed drops to a low speed (see action in Fig. 5, page 333).

Third-Brush Regulated Generator with a Thermostat Control (Remy)

It will be noticed in Fig. 36 that a **thermostat** is provided in addition to the third brush, the purpose of which is explained farther on.

Shunt-field circuit: From the (+) main brush through the thermostat blades (which offers no resistance when cold), through the thermostat closed points (X), through the field windings (two-pole generator), to the third brush. (Note that the third brush is on the (−) side in this instance.) Thus a third brush regulates the output of the generator.

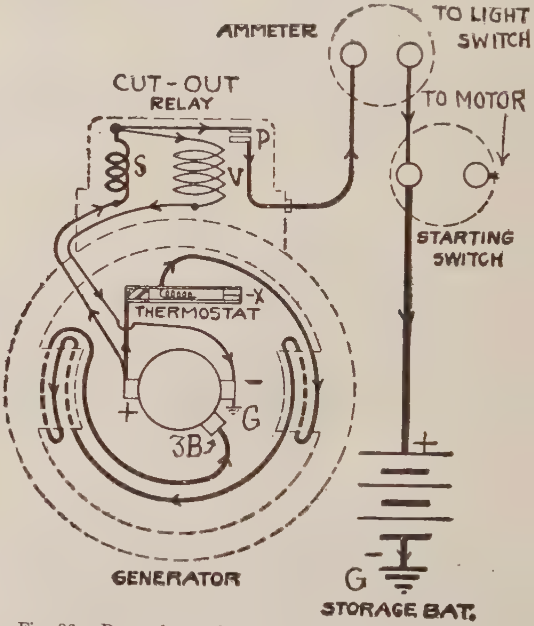

Fig. 36. Remy four-pole, third-brush regulated generator using a thermostat control.

The thermostat, more clearly shown in Fig. 37, **is in series with the field circuit** (Fig. 36). Its purpose is to permit setting the third brush to a much higher charging rate. Thus when first starting with a cold generator, the charging rate will be higher than if there was no thermostat. Thus a heavy charge goes to the battery.

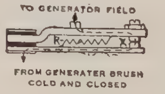

Fig. 37

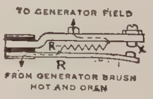

Fig. 38

Fig. 37. Thermostat points (X) closed. Resistance (R) not in the circuit.

Fig. 38. Thermostat points (X) open. Resistance (R) is now in the field circuit.

When the generator is cold, the thermostat springs hold the contact points closed, and no resistance is offered to the flow of current from the armature through the field windings, which, as stated, is higher than if the thermostat was not used.

---

[1] Thus the cut-out consists of two cores, one for the voltage winding and one for the cut-out series winding.

Owing to the heavy current flowing through the thermostat blades, the temperature rises quickly to a degree of approximately 175° F., at which time the blades warp and the points separate, thus inserting the resistance (see Fig. 38) into the field circuit. With this resistance in the field circuit, the charging rate is then about what the average third-brush regulated generator would be set for, or the regular charging rate, though the strength of the field circuit is normal.

Thus **the thermostat is not classed as a regulator** for cutting down the output at high speeds, but is merely used so that a heavier charging current will go to the battery when first starting or when the generator is cold, thus, termed a **"thermostat control."**

On some of the Remy systems, for instance in the 1919 Stearns, a multiple of four of the thermostat blades were used, connected in parallel, and set for different temperature openings.

The blades of thermostat are made of a strip of spring brass welded to a strip of nickel steel, a combination which warps when heated, because of the greater expansion of brass.

The thermostat is generally used with only the third-brush regulated type of generator.

The third-brush constant-current regulation is the principle used on this generator at high speeds, the principle of which is explained on page 361.

The cut-out voltage or shunt circuit: Current flows from the (+) brush through the current or series winding (S) of the cut-out, through voltage winding (V), to the (−) main brush.

Charging circuit: When the voltage of the generator is higher than that of the battery, the magnetic strength of the voltage winding around its core will be sufficient to draw the cut-out armature blade, thus closing points (P); the charging circuit is then from the (+) brush, through series winding (S) of the cut-out, through the blade, through points (P), to the ammeter, to the (+) terminal of the battery, to the (−) terminal of the battery, to ground, to ground of the (−) main brush.

Remy Generator Adjustments

Third-brush adjustment. To raise the output of a generator on which the third-brush regulation is used, it is necessary to move the third brush near the main brush, which is not connected to the field windings, or farther away from the "leading" main brush, which is connected to the field windings. Since the field is connected between this latter main brush and the third brush, it can readily be seen that increasing the distance between these brushes will increase the voltage impressed upon the field, which will also increase the field strength, and will in turn increase the generator output. On the other hand moving the brush farther away from the trailing main brush or nearer the leading main brush will decrease the field strength and decrease the output.

E is the third brush; D, connection to field winding; G, first main brush on the brush holder to which the thermostat assembly (H) is attached; C is the field lead showing the return from the field winding; A is the lead to the cut-out and battery. See also Fig. 36.

Setting brushes on generators: All generator brushes should be set in the position of least sparking when carrying full load, which position will be located a short distance ahead (in the direction of rotation) from the neutral plane. (See page 360 explaining the "neutral plane.") The brushes are in the neutral plane when at the position where the current is reversing in the winding, and, therefore, at the position where the highest voltage is obtained between brushes of opposite polarity.

This position can be located by connecting a voltmeter between the brushes and moving the rocker-ring until the point of highest voltage is reached. The voltage will decrease as the brushes are moved away from the neutral plane.

The cut-out used with the Remy generator (Figs. 35 and 36) is explained on pages 351 and 350.

Third-brush adjustment (fixed type): Fig. 40 illustrates the method of regulating the output of a stationary third-brush type generator, such as models "O" and "OB." Filing away a portion of the third brush so as to reduce the seat will tend to throw the brush nearer or farther away from the trailing main brush.

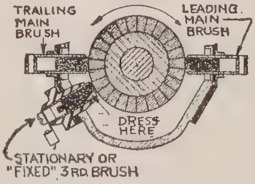

Fig. 40. Third-brush "fixed type." Seldom used.

To increase the output, file the third brush as shown in Fig. 40, which places the brush ahead, or towards the trailing brush, which is the same as moving it in the direction of rotation.

To decrease the output, file the top side, so as to place the brush away from the trailing main brush.

File only a small portion of the brush at a time, making tests by installing it and running the generator until desired maximum output is obtained.

If the armature revolves in the opposite direction to that in Fig. 40, employ the same principle.

The third brushes in Remy generators (Figs. 35 and 36) are **adjustable.**

The cut-out, as used with the Remy third-brush regulated generator, and the method of adjusting them, is shown on page 351.

Remy generators with a plain shunt-winding and with an "electromagnetic principle of regulation" have no adjustment, except that the brushes should be adjusted and seated for good commutation.

The relay-regulator, however, is adjustable. This is explained on page 350, and thus the plain shunt-wound generators which are used with this "electromagnetic" regulation method can be adjusted in the manner explained on page 352.

BIJUR THIRD-BRUSH REGULATED GENERATORS

Two examples of the Bijur generators are shown: one with the cut-out external of the generator, and the other with the cut-out internal of the generator.

Example of a Third-Brush Regulated Generator (Bijur) with an "External" Cut-Out

The Bijur third-brush regulated generator[1] is of the constant-current type. Models L-220, P-230, K-230, and U-250 are shown in Fig. 41.

Note that the cut-out is external of the generator, being placed on the top of the generator. There are four field-poles, consequently there are four shunt-field windings (SHF).

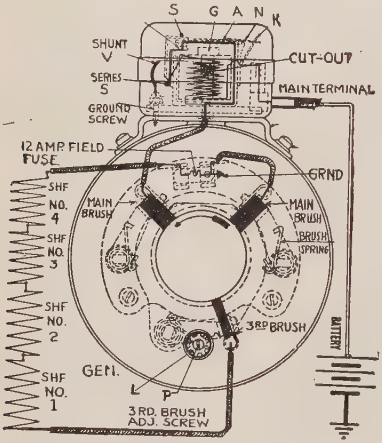

Fig. 41. Bijur third-brush regulated generator with cut-out external.

Shunt-field circuit: From the third brush, through field windings (SHF), through the fuse, to the (−) main brush (top right).

Cut-out voltage circuit: From the (+) main brush (top left), through cut-out voltage winding (V), to the ground screw, to ground of the (−) main brush at the fuse.

Charging circuit: From the (+) main brush (top left), to closed points (S), through the series cut-out winding (S), to the main cut-out terminal, to (+) of the battery, through the battery, out the (−) battery terminal, to ground, to ground (GRND) of the (−) main brush at fuse.

Example of a Third-Brush Regulated Generator (Bijur) with an "Internal" Cut-Out

The Bijur third-brush regulated generator of the constant-current type, model L-61, used on 1919 cars, is shown in Fig. 42.

Note that the cut-out is placed inside of the generator. There are four field poles and field windings.

Shunt-field circuit: From the third brush, through the four field windings, through the fuse, to ground, to ground (G) of the (−) main brush (B1), thus completing the shunt-field circuit.

Cut-out voltage circuit: From the (+) main brush (B2), through the fine wire voltage winding (V), to ground (G), to ground (G) of the (−) main brush (B1).

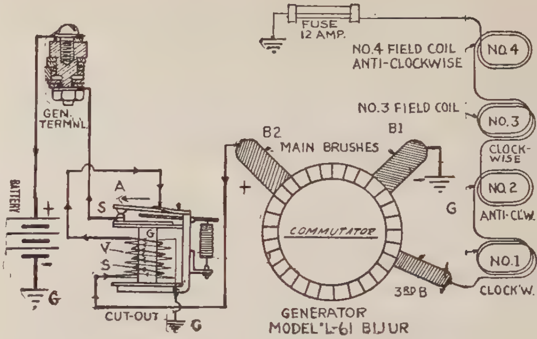

Fig. 42. Bijur third-brush regulated generator with cut-out internal of the generator.

Charging circuit: From the (+) main brush (B2), to the cut-out series coil (S), to blade (A), through cut-out closed points (S), to the generator terminal, to (+) of the battery, to the battery (−) ground (G), to ground (G) of the (−) main brush.

Remarks on the Bijur Third-Brush Regulated Constant-Current Generator (Figs. 41, 42)

The wiring: A single wire, grounded-return system is shown in Figs. 41 and 42. With the constant-current third-brush regulation, the generated current is independent of the voltage of the battery or the amount of lamp load connected, but depends upon the speed at which the machine is driven and the position of the regulating third brush with respect to the two main brushes. The cut-out (V) closes when the generator reaches 6.5 volts, or a generator speed of 500 or 600 r.p.m. With increasing speed the current increases to maximum value, at speeds about 1,000 to 1,600 r.p.m.; at higher speeds the current gradually decreases.

Adjustment: Moving the brush (by loosening the nuts) in the direction of rotation of the armature increases the generator output; in the opposite direction, it decreases. At 1,400 to 1,600 r.p.m. of the generator (20 to 25 miles, car speed) the amperage should be not less than 12 nor more than 15. Approximately a shift of the third brush 1/16″ will change the output 2 to 3 amperes. If adjusted on the car, remove generator cables and tape ends, then replace, after adjusting, and run the generator and test. Two or three trials may be necessary. Best results are obtained after running the car when the generator is hot and connected to the battery with 1,250 specific gravity (s.g.).

Fuse: A 6 to 12-ampere fuse is placed in the field to protect the coils from burning out.

It is not feasible to supply current for lights from a constant current generator without a battery being connected in circuit. For instance, if lamps require 7 amperes and the generator at speed delivers 15 amperes, the generator voltage would rise until the additional 8 amperes not required by the lamps will be forced through the lamp circuit and burn them out.

Circuit of Bijur Cut-Out and Generator (Fig. 41)

The path of the circuit from the generator through the cut-out is through the "shunt-winding" on the cut-out. When core (G) is sufficiently magnetized by the increased speed of the generator and current through this voltage shunt-winding (V), then the cut-out points close at (S). The charging current will then pass from the generator through the cut-out armature (A), through closed points (S), through cut-out "series coil" (S), to the main terminal on the cut-out to the battery, through the ground connection of the battery to ground connection in the generator through fields and brushes.

---

[1] See page 349 for description of the Bijur "voltage-regulated" generator where a plain shunt-wound generator without a third brush is used.

Cut-Out Adjustment (Fig. 41)

The generator should be connected up with a fully charged battery when testing.

Testing cut-out on generator (Fig. 41): The correct voltage at which the cut-out should close is 7.5 to 8 volts. It is not necessary to consider the speed. This can be tested by placing the leads of a voltmeter across the two main brushes of the generator and by noting the voltage at the instant that the generator automatically connects itself to the load, or to the battery connected.

The voltage at which the contacts (S) **close** is dependent upon the tension exerted by the spring (N), attached to the cut-out armature (A). Bending the bridge (K) up or down decreases or increases the tension, thus decreasing or increasing the voltage at which it closes.

Adjusting Generator (Fig. 41)

Adjusting current output: When driven at a speed of 1,400 to 1,800 r.p.m., the generator should show not less than 12 nor more than 15 amperes when cold, or 9 to 12 amperes when hot, and its output should be adjusted accordingly. Place a "test" ammeter[1] between the generator terminal and the cable leading to it. It is not necessary to remove the generator from the car for adjusting. If the current delivered by the generator is less than 12 or more than 15 amperes, then adjust.

The regulating third brush can be adjusted by loosening the nut (L), and then turning the shaft (P) with a screwdriver. The third brush can then be moved. Lock the nut (L) securely after adjusting.

Moving the third brush in a direction opposite to the rotation of the generator armature decreases the current output; and moving it in the same direction as that of the armature rotation increases the output.

Adjusting the third brush should be made when the generator is hot and connected to the battery through the cut-out. The battery should be fully charged and have a specific gravity of 1.250 or more. Be sure that the battery connections are tight.

When a generator is adjusted on the bench, the cut-out, battery, etc., should be connected as if on the car. Owing to a line drop in the car wiring, which is to allow for normal operating conditions when current must pass through the longer length of the car wiring, the output should be set for 12 amperes at a voltage of 8.2, measured across the two main brushes when the generator is driven at speeds of from 1,400 to 1,800 r.p.m.

Adjusting Bijur Cut-Out and Generator (Fig. 42)

Testing cut-out: The cut-out on model L-61 third-brush generator is inside of the generator. A voltmeter should be placed across the two main brushes (Fig. 42).

The cut-out armature (A) should close at points (S) when the generator voltage reaches 6.5 to 7 volts; if the voltage is above or below this, the cut-out can be adjusted by inserting a small fiber-handle socket-wrench in the adjusting hole. Turn the cut-out tension spring adjusting nut until points (S) of the cut-out close at the correct time. This adjustment is on the outside of the generator, as the cut-out in this instance is on the inside of the generator.

To adjust the current output of model L-61 generator (Fig. 42), which is a third-brush regulated constant-current type generator, with cut-out placed inside the generator, place the test ammeter between the generator terminal with the cable removed. Connect the generator with a fully charged battery (1.250 specific gravity), or more, then drive the generator at 1,400 to 1,600 r.p.m.; it should show not less than 12 nor more than 15 amperes when cold, or 9 to 12 amperes when hot, and should be adjusted accordingly.

If the current delivered is less than 12 amperes, increase the output by moving the third brush in the direction of rotation of the armature until the required amperage shows on the meter. If more than 15 amperes, then move the third brush in the opposite direction until the proper amperage shows.

It is not necessary to remove the generator from the car for adjusting the third brush. It can be moved by inserting a special-toothed adjusting wrench in the adjustment hole, and engaging the ratchet. The entire regulating brush assembly can then be shifted in the direction required. To get the best results, set when the generator is hot, and be sure that a fully charged battery (1.250 specific gravity or more) is used.

When adjusted on the bench, the generator should be connected to a fully charged battery, and in order to allow for the line drop in the car wiring, the output should be adjusted for 14 amperes at a voltage of 7.4 measured across the two main brushes, when driven at a speed of 1,400 to 1,600 r.p.m.

This type of generator does not employ an external regulator and would be termed a "constant current" or "inherent" regulated generator; a cut-out, however, is used.

A point worth mentioning here is the importance of having a battery in the circuit at all times and having good connections at all points.

REMARKS ON THE POLARITY OF A SHUNT-WOUND GENERATOR RELATIVE TO CONNECTION TO BATTERY

Connection of battery to generator: The proper method of connecting a generator to a battery is to connect the (+) terminal of the generator to the (+) terminal of the battery. If the generator (+) brush is grounded, then the battery (+) terminal should be grounded. If the generator (−) brush is grounded, then the (−) terminal of the battery should be grounded.

If a shunt-wound generator is wrongly connected to the battery, that is, the (−) terminal of the generator to the (+) terminal of the battery, the vibrator points on the cut-out will open and close or vibrate at first until the polarity of the core changes. It will then close and charge in the proper direction, or with the polarity of the battery, if the generator is running at sufficient speed. The polarity of the generator fields will change to the polarity of the battery, because if the battery is charged, it will send sufficient current through the fields to overcome the field current from the generator. The disadvantage will be that the ammeter will read in the wrong direction.

---

[1] If a dash ammeter on the car is used to make this check, it is probably connected so that the ignition circuit of 1 to 3 amperes will be taken through the ammeter. Therefore the current reading will then range from 6 to 9 amperes. The best plan is to use a separate test instrument.

The following explanation will probably make the statement clearer. When the cut-out contact points are drawn closed, with the generator and battery connected in the reverse polarity, for normal operation, the battery voltage and generator voltage are of such a polarity that they are connected in series with a short circuit across the sum of these two voltages. This causes a short-circuiting current to flow from the battery through the generator and generator fields, and through the series winding to the cut-out, in such a direction as to open the cut-out contacts and to reverse the polarity of the fields and generator. As soon as the cut-out contacts have opened, the current just described permits the generator to build up in the correct polarity. The contacts are then closed, and the generator is then properly connected to the battery.

If the battery is discharged, the battery cannot overcome the polarity of the generator fields, and the cut-out points will close, but the battery will be charged in the wrong direction. Some of the old-style cut-outs with permanent magnet cores will not change polarity, and the battery must be connected properly. It is best to connect the (+) terminal of the generator with the (+) terminal of battery.

DISCONNECTING BATTERY FROM GENERATOR

The question what to do when disconnecting the battery from the electric system of a car depends upon the kind of system involved. There are many different systems, and what would be satisfactory on one may be injurious on another.

It is not possible to operate lamps from a "constant current" generator when the battery is disconnected, unless the lamps so connected consume the entire current output of the generator; otherwise the lamps would burn out.

The answers appended to the following questions are those furnished by the Remy, Delco, Bijur, Westinghouse, and Ward-Leonard Electric Companies:

Question 1: What method should be adopted if a battery is disconnected from an electric system using a shunt-wound generator with "third-brush regulation"?

Answer (Remy): The generator should be short-circuited with a piece of heavy copper wire.

Answer (Delco): Probably the most effective and the surest method would be to lift all the brushes on the generator. This will eliminate any possibility of damaging the generator windings, and will hold good in all cases, regardless of the generator connections or methods of regulation.

Answer (Bijur): When a Bijur third-brush regulated generator is operated without battery, the field fuse should first be removed. If this is not done, the fuse will blow as soon as the field current builds up. This automatically opens the field circuit, but a new fuse must be put in place before the generator will again charge the battery.

Answer (Westinghouse): Remove the field fuse. If the generator is not equipped with a field fuse, then remove the field or third brush, which is smaller than the armature brushes.

Answer (Ward-Leonard): If either the cut-out or battery is disconnected, the field fuse should be removed, or the generator short-circuited by grounding the insulated terminal. If these generators are run on open circuit, the voltage will build up to probably five or six times its normal value, which in a short time would result in a burned-out field.

Question 2: What method should be adopted if a plain shunt-wound generator is equipped with an external electromagnetic "voltage regulator"?

Answer (Remy): A generator equipped with a voltage regulation can be operated without a storage battery in the circuit, since the regulation is independent of the charging current.

Answer (Bijur): When a Bijur generator is fitted with an external voltage regulator and is to be operated without a battery, the regulator should be removed. This opens the field circuit. The generators in question are plain shunt-wound generators.

Answer (Westinghouse): Machines of this type are usually equipped with a field and armature terminal on the exterior of the generator. In this case, it is necessary to disconnect the field lead and tape it up. This opens the field circuit and the machine can be operated without danger of burning up.

Answer (Ward-Leonard): The answer to No. 1 can be applied to this question also, with the exception of the regulator. As a rule, when a vibrating type of regulator is disconnected, it automatically opens the shunt-field circuit, and gives the necessary protection to the generator.

Question 3: What method should be adopted if a plain shunt-wound generator is equipped with an external electromagnetic "current regulator"?

Answer (Remy): A generator having its output controlled by a vibrating-current regulator should have its field circuit open whenever it is operated with the battery disconnected. Removing the fuse on our relay regulators will protect the generator.

Answer (Bijur): The same action is advised in the case of generators having external vibrating current regulators. The external construction of these is the same as that of generators fitted with voltage regulation.

Answer (Westinghouse): In this case, it would be advisable to remove one brush if the machine is equipped with two brushes, and if equipped with four brushes remove the two brushes opposite each other. This method is always safe.

Question 4: What method should be adopted if the generator is a compound-wound, constant-current machine?

Answer (Remy): The only generators which we manufactured with compound windings are our models "M" and "J." On this type of machine the shunt circuit should be opened when the generator is operated with the battery disconnected. This is accomplished either by removing the fuse, or by disconnecting the lead which is connected to the brush holder.

Answer (Westinghouse): This should be taken care of in the same manner as described in the answer to question No. 3. We suggest that you advise your readers that, regardless of what type of generator a car is equipped with, when in doubt as to what to do, they should remove the brushes in order to protect the generator when the battery is removed. Of course, this is not always convenient, but it is a sure method.

Answer (Ward-Leonard): The "bucking field," or "shunt-series wound" generator, should be handled in the same manner as the third-brush regulated generator referred to in No. 1.

Question 5: If the battery is disconnected how could ignition be obtained?

Answer (Ward-Leonard): The simplest way to obtain ignition under the three conditions mentioned, would be to connect four or five dry cells in place of the storage battery, leaving the generator disconnected. The current for the side and tail lights can be obtained temporarily in this same manner, or, if necessary, by putting two or three sets of dry cells in parallel.

INSTRUCTION No. 34

MOTOR-GENERATORS: North-East (with Ignition System); Simms-Huff; U.S.L.

MOTOR-GENERATORS

Motor-generators are of two general types:

First: Those with one set of field poles on which there are two, or compound windings: a "shunt winding" and a "series winding."

It is not necessary that the "series winding" be placed on all four poles. In fact, on many four-pole motor-generators, all four poles have "shunt windings" on them which fact determines the polarity of the poles, because there are more turns of wire in the shunt winding, and only two of the poles have "series" windings.

One **armature with one winding** and **one commutator,** with compound windings on the four field poles is the principle of the North East four-pole motor-generator as used on the Dodge. The Simms-Huff, formerly used on the Maxwell, was a six-pole motor-generator with one winding on the armature and one commutator. There are shunt windings on all six field poles, but series windings on only three poles.

The two field windings oppose each other when operating as a generator; thus the result is a "differential" action, as explained on page 354.

A **third-brush regulation** is used on the North East system, and also on some of the Simms-Huff; on early model Simms-Huff six-pole motor-generators, the regulation was by means of an electro-magnetic resistance method.

The two field windings assist each other when used as a starting motor, and thus the result is a "cumulative" action.

Second: the Delco motor-generator is similar in principle, except that many of these motor-generators have **two windings on the armature** (see "Buick armature windings," page 343) with **two commutators.** (See also Index for Delco generator instructions.)

A motor-generator of an early type, where there were two sets of field poles and two armatures, but mounted together in one unit, is shown in Fig. 1.

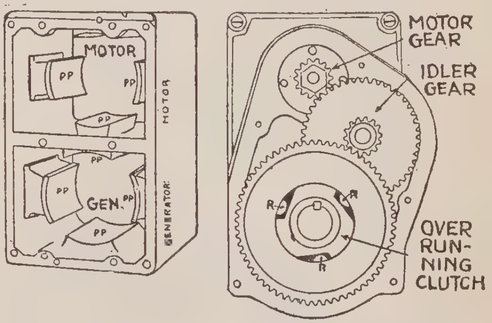

Fig. 1. An **early type of motor-generator** consisting of a generator below and a motor above, using two separate armatures and two separate fields, and termed a "double decker," since the motor armature is superimposed over the generator armature.

The two armatures are connected together with a system of gearing and an over-running clutch (**R**) (similar to clutch explained on page 324). The motor armature and the gearing are in operation only when the starting switch is pressed.

The generator armature is the only moving part under running conditions, as the over-running clutch of the roller type is provided to disengage the motor armature and reduction gears, which remain idle and inoperative when the engine is started and running under its own power. The generator armature revolves in the lower field. The motor and generator are entirely separate—armature is of the drum type. A regulator and automatic cut-out of the usual type are provided.

A modern type of motor-generator is where only one armature and one set of field poles are used for both the motor and generator, such as the North East and Delco.

As an example of the construction of a modern motor-generator and of its principle and its relation to the other parts of the electric system, the North East model "G" motor-generator will be discussed.

THE NORTH EAST ELECTRIC SYSTEM AS USED ON THE DODGE. A TYPICAL EXAMPLE OF A MOTOR-GENERATOR (TWELVE-VOLT SYSTEM)

In order to explain just how the same windings serve for both a motor and a generator, simplified illustrations are shown in Figs. 2 and 3 (page 368), which represent the North East model "G" system as used on the Dodge Bros. car.

Both actions do not take place at the same time. That is to say, if used as a motor, the generator action is not in operation; if used as a generator, the motor action is not in operation. Both windings on the field poles, however, are used for both the generator and motor action.

Note that there are four poles, each with a "shunt-field" winding and a "series-field" winding. Note also the cut-out which is used with the generator action. The generator is a third-brush regulated generator. The starting switch is used with the motor action.

Parts of the North East Electric System on the Dodge[1]

The principal parts of this system are enumerated as follows: (1) motor-generator (12 volt); (2) battery, 6 cells (12 volt); (3) ignition system (12 volt); (4) wiring system (single-wire grounded return).

The motor-generator (model "G") is a "single-unit" machine and operates either as a starting motor or as a generator, depending upon whether the current is supplied to it from the battery, in which case it acts as a **starting motor,** or whether it is driven by the engine, at which time it **generates current** and charges the battery.

The same field windings, armature, commutator, and brushes serve both for starting and for generat-

---

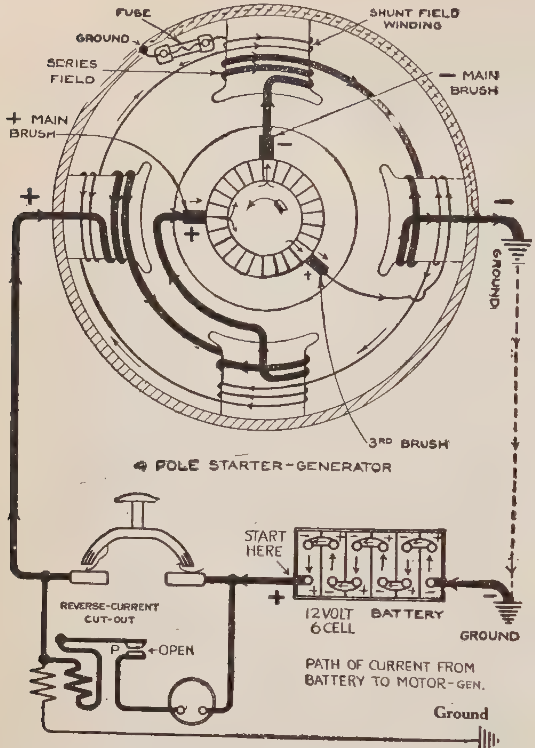

Fig. 2. Path of current from battery when used as a starting motor to crank the engine. Note that the current flow around the field poles of both the series and shunt-field windings is in the same direction, and thus is "cumulative" in action, which strengthens the polarity of the field poles.

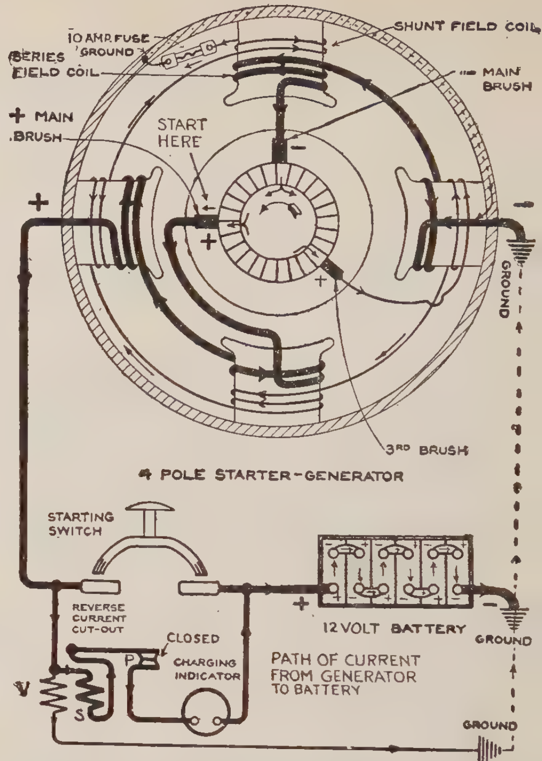

Fig. 3. Path of current from generator, when generator is charging battery. Note that the current flow around the field poles of both the series and shunt-field windings is in the opposite direction. Thus it is "differential" in action, which tends to weaken the field strength at high speeds (explained in the text).

ing purposes. In its general construction it differs very little from the ordinary compound-wound generator, except for the third-brush regulating feature and certain mechanical details.

Fig. 4. The motor-generator is driven by a silent chain from the crank shaft of the engine.

The motor-generator is mounted on the front left side of the engine and is driven from the crank shaft by means of a silent chain (Fig. 4). The driving ratio is three revolutions of the armature to one of the engine crank shaft.

Starting Motor Action

When running as a starting motor (see Figs. 2 and 5), the electric current from the battery flows from (+) of the battery to the switch terminals (1 and 2) on the cut-out. The starting switch connects these two terminals, thus closing the circuit around the cut-out, direct from the battery to the motor-generator, through the (+) terminal of the motor-generator, through half of the series field winding to the (+) main brush, through the armature coils out of the (−) main brush, through the other half of the series field winding, to the grounded terminal (−), back to the grounded terminal of battery (−).

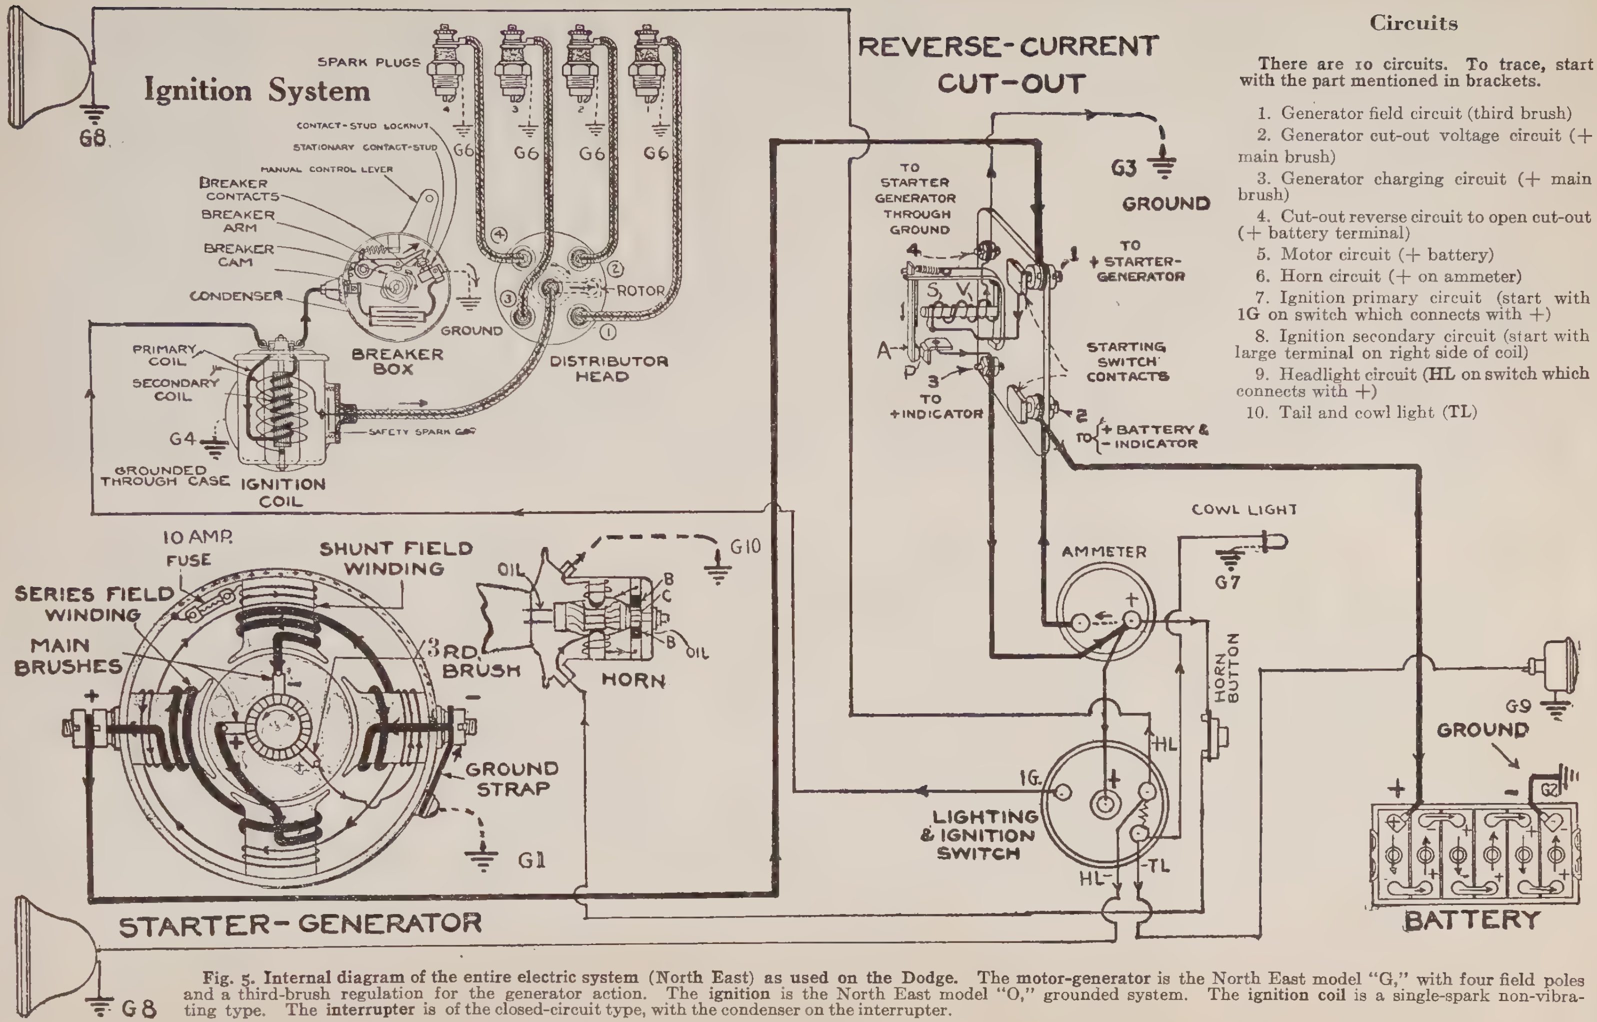
The current from the (+) terminal also flows through the armature out the third brush around the field poles to the fuse, thence from the grounded end of the fuse through the motor-generator frame, through the (−) grounded terminal, to the (−) grounded battery terminal (G2).

It will be noted (in Fig. 2) that the current flow around the "series-winding" and the "shunt-winding" is in the **same** direction, therefore the two windings assist each other in producing a strong magnetic field. The "series coil" provides the bulk of the magnetic field under starting conditions, and the "shunt-field coils" serve simply to assist in raising the magnetic field to its maximum strength. In other words, the greater part of the current flows through the "series-windings" when used as a motor.

Where the two windings assist each other by being wound so that the current flows through the two windings in the same direction, it is called a "cumulative-compound field winding."

Generator Action

When driven as a generator, the operation is practically that of a constant-current generator (see Figs. 3 and 5). The magnetic field resulting



Circuits

There are 10 circuits. To trace, start with the part mentioned in brackets.

1. Generator field circuit (third brush)
2. Generator cut-out voltage circuit (+ main brush)
3. Generator charging circuit (+ main brush)
4. Cut-out reverse circuit to open cut-out (+ battery terminal)
5. Motor circuit (+ battery)
6. Horn circuit (+ on ammeter)
7. Ignition primary circuit (start with 1G on switch which connects with +)
8. Ignition secondary circuit (start with large terminal on right side of coil)
9. Headlight circuit (HL on switch which connects with +)
10. Tail and cowl light (TL)

Fig. 5. **Internal diagram of the entire electric system (North East) as used on the Dodge.** The **motor-generator** is the North East model "G," with four field poles and a third-brush regulation for the generator action. The **ignition** is the North East model "O," grounded system. The **ignition coil** is a single-spark non-vibrating type. The **interrupter** is of the closed-circuit type, with the condenser on the interrupter.

from the current flowing around the windings on the field poles is produced by the current generated in the armature coils flowing through the "shunt-field" windings. The generated current from the armature also flows through the "series-field" windings, but in an **opposite** or reverse direction from that in which it flows through the "shunt-field windings." Thus the "series-winding" **opposes** the "shunt-field winding" instead of assisting it in building up the magnetic field, and this winding is termed a compound winding with a "differential" action, or a so-called "bucking" effect.

This bucking effect of the "series field" aids the "third brush" in preventing the output of the machine from rising above a definite output. The third brush could do this unassisted, but it is necessary that the series winding should be on the generator for starting purposes; its effect is utilized in conjunction with the third brush, which is desirable.

The path of the current (Fig. 5) through the shunt-field winding is as follows: When the generator is started, the current from the armature flows from the third brush (+), through the shunt-field windings in the direction shown by the arrow marks, through the fuse, through the frame of the motor-generator, through two of the series field coils, through (−) main brush back to the armature. This causes the magnetic field to start building up.

The cut-out voltage winding circuit is from the (+) main brush, through the series windings around two poles (note that it is in the direction opposite to the flow of current through the shunt field) out the (+) main brush to connection (1) on cut-out, through the cut-out shunt or voltage winding (V), to terminal (4), to ground (G3), to ground strap on the generator (G1), through two series field coils, to the (−) main brush, through to the armature (+) main brush, thus completing the cut-out voltage winding circuit.

This circuit through the fine wire voltage winding (V) on the core of the cut-out is to magnetize the core so that it will pull the cut-out armature (A) to the core and close the cut-out points (P), in order that the generator charging current can pass to the battery.

It is not desirable to have the points (P) close until the generator has built up sufficient voltage to overcome the voltage of the battery, otherwise the rush of current from the battery through the field windings would oppose its action of building up in the right direction.

Charging circuit:[1] At about 1,000 r.p.m. of the generator (which corresponds to 9 to 10 miles per hour car speed) the generator has built up to 14.5 volts at which voltage the cut-out shunt, or voltage winding (V) has sufficient voltage through its winding to magnetize the core so that it will have magnetic strength to pull the cut-out armature (A) down against the tension of the spring and thus close the cut-out points (P). The voltage of the battery being 12 volts and of the generator 14.5, the generator therefore has a slightly greater voltage than the battery. Thus the battery is charged by the generator, and the path of the charging circuit is then from the (+) main brush of the generator, to terminal (1) of the cut-out, through series winding (S) on the cut-out, through the frame of the cut-out armature blade (A), through points (P), to cut-out terminal (3), through the ammeter to cut-out terminal (2), to the battery (+) terminal, through the battery, to the (−) grounded battery terminal (G2), to the (−) ground strap on the generator, through two series coils, to the (−) main brush. Note that the current flow in the series-field windings is in the opposite direction to the flow of current in the shunt-field windings.

From 1,000 r.p.m. of the generator, to 1,700 or 1,800 r.p.m. (15 or 16 miles per hour car speed) the charging rate rises rapidly (see page 374). The maximum charging rate of 7 amperes is reached at from 1,700 to 1,800 r.p.m., and remains unchanged with further increase of speed up to approximately 2,100 r.p.m., at which point it begins to decrease. The decline in output continues from this point on, becoming more and more gradual as the upper limit of the speed range of the engine is reached. At 5,500 r.p.m. (50 m.p.h.) the charging rate usually drops as low as 4 amperes; and at still higher speeds it declines even more.

When the speed of the generator drops to less than 1,000 r.p.m., then the voltage will also drop, and the cut-out points (P) will open and thus prevent the battery from sending a reverse current back through the motor-generator.

It is necessary, however, to have the battery **discharge back through the cut-out series winding** in order that the points open. This is explained as follows: When the voltage coil (V) has gained sufficient strength to pull the cut-out armature (A) down, the current flows through the series winding (S) around the same core, and as it flows in the same direction as the cut-out shunt winding (V), each combines to hold the points tightly together. Although soft iron is supposed to lose its magnetism when current is stopped from flowing around the winding, it is slow in demagnetizing and has a tendency to retain some of its magnetism even though the current flow should stop altogether. In this instance however, the current flow has not stopped altogether, and although only a small amount of current is flowing through the cut-out shunt fine wire winding (V) when the generator is below 1,000 r.p.m., it has a tendency to hold on until the last. The action of opening and closing of points (P) must be quick, and in order to cause it to open quickly at the correct time, the battery discharges back through this series cut-out winding (S) in a reverse direction, which reverses the polarity of the core and demagnetizes it. Instantly the cut-out armature (A) is released and the points (P) are opened, because the strength of the battery current is greater than the current then flowing from the generator through the fine wire winding (V) of the cut-out in an opposite direction. (This is the principle of all reverse-current cut-outs.)

This discharge back from the battery, however, must not be over 1 ampere in this example, and the cut-out is set originally by adjusting the spring tension. If it should permit a greater discharge, this spring tension can be adjusted to correspond to a given degree of magnetic pull of the cut-out core, and the cut-out armature (A) can be made to open or close at any desired voltage within reasonable limits.

Thus the reverse current cut-out keeps the charging circuit closed between the generator and battery only when the generator is capable of charging the battery, and under all other conditions it automatically opens the circuit to prevent the battery from discharging back through the motor-generator.

---

[1] The current for headlights, horn, and ignition flows through the ammeter only when the generator is not charging, that is, when the current flows direct from the battery. At all other times it does not flow through the ammeter. The return path for all the circuit is by way of ground to the battery.

North East Ignition System (Model "O") as Used on the Dodge Car[1]
